Introduction: Open fetal surgery has resulted in considerable neurological damage in human fetuses. Alternatively, minimally invasive fetoscopic approaches that avoid maternal laparotomy and hysterotomy are being developed in sheep. The purpose of this pathohistological study was to assess any discernable damage from fetoscopic cardiac interventions in newborn lambs.
Methods: 12 ewes continued gestation following fetoscopic fetal thoracotomy for cardiac pacing lead insertion (n=8) or fetoscopic fetal cardiac catheterization (n=4) between 92-109 days of gestation (term = 145 days). At term, 10 of the 12 operated fetuses, and 9 unoperated siblings were delivered. The 19 newborn sheep were examined for neurological deficits presenting as movement disorders or the inability to establish a normal feeding pattern. Two of the 12 operated fetuses died early after the procedure yet the ewes continued gestation. At term, life twin and triplet siblings, respectively, were delivered and available for brain studies; the dead fetuses, however, were too mummified to be studied. All brains were fixated in formalin. Following sectioning and mounting, H.E., Klüver-Barreira, and Van Gieson stains were performed. In addition, immunohistochemical staining was performed with KiM1P-, LCA-, and GFAP-antigens. All brains were examined for bleeding complications, embolic events, infarctions as well as acute inflammatory tissue reactions or abnormal cortical maturation.
Results: In all but one prenatally operated lamb (and its unoperated sibling), minimally invasive fetoscopic cardiac interventions did not result in any discernible changes to the brain by the various staining methods. In none of the brains studied, hemorrhages, embolic events, inflammatory tissue reactions or abnormal cortical maturation were observed. In the two affected lambs, chronical cortical frontal lobe infarction (Stage III), compatible with an unobserved period of maternal hypotension, was observed. Despite these changes, the two lambs exhibited normal movements, feeding patterns, and social interactions during their neonatal period.
Conclusions: Fetoscopic cardiac interventions in fetal sheep carry a low risk for the occurrence of brain damage that can be detected following completion of gestation. This safety is encouraging for the clinical introduction of some of these minimally invasive procedures in the near future.

P2269 Intraamniotic fetal echo in sheep permits imaging during cardiac interventions and in fetuses in whom other imaging methods fail

T. Kohl[1], M.A. Große Hartlage[2], M. Westphal[2], D. Kienitz[1], S. Achenbach[1], T. Buller[1], S. Aryee[1], H. Van Aken[2]. *[1]Münster University Children's Hospital, Department of Pediatric Cardiology, Münster, Germany; [2]Münster University Medical School, Department of Anesthesiology, Münster, Germany*

Introduction: During fetoscopic cardiac interventions intraesophageal placement of intravascular ultrasound catheters for fetal hemodynamic monitoring may result in esophageal injury in very small fetuses. Moreover, conventional fetal cardiac imaging by the transvaginal or transabdominal routes may be impossible in some high-risk pregnancies. Therefore, the purpose of our study in sheep was to assess the potential of a 10-F phased-array intravascular ultrasound catheter for intraamniotic fetal echocardiography.
Methods: The catheter was percutaneously inserted into the amniotic cavity of 7 pregnant ewes between 78-98 days of gestation. We assessed the feasibility of imaging the fetal heart by 2-dimenstional as well as pulsed and color Doppler echocardiography. Following intraamniotic imaging, a small fetoscope was inserted into the amniotic cavity in order to assess any injury to intraamniotic contents from the procedure.
Results: The intraamniotic imaging approach permitted high-quality two-dimensional imaging of the fetal heart as well as multimodal Doppler assessment of fetal cardiovascular flows within 10 minutes following intraamniotic catheter insertion in all but one fetal sheep. In the fetal sheep in that imaging was inadequate, the image quality was impaired by beam scattering from the spine. In all fetuses, fetoscopic examination of intraamniotic contents after intraamniotic imaging was finished did not display any injury to intraamniotic contents. In one fetus, intraamniotic ultrasound imaging was instrumental for defining the exact incision site for fetal thoracotomy in order to insert a pacing lead.
Conclusions: The intraamniotic imaging approach may provide an effective alternative in the human for monitoring of fetoscopic cardiac interventions, and for assessment of fetal cardiac anatomy and hemodynamics in high-risk pregnancies when sufficient images cannot be obtained by conventional routes.

P2270 Improved assessment of fetal cardiac function using Doppler tissue imaging and long axis function

H M. Gardiner, J. Wolfenden, W. Lei, M. Henein. *Royal Brompton Hospital, Paediatric Cardiology, London, United Kingdom*

Background: Assessment of gestational changes in fetal cardiac function has been held back by available methodologies and the interpretation of changes confounded by the gestational increase in ventricular preload. Fetal ejection fraction is unchanged throughout the second half of pregnancy and poorly reflects the known maturational changes in the myocardium and improved calcium handling. Assessment of diastolic ventricular function using inflow velocities is confounded by increasing preload, with the normally reversed early to late inflow ratio precluding its use as an indicator of diastolic dysfunction.
Aim: To examine the feasibility of assessing fetal free wall myocardial function at different gestational ages using its long axis amplitude of motion and to compare it with inflow velocities.
Methods: We examined 63 fetuses; 23 (20-23 weeks), 8 (24-27 weeks), 12 (28-31 weeks), 11 (32-35 weeks) and 9 (36-39 weeks) using long axis amplitude (M-mode) and shortening & lengthening velocities (Doppler Tissue Imaging, DTI).
Results: RV and LV systolic velocities correlated with the progressive increase in the free wall amplitude of motion with increasing gestation, RV: R=0.59, $p<0.0001$; LV: R=0.33, $p<0.01$. This was associated with a progressive gestational increase in outflow tract velocities, RV p=0.00007 and LV p=0.0004. Early (p=0.009) and late ($p<0.03$) diastolic free wall velocities increased with age along with the corresponding increase in trans-tricuspid flow velocities ($p<0.00001$ and p=0.04) but late diastolic left free wall velocities increased (p=0.004) in the absence of increased trans-mitral flow (p=0.44).
Conclusion: DTI and long axis studies confirm that fetal systolic and diastolic function improves significantly throughout gestation. These findings form the basis for normal fetal ventricular data that can be applied in disease states.

RISKS OF CARDIAC SURGERY

P2271 Reoperation for mechanical prosthetic heart valve thrombosis. A single center study about 136 patients

R. Roudaut, S. Lafitte, X. Pillois, N. Laborde, F. Madonna, X. Roques, C. Deville, E. Baudet. *Hôpital Cardiologique, PESSAC, France*

Prosthetic heart valve thrombosis (PHVT) is a potentially fatal complication of heart valve replacement surgery. The purpose of this report is to present experience of a single center about 136 consecutive patients operated on between 1978 and 2001.
The diagnosis of PHVT was established mainly by fluoroscopy and/or echocardiography. Obstructed valves consisted of 82 bileaflet; 47 tilting disc and 7 ball cage valves. Thrombosis concerned 94 mitral valves, 41 aortic valves, 1 mitro-tricuspid valve.
The mean interval between the initial surgery and thrombosis was 7.4 ± 66 years (1 day to 28 years), 37 pts underwent preoperative medical therapy with incomplete or no results (21 fibrinolysis, 16 heparin therapy).
Operative procedure included valve replacement in 101 cases and declotting in 30 cases.
Overall, full success was observed in 121/136 pts (89%). The perioperative mortality rate was 10.3% (14 patients) particularly NYHA class III or IV patients. One documented perioperative embolic event occurred. Finally PHVT recured in 10 patients (7.4%) during follow-up.
It is concluded that nowadays for most PHVT early reoperation is effective and safe, particularly in patients who are in stable condition preoperatively.

P2272 Mechanical prosthetic heart valve thrombosis: fibrinolysis or surgery? A single center study about 253 patients

R. Roudaut, S. Lafitte, M.F. Roudaut, C. Jaïs, P. Coste, X. Roques, C. Deville, E. Baudet. *Hôpital Cardiologique, PESSAC, France*

Prosthetic heart valve thrombosis (PHVT) is a serious complication of mechanical valve replacement. Surgery is the favoured treatment but fibrinolysis has been proposed as an attractive alternative. We report a larger single center series in order to better define efficacy and safety of these 2 options.
From 1978 to 2001, 253 cases of PHVT were managed in our institution either by surgery (n = 136) or by fibrinolysis (n = 127). Obstructed valves were 169 mitral, 84 aortic and 4 tricuspid, 161 bileaflet, 95 tilting disc and 7 ball cage valves. 37 patients underwent preoperative medical therapy with incomplete or absent results (21 fibrinolysis, 16 heparin therapy). Main results are summarized on the table.

Results	Surgery	Fibrinolysis	p
Full success	88.9% (120)	70.9% (90)	< 0.01
Incomplete	0 (0)	17.3% (22)	< 0.01
Failure	0 (0)	11.8% (15)	NS
Haemorrhage	0.7% (1)	3.9% (5)	0.08
Embolism	0.7% (1)	15.0% (19)	< 0.01
Death	10.4% (14)	11.8% (15)	NS
Total complications	11.1% (16)	24.4% (31)	< 0.01
Reccurences	7.4% (10)	18.9% (24)	< 0.01

In conclusion, nowadays, in patients with PHVT, surgery is the treatment of choice. However, fibrinolysis may be indicated for selected patients right sided PHVT, critically ill patients at high risk with surgery.

P2273 Perioperative myocardial infarction following coronary bypass: short and long-term follow-up

A. Sanchez-Recalde, D. Sanchez, I. Mate, J.L. Merino, G. Galeote, M.A. Arias, P. Robles, J.A. Sobrino. *Hospital General "La Paz", U.M.Q. Cardiologia, Madrid, Spain*

Perioperative myocardial infarction (PMI) is a major complication following coronary artery bypass graft. Clinical significance of PMI is controversial and has not been sufficiently studied. The aim of the present study was to assess the short and long-term follow-up of a large cohort of patients with PMI.
Methods: 702 patients who had undergone coronary bypass grafting between 1993 and 2000 were retrospectively studied. PMI was defined when new pathological Q waves and CK-MB elevation were demonstrated after surgery. Patients were divided into two groups: 97 patients (13,8%) with PMI (group A) and 605 patients without PMI (group B).
Results: Baseline demographic and clinical characteristics were similar between the two groups. In-hospital mortality was higher in group A than in group B (14% vs 4%, RR:1,39 95% CI 1.1 to 1.8; $p<0.001$). Also hospital mean stay was longer in group A compared with group B (25 days, SD 14 vs 13 days, SD 5; $p<0.001$) At 53.6 months (SD 25.3, range 9-100 months) follow-up more patients in group A than in group B had cardiac events: unstable angina (25% vs 11%, RR: 1,18 95% CI 1.1 to 1.4, p=0.001), congestive heart failure (32% vs 8%, RR:1,43 95% CI 1.2 to 1.8, $p<0.001$), and repeated revascularization procedures (23% vs 9%, RR:1,19 95% CI 1.1 to 1.4, p=0.001). The 8-year event-free survival rate (Kaplan-Meier) was lower in the group A (76 months, 95% CI; 68 to 84 months) than group B (85.5 months, 95% CI; 82 to 87 months), p=0,02. However, after excluding in-hospital deaths, the long-term mortality between the two groups was not significantly different (14% in group A vs 12% in group B).
Conclusions: PMI was associated with both a high in-hospital morbidity and mortality. However, a high number of long-term cardiac events in patients with PMI was not associated with a worse long term survival than those without PMI.

P2274 Relationship between body mass index and postoperative complications after cardiac surgery

E. V. Potapov[1], M. Loebe[2], S. Anker[3], J. Stein[1], R. Sodian[1], H. Hausmann[1], R. Hetzer[1]. *[1]Deutsches Herzzentrum Berlin, Cardiothoracic and Vascular Surgery, Berlin, Germany; [2]Baylor College of Medicine, Michael E. DeBakey Dept. of Surgery, Houston, Texas, United States of America; [3]National Heart & Lung Institute, London, United Kingdom*

Background Among other preoperative parameters, severe obesity and cachexia are regarded as substantial risk factors for postoperative complications. However, the exact relationship between body mass index (BMI) and postoperative risk has not yet been defined.
Methods We retrospectively investigated consecutive patients (n=20,680) who underwent cardiac surgery between 1990 and 2000 in our institution. BMI, age, gender and type of surgery were used as covariates in a logistic regression model. The adjusted odds ratios (OR) for increases in BMI of 1 kg/m^2 were calculated for three endpoints, re-intubation, early infection and 30-day mortality.
Results With increased BMI the OR for re-intubation, infection and 30-day mortality continuously decreased. The BMI with the lowest OR was between 25 and 35, between 25 and 27 and between 33 and 35 kg/m^2, respectively. The OR for postoperative complications, except for infections were significantly higher in cachectic patients compared with obese or severely obese patients (table).

Odds ratios for postop. complications

BMI (kg/m^2)	OR and CI for re-intubation	OR and CI for infection	OR and CI for 30-day mortality
<20	2.18 (1.83-3.11)	1.66 (1.29-2.14)	1.6 (1.17-2.18)
30 - 40	1.08 (0.87-1.33)	1.34 (1.19-1.51)	0.72 (0.59-0.88)
>40	1.05 (0.26-4.34)	3.91 (2.24-6.82)	0.7 (0.17-2.87)

OR: odds ratio, CI: confidence interval

Conclusion There is a non-linear relationship between BMI and risk for postoperative complications after cardiac surgery. The slightly underweight and cachectic patients were at higher risk after cardiac surgery than obese or even severely obese patients. A preoperative focus on avoiding and/or reversing cachexia may be more efficacious than reducing obesity in decreasing the overall risk associated with heart surgery.

P2275 Low high density lipoprotein cholesterol predicts mortality in long-term follow-up after coronary artery bypass surgery

C.C. Magalhães, A.C.P Chagas, P.L. da Luz. *Instituto do Coração (InCor), Unidade de Aterosclerose, São Paulo, Brazil*

Background: Low HDL-c is an independent predictor of coronary heart disease (CHD) comparable or even stronger than high LDL-c. However the influence of low HDL-c following coronary artery bypass graft (CABG) is less known.
Objectives: To assess the influence of low HDL-c on mortality in patients submitted to CABG, followed for a mean period of 6.3 years.
Material and Methods: We studied 165 patients of both gender, and divided then into two groups: I, HDL-c <=35 mg/dl (n = 101),and II, HDL-c > 35 mg/dl (n=64). The CABG occurred between 1994 and 1996.
Results: Group I and II were comparable (p-ns) as far as gender (75.5% males vs 62.5%), age (65.4 ±8.4 vs 67.4 ±9.2) years, diabetes (40.5% vs 34.3%), hypertension (66.1% vs 70.3%), hipercholesterolemia (61.2% vs 59.3%), family history of CHD (61.3% vs 78.1%), previous myocardial infarction (50.4% vs 51.5%), smoking (39.5% vs 35.5%) sedentarism (42.5% vs 39.0%) and body mass index (BMI 29.6% vs 18.7%). The extent of CAD in both groups was similar: single vessel disease (5.94% vs 9.37%), and multiple vessel disease (94.0% vs 90.6%). The number of graft employed was also similar (1.60 ±0.91 vs 1.40 ±1.0). As far as lipids and glucose, only HDL-c was different between the groups (Table - Lipid profile in mg/dl). At the follow up, there were 21 (20.7%) deaths in group I, but only 4 (6.25%) deaths, in group II (p = 0,01, chi square). When adjusted for cholesterol, sedentarism, B.M.I., diabetes, triglycerides, hypertension, family history of CHD, previous myocardial infarction, smoking, extent of CAD, and number of grafts, HDL-c emerged as an independent predictor of cardiovascular deaths (p value = 0,01), by logistic regression model.

Lipid profile

Mean	Group I	Group II	Mean	Group I	Group II
Glycemia	150.2	119.0	Trygliceride	245.1	152.3
Cholesterol	225.1	231.7	LDL	148.0	155.7
HDL	28.1	44.8	VLDL	58.7	33.5

Conclusion: Low HDL-c level predicted significantly greater cardiovascular mortality after CABG in men and women. Whether its correction would improve outcome needes further investigation.

P2276 Role of myocardial revascularization in patients undergoing high-risk vascular surgery

J.L. Chauvet, D. Blanchard, A. Maudiere, B. Degand, J.P. Cron, F. Baud, D. Bruere. *Clinique Saint-Gatien, Tours, France*

Cardiac events are the major cause of mortality after vascular surgery. Determination of high-risk patients is a major goal for clinicians before surgery; clinical evaluation and non-invasive techniques can help for the determination of risk, but up it has not yet been establisehd whether revascularization is of value, even when feasible.
234 consecutive patients (pts) (65±10 years, 91% males) undergoing staged abdominal aortic surgery were retrospectively studied. Three groups were defined according to clinical data. Group A (n=162): pts without ischemia based on clinical history, and/or negative test (stress echocardiography or treadmill or nuclide myocardial scintigraphy); group B (n=27): pts with ischemia: high ACC/AHA score, and/or positive stress, leading to coronary angiogram (CA) and revascularization (20 pts with PTCA, 7 with coronary bypass surgery); group C (n=45): pts with ischemia, with or without CA, and without revascularization.
Vascular surgery was performed at least 14 days after revascularization; all patients with stents (19) were treated by aspirin and ticlopidine or clopidogrel for at least 21 days.
Thirteen (5.5%) Major Cardiac Events (MACE) (myocardial infarction, cardiac insufficiency, unstable angina, ventricular arrythmia) occurred after vascular surgery; no patient died. The rates of MACE after vascular surgery were significantly different between groups: A: 3.1%, B: 7.4%, C: 13.3%, p<0.05. One myocardial infarction occurred after coronary revascularization, and the total rate of MACE for group B (coronary revascularization and vascular surgery MACE) increased to 11.1%, non significantly different from group C.
The risk of MACE after vascular surgery was correlated with Eagle Score, ejection fraction and number of diseased vessels (NDV) at CA (from groups A and C with CA, and group B after revascularization). Only NDV was predictive of MACE on multivariate analysis.
The theoretical risk of MACE in group B (if they had not been revascularized) according to the relationship between MACE and NDV, would be 6 patients (22.2%) instead of 3. Compared to group C (13.3%), the difference is significant.
In conclusion: the risk of major cardiac events after aortic surgery is currently highly correlated with the extent of coronary disease; the risk associated with pre-surgery revascularization is low, and this strategy allows a dramatic decrease in the occurrence of MACE.

P2277 CABG in women: higher risk?

M. Genoni[1], P. Fries[1], R. Tavakoli[1], D. Odavic[1], A. Künzli[2], M. Turina[2]. *[1]Stadtspital Triemli, Division of Cardiac Surgery, Zürich, Switzerland; [2]University Hospital, Division of Cardiac Surgery, Zurich, Switzerland*

Background: Popular risk scores (Euro Score, Parsonnet) indicate that CABG in women carries higher risk than in men. The reason for this wellknwon finding is not quite clear.
Methods and Patients: 2593 CABG patients operated in 1980, 1990, 1995, 1998, 1999 were reviewed and analysed for gender-associated risk of surgery.
Results: Overall early mortality was 1.9%; 3.8% for women and 1.5% for men (p=0.001). Compared with males, females were older (64.2 years vs 58.3; p=0.01), more symptomatic (74% CCS IV-V vs 50%; p=0.001), preoperative iv heparin was more frequent (31% vs 20%; p=0.01), surgery was more frequently urgent (37% vs 27%; p=0.001), females were more likely to be hypertensive (67% vs. 51%; p=0.001), and diabetic (21% vs 16%; p=0.01) No significant sex-related differences weree found for the incidence of left main stenosis, number of diseased vessels, ejection fraction, use of IMA, and duration of cardiopulmonary bypass. Multivariate analysis revealed that age, poor ejection fraction, intensity of angina, and prior PTCA were indipendent risk factors for early mortality after CABG. There was only a weak trend for female sex as an independent factor (p=0.07).
Conclusions: There is at most only a weak association between female gender and early mortality after isolated CABG. In the multivariate analysis, female sex is a less important risk factor than age, poor ejection fraction, intensity of angina and prior PTCA.

CARDIAC REHABILLITATION

P2278 Respiratory capacity and autonomic modulation in heart transplant patients

F. Beckers[1], D. Ramaekers[2], R. Fagard[3], J. Van Cleemput[4], W. Droogne[4], J. Vanhaecke[4], A.E. Aubert[1]. [1]*Laboratory of Exp Cardiology, Dept of Cardiology, Leuven, Belgium;* [2]*Univ Hosp Gasthuisberg, Dept of Internal Medicine, Leuven, Belgium;* [3]*Univ Hosp Gasthuisberg, Dept of Hypertension and Card Rehab, Leuven, Belgium;* [4]*Univ Hosp Gasthuisberg, Dept of Cardiology, Leuven, Belgium*

Background: In a previous study of heart transplant patients we showed an increase in autonomic modulation towards the native sinus node (NSN) after heart transplantation (HTX), while the donor heart remained extrinsically denervated. This study focussed on the influence of the restoration of autonomic modulation on respiratory capacity.
Methods: 10 HTX patients were enrolled in this study. 5 patients were involved in a voluntary exercise program at home (>3 hours/week) and 5 were used as a control group. Intracardiac electrogram measurements of the NSN started from a few weeks after HTX and then monthly up to 1 year. A progressive climbing exertion test till exhaustion was performed to determine maximal oxygen consumption and maximal power level at 3, 7 and 12 months after HTX. ECG was recorded continuously. Heart rate variability (HRV) was computed on the electrogram of the NSN and the ECG of the exercise test at peak exercise level and low (LF) and high frequency power (HF) determined.
Results: Intracardiac HRV of the NSN showed a progressive increase in LF and HF ($p<0.05$ at 7 months) in all patients. At 1 year the increase in LF and HF levelled off. There was no significant increase in peak oxygen consumption, maximum workload or in any HRV parameter measured at maximum workload up to 1 year after HTX. A minor increase was observed after 7 months in most indices but this evolution did not progress. No difference in evolution was observed between the active group and the sedentary group.
There was a significant difference between the active group and the sedentary group in maximum power (95±27 W vs 56±14 W;$p<0.001$), max HR during exercise (147±26 bpm vs 124±21 bpm;$p<0.05$) and VO2 (1394±329 ml/min vs 829±182 ml/min;$p<0.001$). There was no difference in rest HR or peak exercise HRV indices.
Conclusion: Training causes a larger exercise tolerance, which is beneficial for the quality of life after HTX, but does not stimulate the restoration of autonomic modulation towards the NSN.

P2279 Exercise recommendation for patients with coronary artery disease – Risk of catecholamine overload

U. Tegtbur[1], H. Meyer[2], H. Machold[3], M.W. Busse[4]. [1]*Hannover Medical School, Sportsmedicine, Hannover, Germany;* [2]*Agnes-Karll-Krankenhaus, Laatzen, Germany;* [3]*Pfaffenhofen, Germany;* [4]*University of Leipzig, Sportsmedicine, Leipzig, Germany*

Introduction: Exercise training for patients with coronary artery disease (CAD) is recommended in a wide range between 40-85% of maximum functional capacity (MFC) or 55-90% of maximal heart rate (American Heart Association, American College of Sportsmedicine). During exercise high levels of catecholamines and metabolic acidosis could induce arryhthmias and cardiac ischemia. But catecholamines have never been determined in CAD during exercise in the upper range of recommended intensities.
Methods: In 11 CAD (age 58 ± 8 years, BMI 26.1 ± 4.0 kg/m^2, NYHA I n=7, II n=4) we tested the maximal functional capacity, norepinephrine (NE), epinephrine (E) and blood lactate (Lac) kinetics in a symptom limited incremental ergometer test. Related to exercise recommendation, the kinetics of NE, E and Lac were determined in two 30 min constant load tests in randomized order: one was performed at the anaerobic lactate threshold (CTAT), a second was performed 10% above the individual threshold intensity (CT+10%).
Results: Maximal values at MFC (end of incremental tests), of CTAT and of CT+10% are shown in the table. In CTAT the anaerobic threshold (63 ± 7% of MFC) represented the mean range of recommended exercise intensity for CAD (40-85%) and could validated as steady-state-intensity because Lac and NE concentrations remained constant after the initial increase. In all patients CT+10% (71 ± 7% of MFC) lead to a continous rise in Lac, to a NE overload and to earlier exhaustion, although the intenisties were in the recommended range.

	Work w	NE nmol/l	E nmol/l	Lac mmol/l	HR b/min	VO2 ml/min
MFC	141±54	11.7±5.1	1.6±1.4	5.7±1.9	138±28	1766±532
CTAT	88±35	8.3±3.5	0.8±0.7	3.3±1.4	117±23	1306±402
CT+10%	100±38*	13.9±6.9*	1.5±1.7	5.8±1.9*	129±29*	1589±465*

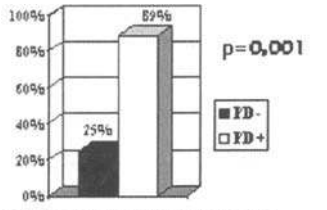
Mean values ± SD at MFC, CTAT and CT+10% (CTAT vs. CT+10% * = $p<0.01$)

Conclusion: In the upper range of recommended intensity for CAD norepinephrine and lactate were higher during endurance exercise than at MFC in incremental tests. Endurance exercise with intensities >70% of MFC could overload the cardiac patient and increase the risk of arryhthmias and cardiac ischemia. Therefore, endurance exercise should be performed below 70% of MFC or below 85% of maximum HR, respectively, whereas higher intensities should apply to interval exercise.

P2280 Beta-blocking agents and erectile dysfunction after acute myocardial infarction: guilty or innocent?

L.J. Vacanti[1], B. Caramelli[2]. [1]*Hospital Ana Costa, Santos, Brazil;* [2]*University of Sao Paulo Medical School, Heart Institute (InCor), Sao Paulo, Brazil*

Background: With the use of beta blocking agents in hypertensive patients, incidence of erectile dysfunction (ED) ranges from 5 to 15%. Conclusive data regarding the incidence of ED is not available neither that on the existence of a correlation with the use of the drug during the post-acute myocardial infarction (AMI) period. We analyzed the incidence of ED in acute myocardial infarction patients and investigated possible predictors of ED after AMI.
Methods: We have evaluated male patients that, prior to the AMI, had an active sexual life, without ED. We have evaluated the influence of the fear of starting sexual intercourse again after the event, age, diabetes, arterial hypertension, smoking, dyslipidemia, presence of psychiatric disorders (PD) and the use of drugs (beta blockers, platelet anti-aggregants, ACE inhibitors and statins)in the occurrence of ED until the sixth month after the AMI.
Results: From September/2000 to March/2001 we surveyed 37 male patients with AMI. Ninety-one percent of the patients reported resumption of sexual activity after AMI. Prior to their illness, the mean frequency of sexual activity was 8 times a month. The mean frequency was reduced to 5 times a month ($p<0.001$). After 6 months, 15 (40%)presented with ED. Patients with PD presented with a more pronounced ED than those without PD (Picture 1). We did not detect a difference with regard to the incidence of ED among the groups with or without beta blockers (35.7 x 55.5%, p=0.4). The remaining variables did not correlate with ED.



Erectile Dysfunctions incidence, regarding PD absent (-) or present (+)

Conclusions: After AMI there is a high incidence of ED. Presence of PD was related to this higher incidence of ED. The use of beta-blocking agents and the other analyzed variables are not correlated to the presence of ED.

P2281 Psychological assessments for cardiac rehabilitation

H.J.N. Bethell, S.C. Turner, J. Evans. *Cardiac Rehabilitation Centre, Alton, United Kingdom*

Purpose: To investigate changes in psychological and quality of life scores before and after a cardiac rehabilitation (CR) program using three simple questionnaires and to test the sensitivity of these instruments.
Methods: Retrospective study of 1403 patients who entered CR over 51 months in a community-based, hospital-linked CR center. Patients completed questionnaires before and after their exercise-based program - Hospital Anxiety and Depression scale, WONCA/COOP charts and an analogue score of wellbeing.
Results: The three instruments took about 4 minutes in total to complete. There were highly significant reductions in mean anxiety score - 6.04 to 4.67 ($p<0.001$, 95% CI -1.52 to -1.16) and depression from 4.00 to 2.52 ($p<0.001$, 95% CI -1.62 to -1.29). The mean analogue of wellbeing score improved from 7.09 to 8.19 ($p<0.001$, 95% CI 0.97 to 1.22). There were highly significant improvements in five of the six WONCA domains. There were significant correlations between improvements in scores from all instruments. The sensitivity indices were in the "good" range for changes in the WONCA physical fitness domain and subjective wellbeing score and in the "moderate" range for changes in depression, well-being and WONCA overall health. Initial physical fitness was significantly correlated with all psychometric scores except anxiety and WONCA feelings, but improvements in fitness were not correlated with improvements of any of the psychometric scores.
Conclusion: The instruments described were quick to administer and showed sensitivities to change superior to those which have been reported for other questionnaires. We believe them to be practical tools for use in CR units.

P2282 Remodelling in patients with left ventricular dysfunction after coronary artery by-pass graft surgery

F. Scapellato, U. Corrà, P.L. Temporelli, E. Eleuteri, P. Giannuzzi. *"S. Maugeri" Foundation, Cardiology, Veruno, Italy*

Although progressive left ventricular (LV)dilation is associated with adverse cardiovascular events, remodeling after coronary artery by-pass graft surgery (CABG)has still to be investigated. We studied 140 consecutive patients (120 males; mean age 65±9 yrs)with moderate to severe LV dysfunction (EF<=35%), who underwent serial 2-D echocardiography at 12±9 days and at 6 months after surgical revascularization. During this study period, both end-diastolic volume index (EDVi, from 85±23 to 86±26 ml/m^2, NS) and EF (from 28%±6% to 32%±9%, p<0.0001)increased, whereas wall motion score index (WMSI) decreased (from 2.19±0.5 to 2.04±0.4, p<0.0001). At 6 months, a subset of 41 patients (30%) showed a >=15% LV dilation (severe dilation), while EDVi decreased more than 5% in 47 patients (33%), it remained unchanged in 29 (21%), and increased from 5% to 14% in 23 (16%). Independent predictors of severe LV dilation were a relatively small EDVi early after CABG (OR 0.94, CI 0.92-0.97, p=0.0008), a relatively high WMSI (OR 5.99, CI 1.05-34.2, p<0.05) and a partial revascularization procedure (OR 1.8, CI 1.2-2.6, p<0.001). In addition, at 1 year follow-up, major cardiovascular events (including death, heart failure, acute myocardial infarction, pulmonary embolism, need of repeated coronary artery revascularization) were higher in patients with severe LV dilation than those without (34% vs 16%, p<0.01). In conclusion, over a period of 6 months, surgical revascularization does not appear to prevent LV remodeling in a sizeable number of patients with moderate to severe LV dysfunction. Patients with not significantly enlarged ventricular volume early after CABG but with extensive asynergy and partial revascularization are at higher risk for progressive LV dilation, which may significantly affect prognosis.

P2283 Preparing patients for rehabilitation: fast remission of pleural effusions following cardiosurgery with spironolactone

S. Dragan, S. Mancas, M. Cocora, D. Nechifor, L. Constantinescu, M. Havrincea, S.I. Dragulescu. *Institute of Cardiovascular Diseases, Cardiac Rehabilitation Centre, Timisoara, Romania*

Pleural effusions represent a frequent complication following cardiosurgery. Fast relief of respiratory symptoms is essential for the efficiency of exercise training during phase I rehabilitation programs. We studied the effect of combined spironolactone + furosemide compared to the usual scheme of furosemide only in the treatment of these effusions. 120 patients (67 following bypass surgery, 50 valvular replacement, 3 following bypass surgery + valvular replacement) out of 483 pts. included in phase I rehabilitation between jan 2000-dec 2001 presented with pleural effusion (right, left or bilateral) at 7-10 days postoperatively. All patients were in stable clinical condition and did not require thoracentesis at admission. Patients with left ventricular ejection fractions <40% were excluded. Cardioactive medication was kept in all cases. The patients were randomly divided into 2 groups: 57 pts. were given spironolactone+furosemide (gr.1), 63 pts furosemide only (gr.2). All medication was oral. In gr.1 mean age was 56,98±11,29 years (20;77), 46 M, 11F, 26 following bypass surgery, 28 after valvular replacement, 3 after both procedures.The mean dosis of spironolactone was 72,37±25,74 mg/daily+furosemide 30,88±13,53 mg/daily. In gr.2 mean age was 60,51 ±8,51 years (39:74) 39 M, 24 F, 41 following bypass surgery, 22 after valvular replacement. Mean dosis of furosemide was 28,73±13,74 mg/daily. **Results:** Complete remission was significant in gr.1, 38 cases (66,7%), compared to 16 cases in gr.2 (25,4%) p<0,01. Duration of treatment to complete remission was significantly shorter in gr.1, 7,84 ± 3,57 days compared to 9,98 ± 4,67 days in gr.2 (p<0,01). K supplements were needed in significantly fewer patients in gr.1, 34 (59,6%) compared to 59(93,7%) patients in gr.2 (p<0,001). Complications: 3 cases needed thoracentesis due to massive accumulation of pleural fluid, nonresponsive to diuretic therapy in each group, 1 case required continous tube drainage due to infection in gr.2. **Conclusion:** Association of spironolactone to furosemide in the treatment of pleural effusions following cardiosurgery appears to have a spectacular effect leading to quick remissions. This result can not be exclusively related to additive diuretic effects, although sequential blockade of the nephrone has to be taken into consideration. The antiproliferative and membrane-modifying effect of canrenone may explain our results. The nature of the fluid (transudate or exudate) could explain differences in duration of remission.

P2284 Neurohormonal abnormalities and the excise trainging effects in cachexic patients with acute myocardial infarction

N. Osada[1], K. Omiya[2], K. Inoue[2], Y. Akashi[2], M. Tamura[2], K. Itoh[2], K. Suzuki[2], F. Miyake[2]. [1]*Yokohama, Japan;* [2]*St. Marianna University, Cardiology, Kawasaki, Japan*

Exercise training after acute myocardial infarction is widely accepted because of its beneficial effects. This study was designed 1) to evaluate whether cachexic and overweight patients with acute myocardial infarction (AMI) are affected differently when they undergo exercise training, and 2) to evaluate whether differences in body weight influence the effects of exercise training in AMI patients.

Methods: 192 patients who performed cardiopulmonary exercise training after AMI were enrolled in this study (average 60.4 years). All patients performed regular exercise training for 6 months. Cardiopulmonary exercise testing was performed at 1 month (1mo), 3 months (3mo), and 6 months (6mo) after the onset of AMI. Plasma concentrations of noradrenaline (NA), brain natriuretic peptide (BNP), and tumor necrosis factor-soluble receptors (TNFR-I and TNFR-II) were measured. Patients were divided by the obesity index (OI=body mass index/22) into three groups (body wasting (BW n=31) OI<0.95, normal body weight (NB n=114) 96<OI<110, overweight (OB n=47) OI>111).

Results: Ejection fraction (EF), NA, BNP, TNF R-I and TNF R-II values were similar in the three groups before exercise training.

There were no relationships between peak VO2 and the levels of TNFR-I (r=0.33) and TNFR-II (r=0.33). The peak VO2 was related to TNFR-I (r=0.54, p<0.0001) and TNFR-II (r=-0.56, p<0.001) in the body wasting group, but not in the overweight group. Peak VO2 was related to the level of BNP in both the body wasting group (r=0.61, p=0.003) and overweight group (p=0.49, p=0.009). While peak VO2 showed no significant change from 1mo to 3mo, it increased significantly from 3mo to 6mo (22.6±5.4 to 25.0±6.4 ml/min/kg) in the BW group. In both the NB and OB groups, peak VO2 improved from 1 mo to 3 mo (23.9±4.5 to 25.8±5.8, 22.3±4.1 to 24.4±5.0), but not from 3mo to 6mo. The change in peak VO2 from 1mo to 3mo was lower in the BW group than in the NB and OW groups.

Conclusion: While the level of TNF receptor was similar in all three groups, it was related to the exercise capacity in only the body wasting group. In these patients, exercise training should be continued for at least 6 months. This result suggests that cytokines may be important factors for anticipating exercise tolerance in AMI patients with body wasting due to loss of skeletal muscle volume.

P2285 The effect of short-term endurance training on the insulin resistance indicators in patients with arterial hypertension rehabilitated after CABG

S. Borowicz-Bienkowska[1], P. Dylewicz[2], L. Szczesniak[2], I. Przywarska[3], T. Rychlewski[2], M. Wilk[3]. [1]*University School of Physical Educatio, Cardiac Rehabilitation, Poznan, Poland;* [2]*University School of Physical Educatio, Cardiac Rehabilitation, Poznan, Poland;* [3]*Rehabilitation Hospital, Cardiac Rehabilitation, Poznan, Poland*

There is ample evidence indicating that a 3-week endurance training beneficially modifies carbohydrate metabolism in patients with ischaemic heart disease. The aim of our study was to assess training-specific effects in patients after coronary artery bypass graft surgery (CABG) with arterial hypertension (AH) in whom a problem of insulin resistance can be expected more frequently. The study was conducted in a group of 30 male patients (15 hypertensive and 15 normotensive), aged 55.5 ± 2.1 years (mean ± SEM), with BMI 26.2 ± 0.8, within 1 to 6 months after CABG. Before and after training program, the cardiopulmonary exercise test was carried out and glucose, insulin, and C-peptide blood levels, as well as binding and degradation of 125I-insulin by erythrocyte receptors, were determined. All patients were submitted to 15 training sessions on a bicycle ergometer for 3 weeks.

At the beginning of rehabilitation, hypertensive subgroup had statistically significant lower degradation of labelled insulin compared to normotensive one (6.703 ± 0.470 in hypertensive, 9.367 ± 0.430 pg 125I/1011RBCs in normotensive subgroup). It seems possible to consider this as one of indicators of the insulin resistance accompanying AH.

After rehabilitation, a statistically significant improvement in insulin resistance indicators (binding and degradation of labelled insulin) occurred only in the subgroup with arterial hypertension. There was a significant increase in insulin binding, from 0.496 ± 0.064 to 0.705 ± 0.064 pg 125I/1011RBCs (p<0.01), and degradation from 6.703 ± 0.470 to 9.644 ± 0.870 pg125I/1011RBCs (p<0.01). In this subgroup, there was also a significant increase in HDL-cholesterol level, from 43.7 ± 1.65 to 49.28 ± 2.87 mg/dL (p<0.05).

In the subgroup with AH, metabolic improvement was accompanied by a favourable modification of exercise systolic and diastolic BP measured in initial and final exercise tests at the same workload and the same drug treatment. Mean systolic BP fell from 185.4 ± 7.3 mm Hg in the preliminary test to 168.5 ± 5.0 mm Hg (p<0.05) in the final test and mean diastolic BP decreased from 106.5 ± 3.0 mm Hg in the preliminary exercise test to 100.0 ± 1.5 mm Hg (p<0.01) in the final test.

Conclusions: Rehabilitation after CABG based on the endurance training was especially efficient in hypertensive patients in whom, besides beneficial influence on the exercise blood pressure, a significant improvement in some metabolic risk factors of ischaemic heart disease was observed.

P2286 Combined endurance–resistance training increases linear isokinetic parameters of skeletal muscles in patients with chronic heart failure

P. Beckers[1], V.M. Conraads[2], N.M. Possemiers[2], D.L. Brutsaert[2]. [1]*University Hospital Antwerp, Cardiology, Edegem, Belgium;* [2]*University Hospital Antwerp, Cardiac Rehabilitation Center, Edegem, Belgium*

Purpose: Skeletal muscles(SM)of patients with chronic heart failure CHF) are characterized by lower maximal strength and earlier fatigue than healthy controls. These impairments are due to SM atrophy, impaired nutritive blood flow and abnormalities in histology and metabolism. Several controlled studies show improvement of these impairments by exercise training. Linear Isokinetic (LI) assessment provides important information on functional capacities of the SM such as power, force, speed and explosive force.
Methods: LI parameters of SM were measured in patients (N=25) with stable CHF (mean EF = 28,8%) before and after a 6- month exercise-training program. The physical reconditioning consisted of a combined aerobic training and a specific designed resistance training for multiple small muscle groups.
Results: Training induced a highly significant increase of Maximal Mechanical Work Capacity on treadmill of more than 38% (p=0.001) and a significant increase in Maximal Oxygen Uptake of 17% (p=0.01). LI parameters of the SM during a multifunctional test increased significantly (see table)

	Start	After	Unit	P-value	Gain
Mean Max P	323	487	Watt	0.03	+ 51%
Max Power	570	432	Watt	0.01	+ 63%
Work	347	561	Joule	0.03	+ 61%
Max Force	571	926	Newton	0.01	+ 62%
Time to Fm	0.33	0.34	seconds	ns	ns
Max explo	16940	30314	Newton/sec	0.01	+79%
Mn Expl F	1879	3423	Newton/sec	0.006	+82%
F at 0.25s	512	861	Newton	0.01	+68%
P at 0.25s	86	154	Watt	0.01	+79%

Conclusions: Combined aerobic-resistance training of patients with CHF induces beneficial effects on both maximal and sub-maximal physical performance. Patients trained in this programme move faster with more force and more power, thus performing with better locomotive coordination and with much more efficiency.NYHA functional class,sub-maximal and maximal workrate improved in these immobile patients. LI measurement of muscular performance is a valuable tool to assess functional capacity in patients with CHF.

P2287 Heart rate variability improvement in patients after surgical myocardial revascularization undergoing physical rehabilitation

L. Bryniarski[1], J. Kawwa[2], B. Bacior[1], M. Rajzer[1], K. Kawecka-Jaszcz[1]. [1]*Jagiellonian Univ. Medical College, I Cardiac Dept., Krakow, Poland;* [2]*Centre of Cardiac Rehabilitation, Rabka, Poland*

Patients after coronary artery bypass grafting (CABG) have impaired heart rate variability (HRV). The influence of physical rehabilitation on HRV in this group of patients is unknown.
The aim of the study was to assess HRV and left ventricular function in patients after CABG undergoing a 21-day program of interval training with constant workload.
Material and methods: We studied 103 patients after CABG divided into group A (72 pts) undergoing group physical rehabilitation (started 7-8 days after CABG in the centre of cardiac rehabilitation) and group B (31 pts) without rehabilitation. In all patients echocardiography, 24hr ECG recording (to assess time- and frequency-domain HRV), exercise stress test (EXT) were performed at baseline, at 21 days, and after 6 months.
Results (at baseline and at 21 days presented in the Table): At baseline time domain parameters were similar in both groups, frequency domain HRV was significantly higher in group A.

	SDNN [ms]	pNN50 [%]	EF [%]	EXT [min]	LF [ms2]	HF [ms2]
Group A (n=72)						
at baseline	55.6±19.9	0.8±1.9	49.6±10.2	6.3±3.1	146.2±96.5	31.5±28.4
p	<0.001	<0.05	<0.05	<0.001	NS	NS
at 21 days	64.9±25.8	1.1±2.8	51.7±9.6	8.0±2.7	201.6±139.0	49.7±43.7
Group B (n=31)						
at baseline	50.5±21.7	0.3±1.1	51.9±10.0	5.4±2.6	103.5±77.0	8.4±10.8
p	NS	NS	NS	NS	NS	NS
at 21 days	51.3±18.4	0.4±1.4	51.3±8.1	5.9±2.5	146.6±152.0	31.4±28.5

At 21 days time domain HRV parameters improved only in group A, whereas frequency domain HRV remained unchanged. At 6 months time and frequency domain parameters increased significantly in both groups, but they were significantly higher in patients undergoing rehabilitation.
Exercise tolerance was significantly higher in group A after rehabilitation and at 6 months. There were no differences in EF at 6 months.

Conclusions: After CABG time domain HRV is improved in the short (21 days) and long run, whereas frequency domain parameters increase at a later time. Physical rehabilitation speeds up the time domain HRV improvement and influences positively the time and frequency domain parameters in the long term follow-up (6 mths).

P2288 Should there be gender-separated cardiac rehabilitation programs?

D. Jenni[1], G. Kuster[2], C. Kaufmann[2], S. Piazzalonga[2], P. Rickenbacher[3], M. Pfisterer[2], A. Hoffmann[2]. [1]*Cardiology, Basel, Switzerland;* [2]*University Hospitals, Cardiology, Basel, Switzerland;* [3]*University Hospital, Cardiology, Bruderholz, Switzerland*

Background: Underrepresentation of women in cardiac rehabilitation may have different reasons. Selection mechanisms may lead to different outcomes. We investigated the benefit and course of rehabilitation of women compared to men in our outpatient cardiac rehabilitation program (OCR).
Methods: In a period of 30 months a total of 83 women (15%) and 456 men (85%) participated in an OCR. They were compared regarding risk factors, previous revascularisation, LVEF, exercise capacity, quality of life scores and complications at the beginning and at the end of OCR.
Results: Women were slightly older (62±9 years vs 60±11 years, p=0.09) and had a higher prevalence of myocardial infarction (70% vs 59%, p=0.09). Revascularisation before OCR was less often performed in women (65% vs 84%, p<0.05) due to a lower rate of CABG(17% vs 36%, p<0.001) while the proportion of PCI (48% each) was equal. In the female cohort were less diabetics (6% vs 15%, p<0.05) and ex-smokers (31% vs 44%, p<0.05), but more persisting smokers (22% vs 15%, p<0.05). There was no difference in the history of hypertension and hypercholesterolemia. LVEF was not significantly different (56,8±12,8% vs 55,3±13,8%, p=0.17), but women had a lower exercise capacity in % of predicted target workload at baseline (73.9±18 vs 78.0±18, p<0.05) and a lesser increase in % of target workload after OCR (14.3±16 vs 20.8±16, p<0.001). Quality of life scores (PLC-questionnaire, Siegrist 1996) were similar at the beginning of OCR but men had a slightly greater improvement (p=ns) in all subscores during OCR. Women experienced more noncardiac complications (7% vs 2%, p<0.05) resulting in more discontinuation of OCR (12% vs 4%, p<0.01). There was no significant difference in cardiac complications (6% vs 3%, p=0.19).
Conclusion: Women are a minority in OCR. They are older, have a somewhat lower risk profile and less previous revascularizations but similar cardiac function. They start at a lower exercise capacity which they also increase less than men during OCR. Their benefit in quality of life is somewhat less than that of male and they are more prone for noncardiac complications. Due to these differences women may often be misplaced and should probably be offered gender-specific programs.

P2289 Prevalence of venous thromboembolism among patients entering a cardiac rehabilitation program after coronary artery bypass surgery

M. Ambrosetti[1], M. Salerno[1], M. Zambelli[2], F. Mastropasqua[3], D. Scrutinio[3], R. Tramarin[2], R.F.E. Pedretti[1]. [1]*Fondazione Salvatore Maugeri, IRCCS, Cardiology, Tradate, Italy;* [2]*Fondazione Salvatore Maugeri, IRCCS, Cardiology, Pavia, Italy;* [3]*Fondazione Salvatore Maugeri, IRCCS, Cardiology, Cassano delle Murge, Italy*

No specific guidelines on venous thromboprophylaxis after cardiac bypass (CABG) have been issued as in other surgical subspecialties. Few information is available about the prevalence of deep vein thrombosis (DVT) and pulmonary embolism (PE) in postoperative rehabilitative facilities.

Aim of this study was to evaluate 1) prophylaxis habits in the surgical setting and 2) the rate of DVT and symptomatic PE in patients with a recent CABG entering a cardiac rehabilitation program.

Two hundreds and seventy consecutive patients discharged from 19 surgery units (men 81%, mean age 64±9 years, mean interval after operation 8 days) were evaluated for postoperative venous thromboprophylaxis, underwent serial bilateral legs venous ultrasound examinations (day 1 an 7 after admission, then if specific symptoms occurred; duplex and color doppler imaging adopted) and were closely observed for clinical presentation of PE in three cardiovascular rehabilitative centres. Patients with previous DVT or PE, concomitant other cardiac surgery or planned anticoagulation were excluded.

At admission, aspirin treatment (to maintain graft patency) was present in 96% of cases. In 171 (63%) cases treatment with low, fixed doses of subcutaneous heparin was reported. Of these, heparin was limited to the early postoperative period (<4 days) in 102 (38%) cases. Graded compression stockings (GCS) were prescribed in 200 (74%) cases.

DVT was detected in 47 (17.4%) patients (proximal DVT 2.6%, isolated distal DVT 14.8%), complicated in 2 (0.7%) by symptomatic PE (fatal PE 0.4%). Clots were found in contralateral leg to the saphenous vein harvest site in half of all DVT cases. Serial testing permitted to diagnose 4 (8.5%) isolated distal DVT cases lost at day 1 examination. On multivariate analysis the following variables were independently associated with the presence of DVT: female sex ($p<0.001$), length of stay in surgery units >8 days ($p<0.05$) and no adoption of heparin prophylaxis ($p<0.05$).

This study showed a high rate of DVT in patients entering cardiac rehabilitation after CABG, while symptomatic PE appeared to be an uncommon complication. Wearing monolateral GCS after CABG had limited efficacy, as clots were often localized bilaterally. The role of routine heparin prophylaxis should be extensively investigated.

P2290 Disability, emotional and cognitive factors in over-70 patients undergoing in-hospital rehabilitation after cardiac surgery

S. De Feo, M. Capietti, M. De Salvo, A. Mazza, L. Nicola, A. Aldrovandi, C. Opasich, R. Tramarin. *IRCCS Fondazione Salvatore Maugeri, Cardiology, Pavia, Italy*

Depression and cognitive disorders are frequently observed after cardiac surgery (CS) and may poorly affect prognosis. Elderly pts usually have more advanced cardiac disease with comorbidity and cognitive decline, carrying an increased risk for disability conditioning rehabilitation (Rehab) process. We investigated the role of disability, comorbidity, well-being self-perception, emotional and cognitive status in elderly pts early after CS on: 1) short-term functional recovery, 2) medium-term pts satisfaction about CS&Rehab process.

Methods 26 consecutive over-70 pts (75±4.5 yrs) admitted to our Rehab unit 14 (range 6-47) days after CS (9 CABG, 8 valve surgery, 9 combined) were evaluated as follows. 1. At entry: comorbidity (Charlson Index); length of stay (LOS) and complications during CS stay; disability (nursing needs: Maslow and nursing chart), ability to perform basic (BADL) and instrumental (IADL) daily living activities, cognitive function (Mini Mental State, Wais-Digit Symbol, Verbal fluency), self-perceived health-status (Euroqual questionnaire, Eq1), distance walked at 6-min test (WT1), depression (GDS-15 item). 2. In Rehab: LOS and complications, left ventricular EF, number of training sessions. 3. At discharge: 6-min test (WT2), self-perceived health-status (Eq2) and depression. 4. One month after discharge: pts satisfaction about CS&Rehab process (visual analogue 1/10).

Results The mean walked distance was 142±76m at WT1 and 266 ±123 at WT2 ($p<.0001$). WT1 significantly ($p<.05$) correlated with nursing needs (r -0.42), depression (r -0.45) and Eq1 (r 0.48), while WT2 correlated with nursing needs (r -0.57), depression (r -0.45) and disability (BADL/IADL r 0.42, WT1 r 0.69). At multivariate analysis only disability at admission resulted as independent predictor of functional recovery (r^2 0.43; $p=.001$; BADL/IADL β 0.45). No correlation was found between functional impairment-recovery and cognitive and clinical variables. Pts satisfaction was high (7.7±2.2), not related with clinical, functional, emotional and cognitive factors.

Conclusions In over-70 CS pts: 1) functional impairment at admission in Rehab unit is an indicator of care needs, emotional status and well-being self-perception; it is also a predictor of functional recovery; 2) depression influences functional capacity; 3) clinical and cognitive factors do not correlate with functional impairment and self-perception; moreover they do not affect the recovery process; 4) pts satisfaction about CS&Rehab process is not related with any of the considered clinical, functional, emotional and cognitive factors.

P2291 Functional and perceived recovery during intensive in-hospital rehabilitation after cardiac surgery in elderly

S. De Feo, M. Capietti, E. Cazzaniga, I. Giorgi, A. Mazza, A. Criffò, C. Opasich, R. Tramarin. *IRCCS FONDAZIONE SALVATORE MAUGERI, CARDIOLOGY, Pavia, Italy*

In elderly the recovery process after cardiac surgery (CS) and Rehabilitation (Rehab) is influenced not only by cardiac conditions but also by comorbidity, cognitive decline and disability.

We evaluated the relationship between objective and subjective factors and their influence on functional recovery in 204 consecutive over-70 pts (75±3.8 yrs) admitted to intensive Rehab unit 12±7 days after CS (108 CABG, 64 valvular, 32 combined). We considered: comorbidity (Charlson index), length of stay (LOS) and complications in CS and Rehab, disability (nursing needs: Maslow/nursing chart), functional status (6-min walking test: WT1 at entry, WT2 at discharge), left ventricular EF, number of training sessions in Rehab, self-perceived health status (Euroqual questionnaire: Eq1 at entry, Eq2 at discharge) and emotional impairment (anxiety/depression, CBA-H/interview).

Results Functional capacity: the mean walked distance was 198±103m at WT1 and 287±121 at WT2 ($p<.0001$). The variables poorly but significantly ($p<.05$) associated with WT1 were: age, LOS in CS and Rehab, depression, complications in CS, nursing needs and Eq1. At multivariate analysis only nursing needs were weak, independent predictors of WT1 (r^2.14, $p<.001$, β -.21). WT2 was significantly associated with WT1, age, LOS in CS, complications in CS and Rehab, nursing needs, Eq1, Eq2 and training sessions. Multivariate analysis showed that WT1 (β 0.49), complications in Rehab (β -0.15), Eq2 (β 0.15) and training sessions (β 0.20) were independently correlated with WT2 (r^2.50, $p<.0001$). Pts perception: anxiety correlated with depression, LOS and complications in Rehab. At multivariate analysis only depression remained as independent factor (r^2.53, $p<.0001$, β 0.69). Emotions did not correlate with functional measures. Age, nursing needs and WT1 were significantly associated with Eq1. At multivariate analysis, only nursing needs were weak, independent predictors of Eq1 (r^2.15, $p<.0001$, β -.29). Eq2 correlated with age, complications in CS and Rehab, WT1, WT2 and Eq1. Eq1 resulted the only predictor of Eq2 (r^2.33, $p<.0001$, β -.42).

Conclusions During a post cardiac surgery rehabilitative program in over-70 pts: a) there is no correlation between clinical and psychological variables; b) functional impairment is strongly influenced by nursing needs which also affect the self perceived health status; c) anxiety and depression are associated but do not influence the recovery process neither correlate with well-being self-perception; d) functional recovery is influenced by disability at admission but favoured by physical training.

CARDIOVASCULAR DISEASE IN THE ELDERLY

P2292 Acute ischaemic syndromes in the elderly: The very elderly (>80yr) have different characteristics and poorer outcomes than the elderly (>70yr)

D.A. Halon[1], S. Adawi[2], I. Meri[2], M.Y. Flugelman[2], B.S. Lewis[2]. [1]*Lady Davis Carmel Medical Centre, Cardiology, Haifa, Israel;* [2]*Lady Davis Carmel Medical Centre, Cardiology, Haifa, Israel*

Background and aims: Patients with acute ischemic syndromes (AIS) presenting in their 80s may have a different clinical profile to pts in their 70s. We maintained a registry of consecutive patients aged => 70 yrs hospitalized for AIS and compared baseline characteristics and clinical outcomes in octogenarians (Octo) vs septuagenarians (Septu).
Patients and methods: The registry included 255 consecutive septu (age 74.3±2.7yr) and 201 consecutive Octo (age 84.1±3.9yr) with definite or suspected AIS hospitalized in 3 internal medicine or cardiology departments in a single medical center.
Results: Octo were less likely to have classic risk factors for coronary artery disease: hypertension 129 (65.2%) vs 185 (73.7%), p=0.05, diabetes mellitus 51 (25.9%) vs 83 (33.2%), p=0.09 and cholesterol/HDL ratio was lower 4.45±1.1 vs 4.72±1.2, p=0.04. Octo also had less prior revascularization 45 (22.6%) vs 90 (35.6%), p=0.003. However Octo were sicker on presentation than Septu (Table). Coronary angiography was performed less in Octo (57, 28.6% vs 110, 44.0%; p<0.001) but prevalence of 3 vessel disease was greater (34, 58.6% vs 39, 43.3%, p=0.07). Revascularization rates were similar overall (44, 22.1% vs 64, 25.5%, ns) but surgery was performed less in Octo (11, 5.5% vs 26, 10.4%, p=0.06). Outcome over a period of 15.8±3.5 months was better in Septu than Octo (table).

Patient Characteristics and Outcomes

	CHF	Renal. Failure*	CVA/TIA**	AMI$	Death	Death/ Rehosp#
Septu (N=255)	48 (19.2%)	30 (12.3%)	19 (7.6%)	23 (9.6%)	31 (12.3%)	126 (49.8%)
Octo (N=201)	66 (33.2%)	41 (21.5%)	24 (12.1%)	40 (22.1%)	51 (25.6%)	126 (63.3%)
p	<0.001	<0.01	0.1	<0.001	0.0002	0.004

*Creatinine >1.4mg%; **Prior CVA/TIA; $CK>2X upper limit of normal; #Death or rehospitalization

Conclusions: 1. Major differences exist in baseline characteristics and clinical outcomes in consecutive septuagenarians and octogenarians hospitalized for acute coronary syndromes. 2. Coronary angiography was performed less frequently in octogenarians. 3. Late mortality was high in both groups and double in octogenarians (26% vs 12%). 4. These data are important in determining applicability of results of controlled clinical trials to these specific age groups.

P2293 Plasma levels of inflammatory C-reactive protein and interleukin-6 predict outcome in elderly patients with stroke

G.M.C. Rosano, A. Silvestri, C. Vitale, C. Castiglioni, F. Frascà, P. Galetta, D. Onorati, M. Fini. *San Raffaele, Internal Medicine, Roma, Italy*

C-Reactive protein (CRP) is associate with unfavorable outcome in patients with acute ischemic syndromes and in patients with chronic stable angina. Elevated CRP levels suggestive of heightened inflammatory state in vascular conditions are often associated with elevated Interleukin-6 (IL-6) levels. The predictive importance of CRP and IL-6 levels in patients with ischemic stroke has never been elucidated. To this end we studied among 647 consecutive elderly patients (>65 years) those with documented ischaemic stroke, presence of significant carotid atherosclerosis and absence of atrial fibrillation. The study population included 150 patients (74 men, 76 women mean age 74±2) Patients underwent evaluation of high sensitive CRP and IL-6 levels at baseline, during hospitalization and at discharge. In-hospital was 6%, 1 year mortality was 15% and another cerebrovascular event occurred in 12% of patients. Patients with in-hospital events had significantly higher CRP and IL-6 levels than patients without events (3.8±1.1 vs 1.9±0.9 mg/l, p<0.01 and 13.8±3.4 vs 6.3±2.1 pg/ml, p<0.01, respectively). Also CRP and IL-6 levels were significantly higher in those patients with an event within 3 months of discharge compared to those patients without an event (3.6±1.3 vs 1.1±0.7 mg/l, p<0.01 and 14.2±3.7 vs 5.4± 1.6 pg/ml, p<0.01, respectively). Both baseline CRP levels and IL-6 were predictor of future in-hospital and 3 months future cerebrovascular events while high CRP and IL-6 levels at baseline were not associated with a poor 1 year prognosis. Elevated CRP levels were associated with an unfavorable outcome only when IL-6 levels were also elevated. In a stepwise multivariate analysis IL-6 levels were stronger predictor of outcome than CRP.
In conclusion elevated CRP and IL-6 levels may identify elderly patients at increased medium term risk while do not predict one year events in this subset of patients. CRP levels predict events only when they are coupled with IL-6 levels.

P2294 Percutaneous coronary intervention in octogenarian population: comparison with elderly patients in Japan

S. Nakamura[1], T. Miyauchi[1], J. Yokoyama[1], A. Kanazawa[1], K. Hozawa[2], S. Nakamura[2], J. Koyama[3], H. Ohira[4]. [1]*New Tokyo Hospital, Department of Cardiorogy, Matsudo-shi, Japan;* [2]*Kasori Hospital, Dept. of Cardiology, Chiba-shi, Japan;* [3]*Kobari General Hospital, Department of Cardiology, Noda-shi,Chiba, Japan;* [4]*Edogawa Hospital, Department of Cardiology, Edogawa-ku, Japan*

Background: Previous studies have suggested the octogenarian have worse outcomes of percutaneous interventions (PCI). However current outcomes of PCI for these patients are still unclear.
Method: We analyzed and compared baseline clinical, angiographical results of 288 consecutive octogenarians (mean age 84.3±4.8 years and 54.9% male) with those of 902 consecutive elderly patients aged from 70 to 79years (mean age 74.7±4.7 and 61.5% male) undergoing PCI from April 1999 to April 2001. The octogenarian group had a higher incidence of LVEF<40%, hypertension, DM, history of CHF, recent MI (<14 days) and total occlusion. Stent and Rotablator use was similar in both groups.
Results: See the table.

octogenarian

	Elderly (70-79 yrs) n=1402	Octogenarians (80> yrs) n=388
Angiographic success (%)	98.8	98.5
Clinical success (%)	98.4	97.4
MACE at 30 days (%)	0	0
MACE at 180 days (%)	12.5 (all: re-PTCA)	10.6 (all: re-PTCA)
Vascular access complications (%)	3.8	4.4
Storoke (%)	0.3	0.3
Event free survival (6 months) (%)	83.4	84.7

MACE: Major Adverse Cardiac Events (death/MI/CABG/re-PTCA)

Conclusion: In octogenarians, PCI can be performed with high success rate without increasing MACE and vascular complications compared with elderly (from 70 to 79 years) patients.

P2295 The presentation and aetiology of heart failure in the elderly – The Hastings heart failure study

S.J. Sutcliffe[1], D.M. Walker[2], J. Barrett[2], S. Murphy[2], R.J. Wray[2]. [1]*Royal Sussex County Hospital, Department of Cardiology, Brighton, United Kingdom;* [2]*Conquest Hospital, Department of Cardiology, St. Leonard's on Sea, United Kingdom*

Introduction: The presentation and aetiology of heart failure in a district general hospital particularly in the elderly is unknown.
Methods: Data was collected prospectively, over a one year period, on all patients in an ageing community of 185,000 presenting to Conquest hospital, Hastings either as an in- or out-patients. Each patient was panelled by one of 2 consultant cardiologists to confirm the validity of diagnosis using ESC guidelines. The history, examination, investigation findings and the contributory causes (aetiology) to heart failure in each patient were recorded.
Results: 1251 hospital presentations of patients suspected to have heart failure were identified. After validation and correction for multiple admissions per patient, 434 patients were confirmed to have true left ventricular systolic dysfunction. The age range was 38 to 101 (average 79, median 80) with prevalence increasing sharply by age. 71% (308) of all patients were older than 75 years old. 49% (214) of all patients were male and 51% (220) female, with an average age of 76 for men and women 82. Dyspnoea was present in 90% of all presentations. NYHA scores were: I – 9%; II – 12%; III – 25% and IV 54%. The resting ECG was abnormal in 95% of all patients and the CXR was abnormal in 95%.
The contributory causes to HF (numbers and percentages) in the elderly is shown below:

Diagnosis:	IHD	HT	Valve	DCM	AF	Alcohol	Unknown
>75:	145 (47%)	116 (38%)	81 (26%)	3 (1%)	146 (47%)	1 (0.5%)	21 (7%)

Conclusion: The Hastings HF study reinforces the dramatic increase in prevalence of systolic HF with age. More than half of all patients identified were in NYHA Class IV. The commonest aetiology in HF is IHD but in >75 multifactorial aetiology is more common. Management strategies for HF need to acknowledge the prevalence, age and complexity of heart failure in the elderly patient in a DGH.

P2296 Patients with 76 or more years admitted with congestive heart failure have a clinical profile different than their younger counterparts

M. Martínez-Sellés, J.A. Garcia Robles, L. Prieto, J.A. Serrano, R. Muñoz, E. Frades, J. Almendral. *Madrid, Spain*

Introduction: Heart failure (HF) is a rapidly expanding syndrome. We need information to design adequate preventive strategies and differences related with age are specially relevant in this condition.
Methods: A total of 1,953 HF or related diagnosis were done among pts admitted consecutively to our institution during 1 year period. Hospital records were collected and retrospectively checked. We excluded 454 pts in whom the presence of HF could not be objectively determined, 69 pts with acute myocardial infarction and 72 pts in whom some data were not available. Therefore we studied 1,358 admissions in 1075 pts (1.27 admission per pt).
Results: Mean age was 74.7 ± 11.6 years. Patients aged >75 y were more frequently females (68 vs 48%). We observed a higher prevalence of: stroke (14 vs 10%), aortic stenosis (11.6 vs 6.5%), cardiomegaly (88 vs 81%) and LVEF >0,4 (65 vs 51%), leg edema (68 vs 62%) and rales (80 vs 73%). They also received diuretics more often (88 vs 80%). However, these older pts had a shorter hospital stay (13.8 vs 17.4 days) and less admissions in the cardiology department (21 vs 31%). We observed a lower prevalence of risk factors (smoking -8.5 vs 25%-, hyperlipidemia -7.4 vs 15%-, severe obesity -4.0 vs 8.7%-, and alcoholism -3,4 vs 13%-), coronary artery disease: (severe coronary stenosis -4 vs 12%- and previous CABG -1.3 vs 8.9%-), and liver disease (2.2 vs 7.5%). Echocardiography was performed less frequently (55 vs 78%) and they received less betablockers (2 vs 7%) and anticoagulants (11 vs 43%). at discharge All differences were significant (stroke and leg edema p=0.05, all the others p<0.01). We found a similar use of ACE inhibitors (67 vs 72%, p=0.25)
Conclusions: 1) Patients with 76 or more years admitted with HF have a different clinical profile, with more comorbidity, less ischemic heart disease and better ejection fraction than their younger counterparts. 2) They undergo echocardiography less frequently. 3) At discharge they receive more diuretics and less betablockers and oral anticoagulants, while the use of ACE inhibitors is similar in both groups.

P2297 Acute ischaemic syndromes in the elderly: Is survival better in patients selected for angiography?

D.A. Halon[1], I. Meri[2], S. Adawi[2], M.Y. Flugelman[2], B.S. Lewis[2]. [1]*Lady Davis Carmel Medical Centre, Cardiology, Haifa, Israel;* [2]*Lady Davis Carmel Medical Centre, Cardiology, Haifa, Israel*

Background: The role of interventions in the elderly with acute ischemic syndromes (AIS) is not clear and may be misrepresented in clinical trials due to high selection bias. We examined characteristics and outcomes in consecutive pts included in a registry of AIS in the elderly.
Patients and Methods: The registry included 251 consecutive septuagenarians and 201 consecutive octogenarians with definite or suspected AIS hospitalized in 3 internal medicine or 1 cardiology department in a single medical center over 1 calendar year. Mean age was 78.6±5.9 yr. Outcomes were examined at a mean time of 15.8±3.5 months.
Results: Coronary angiography (angio) was performed in 168 pts (37.2%) of whom 106 (63.1%) underwent revascularization (68.2% PCI, 31.8% CABG). Patient characteristics and outcomes are presented in table.
In pts undergoing angio without subsequent revascularization (N=62) mortality was less (7.8%) than in the no angio cohort 61 (21.7%) (p=0.01).

Patient Characteristics and Outcomes

	Age(SD)	CHF	AMI*	CVA#	Death	Rhsp**	D/Rhsp$
Angio+ (%)	76.9 (4.9)	25 (15.1)	33 (23.1)	11 (6.6)	21 (12.6)	79 (47.3)	89 (53.3)
Angio- (%)	79.6 (6.3)	88 (31.3)	53 (19.3)	32 (11.4)	61 (21.6)	138 (48.9)	161 (57.1)
p val	0.0001	0.0001	0.36	0.095	0.016	0.74	0.43

*CK>2X upper limit of normal; #Prior TIA or CVA; **Rehospitalization; $Death or rehospitalization

Conclusions: In a registry of consecutive elderly patients (mean age 78.6yr) with acute ischemic syndromes, patients selected for coronary angiography were 1. Younger, had less CHF and less prior cerebrovascular disease 2. Pts undergoing angio had a better 15 month survival, irrespective of whether revascularization was performed 3. Repeat hospitalization was similarly high in patients with and without angiography and whether revascularization was performed or not.

P2298 Effect of multifactorial cardiovascular prevention in 75+ patients: one-year medication and risk factors results of the DEBATE study

T.E. Strandberg, K.H. Pitkala, S. Berglind, M.S. Nieminen, R.S. Tilvis. *University of Helsinki, Department of Medicine, Helsinki, Finland*

Background: There has been a paucity of elderly individuals in cardiovascular prevention trials. Therefore, the aim of the Drugs and Evidence-Based Medicine in the Elderly (DEBATE) study is to test the applicability and effectiveness of established cardiovascular disease (CVD) prevention methods in patients aged 75 and over. We report here the risk factor and medication changes in the intervention and control groups after the first year.
Methods: This population-based study has randomized 400 home-dwelling CVD patients, aged 75, 80, 85, and 90 years at baseline (mean age 80 years, 65% women), for a multifactorial intervention trial (Am Heart J 2001;142:945-51). Of the participants at baseline, 82% had coronary heart disease, 37% history of stroke, 19% NIDDM, and 45% hypertension; only 6% were current smokers. Before randomization, 67% used aspirin, 40% beta-blockers, 14% ACE inhibitors, and 20% lipid-lowering drugs. In the intervention group (n=199), lifestyle factors and CVD treatments are individually tailored by geriatrician-internist according to current guidelines; the control group (n=201) receives the usual care. The primary endpoint will be a composite of major CVD, secondary endpoints include permanent institutionalization, decline in cognitive and physical function, and quality of life.
Results: One-year status of treatments and risk factors is available from 90% of the both groups. In the intervention group as compared to the control group, there has been a significant increase in the use of statins (currently 56% vs. 19%, p<0.0001), aspirin (71% vs. 61%, p=0.03), beta-blockers (60% vs. 47%, p=0.008), and ACE inhibitors (23% vs. 14%, p=0.01). In the intervention group serum total cholesterol and LDL-cholesterol were reduced significantly (p<0.0001 vs. control group), and pulse rate was slightly decreased (p=0.04). Serum high-sensitive C-reactive protein increased significantly less (p=0.009) in the intervention group during the first year. In contrast, body mass index, blood pressure, and blood glucose were not statistically different between the groups. Also serum creatinine, potassium, sodium, and liver enzyme values were similar in the two groups
Conclusion: These interim results suggest that it is feasible and safe to further improve current evidence-based treatments in the oldest cardiovascular patients in real life. Of the risk factors, serum cholesterol and C-reactive protein showed favourable changes in the intervention group. The results are promising for a reduction of clinical endpoints during further follow-up.

P2299 A1 and A2a adenosine receptor gene expression during cardiovascular aging

S. Perlini[1], B. Arosio[2], G. Palladini[1], C. Vergani[2], G. Annoni[2], A.U. Ferrari[3]. [1]*Clinica Medica 2, IRCCS San Matteo, University of Pavia, Pavia, Italy;* [2]*Osp Maggiore, Univ Milano Bicocca, Dept. Geriatrics, Milano, Italy;* [3]*Univ Milano Bicocca, Ctr Fisiol Clinica e Ipertensione, Milano, Italy*

Cardiovascular aging is associated with progressive structural and functional modifications that may contribute to an increased prevalence of heart failure (HF), a situation characterized by excessive catecholamine stimulation. Since HF is also characterized by a reduction of the cardioprotective effects of adenosine (Ado), which are at least in part mediated by the antiadrenergic actions of Ado A1 receptor (A1R) activation and modulated by Ado A2a receptor (A2aR) stimulation, we investigated the relationships between Ado A1R and A2aR gene expression and cardiac function during cardiovascular maturation and aging. Left ventricular (LV) end-diastolic (EDD) and end-systolic (ESD) internal dimensions, and LV fractional shortening (FS, %) were evaluated by M-Mode echocardiography in 2, 5, 12, and 21 month-old Sprague-Dawley rats (2M-old, 5M-old, 12M-old and 21M-old, respectively; n=10 per group). After LV catheterization for the evaluation of systolic LV pressure (LVP), A1R and A2aR mRNA levels were measured in LV myocardial fragments by RT-PCR (densitometric units normalized for the reference gene GAPDH).
Results are shown in the table (means+SEM; *p<0.05 vs 2M-old).

Table

	EDD (mm)	ESD (mm)	FS (%)	LVP (mmHg)	A1R	A2aR
2M-old	7.5+0.2	4.2+0.1	42+1	98+2	1.42+0.14	0.60+0.03
5M-old	8.1+0.2	4.4+0.1	38+2	101+3	1.11+0.05	0.37+0.03*
12M-old	8.5+0.2	4.7+0.2*	39+2	102+3	2.02+0.12*	0.41+0.02*
21M-old	8.8+0.2*	5.1+0.2*	35+2*	105+4	2.11+0.20*	0.40+0.02*

Aging was associated with progressive reduction in systolic function and increases in both end-diastolic and end-systolic LV dimensions, at comparable systolic LV pressure. Concomitantly, Ado A1R gene expression was increased, while Ado A2aR mRNA levels were reduced. These opposing changes in Ado A1 and A2a receptor gene expression during aging indicate that a modification of their cross-talk may be associated with LV morpho-functional alterations and progressive loss of adenosine cardioprotective mechanisms.

P2300 Differences in coronary risk factors between middle-aged and elderly individuals. The CARDIO2000 study

C. Chrysohoou, D.B Panagiotakos, C. Pitsavos, J. Skoumas, J. Skoumbourdis, C. Stefanadis, P.K. Toutouzas. *University of Athens, School of Medici, Cardiology Clinic, Athens, Greece*

Background: It is suggested from several investigators that the relative risks of cardiovascular events in elderly are much different compared to the others. In this work we aim to evaluate differences in the coronary risk factors between elderly and middle aged people, in a Mediterranean population with high life expectancy.

Methods: During 2000-01, we randomly selected 848 hospitalised patients (695 males, 58±10 -153 females, 65±9 years old) for first event of acute coronary syndromes (ACS) and 1078 paired, by sex-age, hospitalised controls without CHD (CARDIO2000), from all the Greek regions. In order to evaluate differences in the risk factors between elderly and the rest of the subjects, we developed multivariate risk models, using "dummy" variables as indicators of age group.

Results: 370 (43%) of the patients and 408 (38%) of the controls were over 65 years old (mean age (SD): 70 ± 4 and 69± 3, respectively). The sex ratio (males/females) was 7-to-3 in the elderly, while it was 4-to-1 in the < 65 years old patients. The following table presents differences in the effect of the investigated risk factors between middle –aged and elderly people.

	Age < 65 yrs		Age > 65 yrs		Differences
Risk factor	OR	P-Value	OR	P-Value	P-Value
Smoking (Y/N)	2.41	0.0001	1.56	0.017	< 0.05
Hypertension (Y/N)	2.04	0.012	1.99	0.001	NS
Diabetes mellitus (Y/N)	1.84	0.017	3.22	0.001	< 0.01
Sex (male-female)	1.41	0.018	2.11	0.001	< 0.05
Age (10-years)	1.04	0.023	1.19	0.001	NS
Physical inactivity (Y/N)	1.12	0.023	1.14	0.51	NS
Unhealthy diet (Y/N)	1.21	0.024	1.76	0.005	< 0.05
Hypercholesterolemia (Y/N)	3.95	0.031	2.75	0.001	< 0.01
Social status (low/high)	1.44	0.032	1.22	0.166	< 0.05
Depression (Y/N)	1.22	0.035	1.51	0.027	< 0.05
BMI (Kgr/m^2)	1.02	0.039	1.00	0.78	NS

Conclusions: In elderly subjects some common risk factors like smoking, sex, diabetes mellitus, unhealthy diet, depression and BMI seem to have different impact on coronary risk than in younger subjects. Recognition of the differences that occur in periods throughout the life span may contribute to understanding their causes and devising more effective strategies for the primary prevention

PROGNOSIS IN HEART FAILURE

P2301 Prognostic value of left atrial functional parameters in congestive heart failure

L.R. Tumasyan[1], A.B. Nargizyan[2], H.S.H. Kamalyan[1], N.N. Khudabashyan[1]. *[1]Institute of Cardiology, Heart Failure, Yerevan, Armenia; [2]Institute of Cardiology, Heart Failure, Yerevan, Armenia*

Background: Prognostic significance of the left ventricular performance in patients (pts) with congestive heart failure (CHF) is well established. However, it has not been clarified whether left atrial (LA) dysfunction influence the mortality in these pts.

The aim of our study was to assess the contribution of the parameters of LA function to the prediction of survival in pts with severe CHF.

Methods: We prospectively studied 172 pts (mean age 60.2±0.8, male 120) in sinus rhythm with dilated cardyomyopathy of ischemic (n=132) or nonischemic (n=40) origin and NYHA III-IV functional class CHF. LA end-systolic dimension, volume, late diastolic (A) transmitral flow velocity, LA kinetic energy (LAKE), mitral regurgitation (MR) and also atrioventricular place displacement (AVPD) were obtained using M-mode, two-dimensional and Doppler echocardiography. LAKE was calculated using the formula=1/2 LA stroke volume x1.06 x A^2, where the A-transmitral Doppler A velocity. MR was quantified as a MR area/LA area ratio.

Results: During a mean follow-up period of 50±14 months 58 (33.7%) pts died from cardiac causes. Pts with cardiac events had a more impaired LAKE (4.7±0.8 kdyn/cm/sec vs. 9.1±1.1 kdyn/cm/sec, p<0.001), transmitral filling pattern, depicted by A velocity (29.3±3.6cm/sec vs. 39.2±3.1 cm/sec, p<0.05), and AVPD (5.5±0.8mm vs. 8.9±1.1mm, p<0.01). The MR was markedly severe in nonsurvivors than in survivors (0.41±0.05 vs. 0.2±0.04, p<0.02). In pts free of cardiac events lower LA dimension (62.6±5.3mm vs. 76±4.2mm) and volume (93.6±7.1ml vs. 116±8.3ml, p<0.05) were found. In the univariative Cox proportion hazard model all of these parameters were found to be significant prognostic indicators of survival. However, the multivariative Cox analysis revealed that only LA enlargement, LAKE and AVPD were the significant independent predictors of cardiac death. Kaplan-Meier survival curves demonstrated a survival rate of 68% for pts with LA dimension>70mm and volume>110ml and 87% for those with dimension<70mm and volume<110ml (p<0.01). Similar probability of survival (p<0.01) was shown in pts with LAKE>6.5 kdyn/cm/sec (85%) and AVPD>7.0mm (82%) and in those with LAKE<6.5 kdyn/cm/sec (62%) and AVPD<7.0mm (64%).

In conclusion, LA parameters are the powerful predictors of survival in pts with CHF. LA enlargement allows for identification a high-risk subgroup of pts with a worse outcome. In addition, lower LAKE and AVPD provide similar prognostic information.

P2302 Haemoglobin predicts survival in patients with chronic heart failure with a U-shaped curve: a substudy of the ELITE II trial

S.D. Anker[1], R. Sharma[2], D.F. Francis[2], B. Pitt[3], P.A. Poole-Wilson[2], A.J.S. Coats[2]. *[1]Charite Medical School, Campus Virchow, Cardiology, Berlin, Germany; [2]NHLI, Clinical Cardiology, London, United Kingdom; [3]University of Michigan, Cardiology, Michigan, United States of America*

Background: The correction of anaemia in chronic heart failure (CHF) is associated with an improvement in symptoms and cardiac function. The relationship between haemoglobin and survival in CHF, and whether there is an optimal range, is not known.

Methods: We analysed haemoglobin concentrations in 3044 patients recruited in the Evaluation of Losartan In The Elderly (ELITE II) trial. Patients of mean age 71.5±6.8 years (±SD) and New York Heart Association (NYHA) class 2.5±0.6 were enrolled from June 1997 to May 1998 and followed-up for survival (range 1 to 780 days, median 551).

Results: The mean haemoglobin level was 14.0±1.6 g/dL (males: 14.3±1.5, females: 13.3±1.4 g/dL; p<0.0001). Overall, there were 513 patients (16.9% of the study population) with a haemoglobin level less than 12.5 g/dL (257 males [12.2% of all males]; 256 females [27.1% of all females]). There were 82 females (8.7% of all females) with a haemoglobin level less than 11.5 g/dL. In univariate analysis, age, NYHA class, serum creatinine, left ventricular ejection fraction (all p<0.0001) and sex (p=0.046) all predicted survival. Haemoglobin as a continuous variable for all patients was not a significant prognostic marker (p=0.26). However, subdividing patients according to 1.0 g/dL increments of haemoglobin revealed a U-shaped mortality curve, with 14.5-15.4 g/dL having the best prognosis (2 year survival 85%; 95% CI 81 to 89%), independent of age, sex, NYHA class, left ventricular ejection fraction, creatinine, co-existing chronic obstructive pulmonary disease and treatment allocation (p<0.001). Patients in the lowest (<12.5 g/dL) and highest (>15.4 g/dL) haemoglobin groups had the worst survival (75% and 76%, respectively, at 2 years). Further analysis identified a haemoglobin of 14.5 g/dL as optimal for survival in CHF.

Conclusions: Anaemia is frequently observed in patients with CHF and relates to a poor prognosis. Haemoglobin is an independent predictor of mortality for patients with CHF. The relationship is not linear but follows a U-shaped curve, with anaemic and polycythaemic patients having the worst survival. It may be important to have a specific target range for haemoglobin when treating anaemia in CHF.

P2303 Anaemia is an independent predictor of poor outcome in patients with chronic heart failure

J. Szachniewicz[1], J. Petruk-Kowalczyk[1], A. Kaczmarek[1], T. Witkowski[1], M.F. Piepoli[2], S.D. Anker[2], W. Banasiak[1], P. Ponikowski[1]. [1]*Clinical Military Hospital, Cardiology, Wroclaw, Poland;* [2]*NHLI, Imperial College, Clinical Cardiology, London, United Kingdom*

Background: Mild anaemia frequently occurs in patients with chronic heart failure (CHF), particularly in the advanced stages of the disease. The correction of anaemia with erytropoietin may be possible. The aim of this study was to assess prospectively the relationship between the prevalence of anaemia (haemoglobin level <= 120 g/l) and prognosis in an unselected CHF population.
Methods: All consecutive patients with a diagnosis of CHF admitted to our department between January and April 2000 were considered for the present study. Those with secondary causes of anaemia were excluded. Patients were followed-up until November 2001 (>18 months in all survivors), and the endpoint of the study was all-cause mortality.
Results: One hundred and seventy six patients were enrolled (120 men, mean age: 63 yrs; New York Heart Association [NYHA] class I/II/III/IV: 14/82/52/28; left ventricular ejection fraction [LVEF]: 41%, CHF of ischaemic aetiology in 62%). In the whole population the mean haemoglobin level was 140±16 g/l. Anaemia was found in 18 (10%) patients, and was significantly more common in women than in men (18% vs 7%, respectively, p=0.02) and in those with most severe CHF symptoms (frequency in NYHA I/II/III/IV: 0%/9%/10%/21%, respectively, NYHA IV vs I-III, p=0.03), but not related to the other clinical indices. Univariate analysis revealed NYHA class III-IV (hazard ratio 3.9, 95%CI: 1.7-9.4, p=0.002), low LVEF <= 30% (hazard ratio 2.7, 95%CI: 1.2-6.2, p=0.02) and anaemia (hazard ratio 2.9, 95%CI: 1.2-7.2, p=0.02) as predictors of 18-month mortality. In multivariate analysis, anaemia remained an independent predictor of death when adjusted for NYHA class and LVEF (hazard ratio: 2.7, 95%CI: 1.1-6.8, p=0.03). In anaemic patients, 18-month survival was 67% (95%CI: 45-89%) compared to 87% (95%CI: 81-92%) in patients with a normal haemoglobin level (p=0.016).
Conclusions: Mild anaemia is a significant and independent predictor of poor outcome in unselected patients with CHF. Correction of low haemoglobin level may become an interesting therapeutic option for anaemic CHF patients.

P2304 Prognostic impact of right ventricular disfunction in patients with ischaemic and non ischaemic left ventricular disfunction

L. La Vecchia[1], G.L. Spadaro[1], M. Paccanaro[1], L. Zanolla[2], L. Varotto[1], C. Bonanno[1], A. Fontanelli[1]. [1]*S Bortolo Hospital, Cardiology, Vicenza, Italy;* [2]*Borgo Trento Hospital, Cardiology, Verona, Italy*

Background: Previous observations by our group reported: 1) a higher prevalence of right ventricular (RV) dysfunction in idiopathic dilated cardiomyopathy (IDC) compared to ischemic heart disease (IHD); 2) a significant negative prognostic impact of RV dysfunction in patients (pts) with IDC. Other published studies observed that RV dysfunction is a powerful prognostic marker in heart failure. We sought to investigate the prognostic role of RV function: 1) compared to LV function; 2) in IDC compared to IHD.
Methods: We studied 193 consecutive pts (mean age 57±12 yrs; 83% males) enrolled because of a left ventricular (LV) ejection fraction (EF) <45% secondary to IHD (86 pts, 44%) or IDC (107 pts, 56%). Coronary anatomy was documented in all cases, and 70% of IDC pts underwent endomyocardial biopsy to rule out myocarditis. RV function was assessed angiographically based on Ferlinz's method (normal reference for RV EF in our laboratory: 53±6%). LV and RV parameters were entered in a multivariate analysis according to the Cox proportional hazard method. The end-point considered was transplant-free survival (TFS).
Results: LV EF was 31±9% and RV EF was 38±12%. Mean follow-up was 33 months (range 12-126 mo). Fifty-five events were recorded: 36 cardiac deaths, 3 non-cardiac deaths and 16 transplants. Thus, TFS was 72%. At univariate analysis, significant predictors of TFS were: RV end-diastolic volume (EDV) (p=0.001) but not LV EDV (p=0.108), RV end-systolic volume (ESV) (p<0.0001) and LV ESV (p=0.022), RV EF (p=0.002) and LV EF (p=0.004). At multivariate analysis, RV function was an independent predictor of TFS (EDV: p=0.001; ESV: p<0.0001; EF: p=0.003), but not LV function (ESV: p=0.800; EF: p=0.085). When etiology (IDC vs CHD) was entered in the model, the results did not show any significant change.
Conclusions: In our series, RV function appears to be more powerful than LV function as a predictor of survival, regardless of the etiology of LV dysfunction. These results are intriguing, especially for patients with IHD, which is notoriously characterized by an almost exclusive involvement of the LV.

P2305 Minor myocardial damage detected by troponin T is a powerful predictor of long-term prognosis in patients with decompensated heart failure

E.R. Perna[1], S.M. Macin[1], J.P. Cimbaro Canella[1], N. Augier[1], E.F. Farias[1], J.R. Badaracco[1], P.D. Liva[1], M. Brizuela[2]. [1]*Instituto de Cardiologia J. F. Cabral, Heart Failure Clinic, Corrientes, Argentina;* [2]*Instituto de Cardiologia J. F. Cabral, Laboratorio, Corrientes, Argentina*

Background: Progression of chronic heart failure (CHF) is characterized by frequent hospitalization for decompensation and high mortality. Clinical deterioration is triggering by many factors that could promote ongoing myocytes injury.
Aim: We sought to determine whether a specific marker of cardiac injury, cardiac troponin T (cTnT), would be associated with long-term prognosis in patients admitted for decompensated CHF.
Methods and Results: One hundred and eighty-four patients with decompensated CHF in the absence of an acute coronary syndrome were enrolled. A cTnT value >=0.1 ng/mL in samples drawn at 6, 12 or 24 hours after hospitalization was considered abnormal and it was found in 58 patients (31.5%, Group 1). There were no significant differences between Group 1 and patients with cTnT <0.1 ng/mL (Group 2) in terms of demographic and clinical data, and NYHA functional class. During a median follow-up of 9 months, the mortality in Group 1 and 2 was 31% and 17.5% (p=0.038; OR=2.13, 95% CI, 0.97-4.69). The cumulative 3-year free-CHF readmission survival in Group 1 and 2 was 53% and 25% (log rank test p=0.015). In a Cox proportional hazard model, poor tissue perfusion (RR=2.46, CI95%=1.31-4.6), previous infarction (RR=1.99, CI95%=1.02 - 3.9) and cTnT >= 0.1 ng/mL (RR=1.74, CI95%=1.05 - 2.9) emerged as the independent predictors of long-term outcome
Conclusions: One third of patients with decompensated CHF had elevated levels of cTnT. This subgroup was clinically undistinguished from those without myocardial damage. cTnT >=0.1 ng/mL was an independent long-term prognostic marker and it suggest a role of biochemical stratification in this setting.

P2306 The prognostic value of troponin T and echocardiography in acute pulmonary oedema

Y. Ofran, M. Gatt, D. Leibowitz, A.T. Weiss. *Hadassah University Hospital, Department of Cardiology, Jerusalem, Israel*

Background: Elevated troponin T levels and decreased LV function have successfully predicted elevated risk in acute coronary syndromes, however their independent and combined prognostic value in patients presenting with pulmonary edema (PE) is unknown. This study examined the predictive value of troponin measurement and echocardiography in patients presenting with PE.
Methods: Records of all patients admitted to the CCU with a diagnosis of acute pulmonary edema (PE), measurement of TnT, and echocardiographic study were reviewed. Patients with ST elevation on admission ECG or severe AS were excluded. 124 patients formed the study group (mean age 73.5 ± 10.8, 61M/63F) and six month telephone follow-up of clinical status was performed.
Results: Elevated TnT levels (> 0.1 ng/ml) were noted in 53 patients (42.7%). During six months of follow-up, this group had a significantly increased incidence of ischemic cardiac events (cardiac-related death, non fatal MI or acute coronary syndrome) (26 cases (49.1%) vs 19 cases (26.8%)) compared with the TnT negative group.(p< 0.01) Moderate or severely reduced LV function (75 patients) was also a predictor of recurrent ischemic events with an incidence significantly higher in this group as compared to patients with normal or minimally reduced LV function (35 cases (46.7%) vs 10 cases (20.4%)). (p< 0.04) When cardiac function and TnT levels were analyzed together, the power of prediction was significantly improved. Only 3 (9.7%) of 31 patients with normal heart function and normal levels of troponin, had recurrent ischemic events compared with 19 patients (54.3%) among those with both reduced LV function and elevated TnT. (p< 0.002) Neither reduced LV function or elevated troponin T predicted recurrence of pulmonary edema.
Conclusions: In patients with pulmonary edema, elevated TnT and decreased LV function are independent predictors of recurrent ischemic events and combining provides additive predictive power as compared to each predictor alone. Patients with these findings require a more agressive therapeutic approach while the low event rate in patients with normal troponin and LV function, these patients may be managed more conservatively.

P2307 Risk stratification in asymptomatic or mild symptomatic left ventricular dysfunction: interleukin-6 is a strong predictor for long-term mortality

T. Kleemann, A. Kilkowski, M. Bangert, K. Lindner, W. Greger, K. Siegler, J. Senges, C. Kilkowski. *Herzzentrum Ludwigshafen, Cardiology Department, Ludwigshafen, Germany*

Background: Even after introducing ACE-inhibitors and beta-blockers into heart failure treatment, the mortality rate remains high in patients (P) with congestive heart failure. Therefore risk stratification is warranted to identify high risk P for death in an early stage of heart failure. Aim of the study was to examine the prognostic significance of neurohormones and cytokines in P with asymptomatic or mild symptomatic left ventricular dysfunction (LVD).
Patients and methods: 529 P with an asymptomatic (NYHA I) or mild symptomatic (NYHA II) LVD (ejection fraction [EF] <=45%) admitted to a nonuniversitary tertiary care hospital were prospectively registered. All P were clinically stable and on optimized medical treatment for LVD when blood samples for neurohormones and cytokines were obtained (94% ACE-inhibitor, 56% beta-blocker, 66% diuretics, 59% digoxin and 4% spironolactone). Mean follow-up time was 27 months. P were stratified into two groups according to the median concentrations of the different neurohormones and cytokines. Then multiple logistic regression for all-cause mortality was performed adjusted for age, gender, concomitant diseases and medication.
Results: During the follow-up period of 27 months, 134 (25%) P died.

	Odds Ratio	95% Confidence Interval
Interleukin-6 > 8.6 ng/l	4.1	1.8 - 9.2
EF < 30%	2.3	1.2 - 4.7
Age > 70 years	2.2	1.1 - 4.6
Endothelin > 6.8 ng/l	2.1	1.1 - 4.3
TNF-alpha > 2.5 ng/l	1.9	0.9 - 4.0
Norepinephrine > 307 ng/l	1.9	0.9 - 3.7
ANP > 296 ng/l	0.7	0.4 - 1.5

Multiple logistic regression for all-cause mortality adjusted for age, gender, EF, concomitant diseases and medication

Conclusion: 1. Every fourth P with asymptomatic or mild symptomatic LVD was dead after about two years. 2. In a multivariate analysis a high level of Interleukin-6 was the strongest predictor for all-cause mortality. 3. Among neurohormones, endothelin was best associated with a worse prognosis, having a similar prognostic impact on mortality as a low EF or increased age.

P2308 Smoking status and long-term outcome in a consecutive series of patients with acute myocardial infarction

G. Galasso, F. Piscione, G. De Luca, G. Marrazzo, G. Visconti, O. Viola, F. Furbatto, M. Chiariello. *Federico II University, Cardiology, Naples, Italy*

Background: Cigarettes smoking is one of the most important risk factors for cardiovascular disease. Although it is well recognized that continued smoking confers an adverse prognosis after coronary angioplasty (PCI) in pts with acute myocardial infarction (AMI), recent studies suggest that smokers had better immediate and short-term outcome than nonsmokers, a phenomena so called "Smoker's Paradox". No data exist regarding the relationship between smoking and long term prognosis after AMI. Aim of our study was to evaluate the effects of smoking status on long-terms prognosis in pts with AMI treated with either thrombolysis (154 pts) or PCI (175 pts).
Methods: We evaluated 329 consecutive pts (288 men, 57.6±11.9 years). Two groups were defined according to smoking status before AMI: Smokers (201 pts) and No-Smokers (128 pts). In-hospitals complications were defined as: cardiac death, re-AMI, need of new myocardial revascularization, major ventricular arrhythmias, and heart failure. Major adverse cardiovascular events (MACE) were defined as cardiac death, re AMI, and a new myocardial revascularization. Long-term clinical outcome was based on MACE occurrence rate and obtained in 79% of Smokers and 83% of No-Smokers, during a 20 + 14 months follow up (FU). FU was based on a direct systematic review of all pts clinical documentation during the study period and by a telephone or direct pts interview at the end of FU.
Results: Smokers were younger (55.9±11 years vs 60±12.7 years, respectively, p = 0.001) with prevalence of male sex (94.9% vs 79.2%, p < 0.0001), a lower incidence of diabetes (12.9% vs 23.4%, p = 0.013) and hypercholesterolemia (21.9% vs 35.2%, p = 0.008) but with a higher incidence of previous angina (35.3% vs 24.2%, p=0.034). This group showed a non significant lower incidence of in-hospital events (30.3% vs 36.7%, p = NS). At long-term FU smokers had a significant lower incidence of MACE (18.9% vs 31.1%, p = 0.004). At univariate analysis, presence of diabetes (36% vs 22% p=0.039) and thrombolisys (31% vs 17%, p=0.048) were negative prognostic factors. At multivariate analysis smoking status (p = 0.005) and thrombolysis (p = 0.049) were significant predicting factors, positive and negative respectively, of long-term clinical outcome.
Conclusion: The smoking status was associated to a better long term prognosis confirming the existence of a "Smoker's Paradox". A younger age at presentation, a lower incidence of diabetes and hypercholesterolemia may account for such a paradox.

P2309 Long-term intermittent dobutamine infusion combined with oral amiodarone for end-stage heart failure. A randomized double blind study

J. Nanas, I. Kanakakis, G. Alexopoulos, E. Tsagalou, P. Papazoglou, E. Tsolakis, M. Kopelia, M. Anastasiou-Nana on behalf of Asoc Prof John Nanas. *Dpt of Clinical Therapeutics, University of Athens, Athens, Greece*

Background: Agents with positive inotropic effect have consistently been shown to increase mortality when administered chronically to patients with heart failure. Although controversial, the use of intravenous inotropes as a palliative measure in the small subset of patients with truly end-stage heart failure continuous to be a common practice and may be appropriate. A non randomized study has showed that long-term intermittent dobutamine infusion combined with oral amiodarone, improves the survival of patients with end stage heart failure.The purpose of this randomized double blind study was to evaluate prospectively the effects of long-term intermittent dobutamine infusion (IDI) combined with oral amiodarone in patients with congestive heart failure (CHF), refractory to standard medical treatment.
Methods: Thirty patients with decompensated CHF refractory to standard treatment who could be weaned from dobutamine therapy after an initial 72-hr infusion, were randomized in a double blind manner to Group 1, treated with intravenous placebo infusion for 8 hours every 14 days, and to Group 2, treated with intermittent dobutamine infusion 10ìg/kg/min, for 8 h every 14 days. All patients were treated with oral amiodarone, 400mg/d, started at least 2 weeks before their randomization. Worsening of the patients clinical and/or hemodynamic condition was followed by weekly infusions and if there was no improvement the label was opened and the patients were placed on dobutamine weekly infusions.
Results: There were no differences in baseline clinical, hemodynamic and biochemical characteristics between the two groups. The left ventricular ejection fraction was 24 ±5% and 23±6% in Group 1 and 2 respectively (p=0.563); mean pulmonary capillary wedge pressure 30±8 mmHg and 28±8 mmHg (p=0.528); systolic blood pressure 98±13mmHg and 99±18mmHg (p=0.839); cardiac index 2.2±0.7lt/min/m^2 and 2.1±0.6lt/min/m^2 (p=0.719). The estimated probability of survival at one year was 21% for group I versus 69% for group II, with a median survival time of 20.5 and 52 weeks respectively p=0.007.
Conclusions: Long-term IDI combined with amiodarone added to conventional drugs improves survival of patients with severe CHF.

P2310 Effect of subsequent pregnancy in patients with documented peripartum cardiomyopathy – a prospective echocardiographic and cytokine evaluation

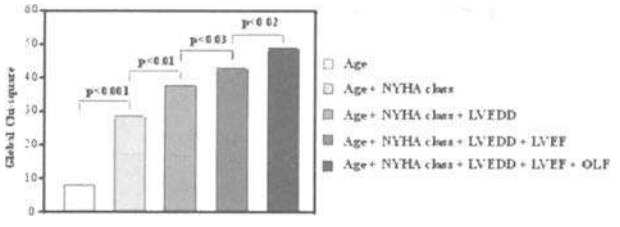
K. Sliwa[1], F. Zhanje[2], J. Kachope[2], R. Essop[2]. [1]*Baragwanth Hospital, Cardiology, Johannesburg, South Africa;* [2]*Baragwanath Hospital, Cardiology Dept., Johannesburg, South Africa*

Objective: To assess the effect of subsequent pregnancy on maternal left ventricular function and plasma levels of TNF-α in patients with previously diagnosed peripartum cardiomyopathy (PPC).
Background: Peripartum cardiomyopathy is a disorder of unknown etiology, and has been reported to be more frequent in African women. Little is known about the time course pattern of left ventricular function in patients with PPC. Serial cytokine measurements have not been done previously in this group of patients.
Methods: We prospectively followed 59 consecutive black women with PPC. Echocardiograms, clinical assessment and cytokine measurements were done at baseline and after 6 months of therapy. After clinical treatment, patients were advised to avoid new pregnancies and a follow-up was obtained. In the patients that had a subsequent pregnancy, echocardiography was performed at onset of the pregnancy (8 weeks), end of pregnancy (8 months), one and three months post partum. At the same time blood for cytokine measurements was taken.
Results: There were 6 subsequent pregnancies in patients aged 26 to 39 years that occurred 1-2 years after clinical treatment of PPC. Four of the 6 patients had a persistent cardiomegaly and impaired ejection fraction (38.4%±6%, n=4 and 56.5%, n=2) at the onset of the subsequent pregnancy. A new pregnancy was initially well tolerated in all patients. None of the patients presented with preeclampsia or worsening heart failure during the pregnancy. The ejection fraction at 8 months of pregnancy remained unchanged (41±6%, n=4 and 54.5%, n=2). One month post partum there was a significant deterioration in the EF in all but one patient (26.5±5%, n=5 and 62.1%, n=1). Three months post partum 2 of the 6 patients died due to heart failure with no improvement in the EF in the remaining patients (25.5±5%, n=4). TNF-α plasma levels were 2.4±1.1 pg/ml at onset of subsequent pregnancy (n=6) and 2.3±0.9 pg/ml at 8 months (n=6). There was a significant increase in the TNF-α plasma levels to 6.8±2.4 pg/ml one month post partum (n=6) and 6.1 ±0.9 pg/ml three months post partum (n=4).
Conclusion: Subsequent pregnancy in this group of patients with PPC had a devastating outcome. The deterioration of left ventricular function occurred in all patients post partum and was accompanied by a significant rise in TNF-α plasma levels.

P2311 Incremental prognostic role of endogenous ouabain-like factor in idiopathic dilated cardiomyopathy towards heart failure progression

M. Iacoviello[1], P. Manunta[2], C. Forleo[1], P. Guida[1], E. Messaggio[2], G. Bianchi[2], P. Rizzon[1], M.V. Pitzalis[1]. [1]*University of Bari, Institute of Cardiology, Bari, Italy;* [2]*Nephrology, Milan University, Milan, Italy*

Plasma levels of endogen ouabain-like factor (OLF) have been demonstrated to be increased in patients with heart failure. No data are available so far as far as their prognostic role is concerned. We sought to verify the predicting value of OLF towards heart failure worsening in a group of patients with idiopathic dilated cardiomyopathy. We prospectively analysed 126 consecutive patients (age 51±15 years; NYHA class 1.9±0.7) with idiopathic dilated cardiomyopathy (WHO criteria), while receiving optimal treatment. Left ventricular ejection fraction (LVEF), left ventricular end diastolic diameter (LVEDD), and OLF plasma levels were evaluated. The progression towards heart failure (worsening in clinical conditions leading to one of the following: sustained increase in conventional therapies, hospitalization, cardiac transplant, death) was considered as end point. After 13±5 months of follow-up, 6 patients had sustained increase of conventional therapy, 16 hospitalization for heart failure, 3 cardiac transplant and one died after heart failure worsening. At univariate analysis, age (HR:1.05; CI:1.01-1.08), NYHA class (HR:5.82; CI:2.92-11.6), LVEDD (HR: 3.35; CI:2.07-5.40), LVEF (HR: 0.89; CI:0.85-0.94) and OLF (HR: 1.005; CI:1.004-1.007) were significantly related to events. By Cox multivariate analysis, OLF was independently associated with heart failure progression (HR: 1.003; CI:1.001-1.005) showing a value incremental over that of demographic, clinical and echocardiographic data (figure). In conclusions in idiopathic dilated cardiomyopathy, high OLF plasma levels are independent predictors of heart failure progression and adding incremental prognostic information to traditional parameters.



P2312 Prognostic value of cytokines and neurohumoral factors in congestive heart failure

M. gwechenberger, M. Hülsmann, R. Berger, B. Stanek, R. Pacher. *Akh, cardiology, Vienna, Austria*

Background: Cytokines and neurohormones have been associated with poor prognosis in patients with congestive heart failure. On the other hand it has been shown that these factors are influenced by medical treatment.
Objectives: The aim of the study was to compare the prognostic value of cytokines and neurohumoral factors in patients with congestive heart failure under maximal uptitrated therapy with ACE Inhibitors.
Methods: We studied 100 patients with congestive heart failure (NYHA II or III), left ventricular ejection fraction <25% and treatment with enalapril 40mg/die, diuretics and digitalis. β-Blocker therapy was started in 91% of the patients during the follow up period. Serum levels of Interleukin-6, TNF-alpha, pro-ANP, ANP, proBNP, BNP, Noradrenalin, big- Endothelin were measured at inclusion of the study. Primary endpoint was death or heart transplantation. Secondary endpoint was defined as combined death, heart transplantation, worsening of heart failure or cardiac arrhythmias. Stepwise multivariate regression analyses were performed using 10 variables (Age, LVEF, bigET, Noa, ANP, proANP,BNP,proBNP, IL-6 and TNF alpha)
Results: During follow-up 39 patients died or had heart transplantation. 54 patients reached the combined secondary endpoint and 46 patient had no events. The mean follow up was 37 months (0.3-60months). A Cox proportional hazards regression analysis identified BNP as independant predictor for the primary endpoint. BNP was 236,4±249,76 fmol/l in patients without primary endpoint and 533,1±539.02 fmol/l inpatients who died or underwent heart transplantation. IL-6 had the strongest predictive value for the secondary endpoint. IL6 was 1.4±1.1 pg/ml in patients without an event and 3.6 ± 5.9 pg/ml in patients with events.
Conclusion: In the present study BNP is the strongest predictor for mortality or heart transplantation. But interleukin-6 is the most potent predictor for the combined end point of death, heart transplantation, worsening of heart failure or cardiac arrhythmias. A single measurement might help identifying patients at high risk of death or complications and should be monitored more closely.

P2313 Pre-trial severity of left ventricular dysfunction in heart failure determines outcomes: Val-HeFT echocardiography study

M. Wong[1], S. Barlera[2], L. Staszewsky[2], M.R.P. Baselier[3], D.P. Naidoo[4], S. Souttern[5], N. Aknay[6], I. Anand[7]. [1]*VA Greater Los Angeles Healthcare Syst, Los Angeles, United States of America;* [2]*Instituto Mario Negri, Milan, Italy;* [3]*Ampia Ziekenhuis, Breda, Netherlands;* [4]*King Edward VII Hospital, Durban, South Africa;* [5]*Wythanshawe Hospital, Manchester, United Kingdom;* [6]*Novartis Pharmaceutical Corporation, East Hanover, United States of America;* [7]*University of Minnesota, Minneapolis, United States of America*

Background: Earlier echocardiography (echo) studies indicated that left ventricular (LV) size and ejection fraction (EF) were predictors of mortality in heart failure (HF). The Val-HeFT (Valsartan in Heart Failure Trial) echo database from 5010 patients enabled evaluating the hypothesis that pre-trial severity of LV dysfunction determines morbidity and mortality.
Methods: Baseline LV internal diastolic diameter (LVIDd)and EF were grouped by quartiles (Q1-Q4): <6.3 to ≥7.5 cm and ≥32 to <22%, respectively. Risk ratios (RR) for morbidity (time to death or time to 1st of: sudden death with resuscitation, IV inotropic therapy, or hospitalization for HF), and mortality (time to death) were calculated from pooled data including valsartan and placebo patients using Cox regression analysis.

	Quartiles	% Morb.	RR vs Q4	P	% Mort.	RR vs Q4	P
LVIDd (cm)	Q1: <6.3	21.1	0.485	**	13.2	0.442	**
	Q2: 6.3 to <6.8	29.4	0.713	**	17.9	0.617	**
	Q3: 6.8 to <7.5	31.1	0.756	**	19.1	0.656	**
	Q4: ≥7.5	39.0	–	–	27.3	–	–
EF (%)	Q1: ≥32	22.6	0.506	**	13.9	0.501	**
	Q2: 27 to <32	29.6	0.687	**	19.1	0.706	**
	Q3: 22 to <27	30.7	0.711	**	19.8	0.725	*
	Q4: <22	40.2	–	–	26.4	–	–

*p=0.0002 **p<0.0001 (log-rank tests)

Results: Grouping the data according to severity of LV dilatation (increasing LVIDd) and systolic dysfunction (decreasing EF) demonstrated gradients of increasing morbidity and mortality at the higher baseline quartiles. RR between baseline quartiles showed the greatest reduction comparing the best (Q1) to the worst (Q4).
Conclusion: Val-HeFT echo data confirm that stratification of patients in HF by severity of increased LVIDd and decreased EF can identify patients most likely to suffer from morbidity and mortality.

P2314 Prognosis in severe heart failure due to Chagas' disease worse than heart failure due to idiopathic, ischaemic or hypertensive cardiomyopathy

H. Freitas, P.R. Chizzola, M.R.P. Markus, M.A.R. Cuoco, A.T. Paes, A.C.P. Lima, E.A. Bocchi, A.J. Mansur. *Heart Institute (InCor), São Paulo, Brazil*

To evaluate clinical determinants of prognosis in a large hospital based series of outpatients with severe heart failure due to different etiologies, including Chagas' heart disease, we have followed up 1220 outpatients in a single Institution since 1991.

Patients were referred for treatment of heart failure in a tertiary care university hospital dedicated to cardiology, and followed-up for 25.6 ± 26 months. Patients' ages ranged between 13 and 72 (45.5 ± 11) years; 952 (78%) patients were men and 268 (22%) women. Heart failure was ascribed to idiopathic dilated cardiomyopathy in 454 (37.2%) patients. Etiologies were Chagas' heart disease in 242 (19.8%) patients, ischemic cardiomyopathy in 212 (17.4%), hypertensive cardiomyopathy in 170 (13.9%), and others in 142 (11.7%). Standard therapy included angiotensin converting enzyme inhibitors titrated to the patients' needs. Survival was assessed through Kaplan Meier method for each clinical variable categorized in terciles, to avoid pre-established categorizations. Subsequently, an univariate Cox proportional hazard model was fitted and multivariate analysis was performed, through pooled non-invasive clinical variables (non-invasive model), and cardiac catheterization variables (invasive model).

Results - 425 (34.8%) patients died in the follow-up, 74 (6.1%) patients underwent heart transplantation and 28 (2.3%) underwent other surgical interventions. In the non-invasive model, Chagas' heart disease etiology (relative risk of 2.72), left ventricular end diastolic diameter (relative risk 1.13) and left ventricular ejection fraction (relative risk 0.96) were identified as the main determinants of prognosis. In the invasive model, Chagas' heart disease etiology (relative risk of 9.13) and the cardiac index (relative risk 0.40) were identified as the most important determinants of prognosis.

Conclusion: In conclusion, prognosis in severe heart failure due to Chagas' disease was worse than prognosis in heart failure due to idiopathic, ischemic or hypertensive cardiomyopathy. In addition, Chagas' heart disease etiology surpassed other clinical markers of less favourable prognosis in this series.

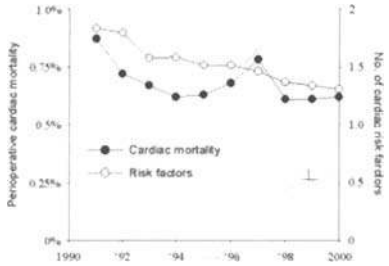
P2315 Perioperative cardiac mortality rates in 109.904 surgical patients. A single-centre experience from 1991 to 2000

D. Poldermans, E. Boersma, M. Kertai, J.J. Bax, M. van Santen, L.L.M. van de Ven, A.F.L. Schinkel, J.R.T.C. Roelandt. *Erasmus Medical Centre, Cardiology Dept., Rotterdam, Netherlands*

Aim: To assess the incidence of perioperative cardiac mortality in daily clinical practice; to identify risk factors; and to study changes over time.

Methods: A hospital database provided information on potential cardiac risk factors (age, gender, hypertension, smoking, angina, MI, heart failure, stroke, diabetes, preexistent renal failure and COPD), and perioperative mortality of all surgical admissions during 1991-2000. Risk factors were determined according to the ICD-9 coding system. The mortality cause was assessed by review of hospital records and autopsy results. Autopsy results were available in 33%. Patients admitted for cardiac surgery and patients under age 16 were excluded. Time trends were identified with chi-square tests and logistic regression analyses were applied to study the relation between risk factors and cardiac mortality.

Results: 109.904 patients underwent surgery. Overall perioperative mortality was 3.1%, and cardiac death 0.68% (22% of all-cause mortality). The incidence of cardiac mortality, and the prevalence of potential risk factors decreased with time (figure). Risk factors that were significantly associated with perioperative cardiac death were: previous MI (odds ratio [OR] 6.6; and 95% CI: 5.4-8.1); heart failure (OR 4.7; 3.9-5.7); renal failure (OR 3.3; 2.6-4.3); age >70 years (OR 3.1; 2.6-3.6); diabetes (OR 1.7; 1.3-2.1); male gender 1.4 (1.2-1.7); and hypertension (OR 1.3; 1.0-1.6). Angina, smoking, COPD, and hypercholesterolemia were not associated with increased cardiac mortality.



Cardiac mortality rates.

Conclusions: Although the incidence of perioperative cardiac death decreased during 1991-2000, patients with established coronary disease or preexistent renal failure still remain at high risk.

P2316 A non-invasive index to identify ambulant patients with chronic heart failure at increased risk of sudden death; results of UK-HEART

N. Gall on behalf of The UK-HEART investigators. *king's college hospital, cardiology, London, United Kingdom*

Background: sudden death is common in patients with chronic heart failure (CHF). Patients with mild to moderate disease are at relatively greater risk of sudden death when compared to those with more severe functional impairment; identifying those at risk is an important goal. UK-HEART was designed to prospectively identify non-invasive predictors of mode of death in mild to moderate CHF.

Methods: between 1993 and 1995, 553 patients with stable mild to moderate CHF were recruited: 76% male, 63±10 (mean±sd) years old, 76% ischaemic heart disease, NYHA 2.3±0.5, EF 41.71±16.9%. Serum biochemistry, cardiothoracic ratio (CTR), echocardiographic and electrocardiographic variables, including QT and QRS dispersion (QTd and QRSd respectively) and heart rate variability and the presence of non-sustained ventricular tachycardia (NSVT) on 24 hour Holter monitoring were assessed. By 2000, after at least 5 years' follow-up, 201 patients had died, 67 (33%) suddenly.

Results: using the Cox proportional hazards regression model, CTR, QRSd, the presence of NSVT and QTd across the chest leads were found to be significant independent predictors of sudden death (all $p<0.04$). The hazard ratio (95% confidence intervals) represents the excess risk associated with the effect in parentheses. CTR (10% increase) 1.43(1.2-1.71); QRSd (10%increase) 1.11(1.04-1.19); NSVT (presence) 2.03(1.27-3.25); QTd (10%increase) 1.04(1.00-1.07).

An index was derived by summing weighted scores for each of the four variables (the 3 continuous variables dichotomized by their medians): CTR>0.52 (score 4), presence of NSVT (score 3), QRSd >42.7ms (score 2), QTd> 37ms (score 2), score 0 otherwise, total a maximum of 11. This index was found to perform well in identifying those at risk of sudden death. (SN-sensitivity, SP-specificity, PPV-positive predictive value, NPV-negative predictive value). For a score of 11: SN 98.5, SP 11.1, PPV 13.3, NPV 98.2; for a score of 0: SN 20.9, SP 95.9, PPV 41.2, NPV 89.8. The C statistic for the Receiver Operator Characteristic curve is 0.7.

Conclusion: an index derived from simple, readily measurable, non-invasive measures can be used to identify patients with mild/moderate heart failure at risk of sudden death.

HEART TRANSPLANTATION

P2317 Relation between left ventricular function and exercise tolerance in heart transplant recipients

M. Dandel[1], M. Hummel[1], E. Wellnhofer[2], R. Meyer[1], R. Hetzer[1]. [1]*German Heart Institute of Berlin, Thoracic and Cardiovascular Surgery, Berlin, Germany;* [2]*German Heart Institute of Berlin, Cardiology Dept., Berlin, Germany*

Background: Reduced post-transplant exercise tolerance is mainly attributed to the altered physiologic responses of denervated hearts to expercise. The contribution of left ventricular (LV) dysfunction is barely known. We assessed the left ventricular (LV) function and exercise tolerance in non-rejecting heart recipients, in connection with transplant coronary artery disease (TxCAD) and amount of interstitial fibrosis.
Methods: Echocardiographic analysis of LV function (M-mode-, 2D-, flow Doppler- and tissue Doppler) was performed in 120 patients (post-transplant time: 3 months -13 years), prior to exercise testing, cardiac catheterization and endomyocardial biopsy. Echocardiographic parameters were tested for relationships with histological, angiographical and exercise findings.
Results: Reduced percentage of predicted peak oxygen uptake was found in 117 patients (97.5%). Even without TxCAD, peak oxygen uptake reached only 73.8 ±9.2% of predicted values. The elevated LV end-diastolic pressure [LVEDP] (11.8 ±5.9mmHg) and reduced transmitral pressure half-time [PHT] (42.3 ±9.9ms) suggest, that without TxCAD, reduced exercise tolerance was mainly related to diastolic dysfunction. All TxCAD patients showed reduced exercise tolerance, which was highest in the angiographic TxCAD group. In patients with angiographic TxCAD, the LV ejection fraction, although lower than without TxCAD (p=0.0011), was in normal range (62.8 ±11.5%). The high LVEDP (14.8 ±5.6mmHg) and short PHT (30.1 ± 8.7ms) in these patients were indicative for a mainly diastolic dysfunction. The significantly reduced systolic wall motion peak velocities measured by tissue Doppler imaging in both TxCAD groups (angiographic and visible only by intracoronary ultrasound), suggests also the contribution of impaired systolic function to the exercise intolerance. Patients with TxCAD showed also reduced chronotropic responses to exercise ($p < 0.01$).
Impaired diastolic function and exercise intolerance appeared also related to interstitial fibrosis. Patients with diffuse perivascular and interstitial fibrosis showed higher LVEDP, shorter PHT and more altered exercise parameters than patients with minimal or reduced fibrosis ($p < 0.001$).
Conclusions: The LV diastolic dysfunction, closely related to interstitial fibrosis, is a major cause of post-transplant exercise intolerance. TxCAD impairs exercise capacity mainly by aggravating pre-existent diastolic dysfunction and reducing the chronotropic response to exercise. Post-transplant exercise intolerance is rarely the prime consequence of impaired LV systolic function.

P2318 Adenovirus-mediated gene transfer of interleukin-1 or RANTES antagonists prolongs heart allograft survival in a rat model

S. Fleury[1], E. Simeoni[1], J. Li[1], J. Dudler[2], G. Vassalli[1]. [1]*CHUV, Cardiology, Lausanne, Switzerland;* [2]*CHUV, Rhumatology, Lausanne, Switzerland*

Chemokines including RANTES (Regulated upon Activation, Normal T-cell Expressed and Secreted) play a key role in mediating leukocyte migration and activation within cardiac allografts, which represent crucial early pathophysiological events after engraftment. Other cytokines including interleukin-1 (IL-1) are also involved in the amplification of early leukocyte recruitment into the allograft. To prevent cellular infiltration and activation within the grafted heart, we have constructed recombinant adenoviral vectors expressing soluble IL-1 type II receptor (sIL-1RII), which antagonizes the IL-1 cytokine, and RANTES(9-68), which acts as an antagonist of RANTES.
Methods and Results: Heart allografts were performed in the F344/Lewis rat strain combination. Ex vivo gene transfer was carried out by intracoronary instillation of adenoviral vectors expressing sIL-1RII (2x10E10 plaque forming units; n = 10), RANTES(9-68) (n = 7), no transgene (n = 5) or saline solution with no virus (n = 6). Allograft survival was prolonged by sIL-1RII (15.6+5.7 days) and RANTES(9-68) (17.0+1.8 days) adenoviral vectors as compared to null-adenovirus (9.8+0.8 days; $p < 0.01$ for sIL-1RII and RANTES) or saline (9.8+2.1 days; $p < 0.01$ for sIL-1RII and RANTES). Immunohistochemical analysis will be presented.
Conclusions: Adenoviral vectors expressing IL-1 or RANTES antagonists may be a useful approach to prevent acute cardiac allograft rejection.

P2319 Role of B cells and macrophages in endomyocardial biopsies with ISHLT grade 0

N.E. Hiemann[1], R. Meyer[1], M. Hummel[1], E. Wellnhofer[2], S. Thomann[1], R. Hetzer[1]. [1]*Deutsches Herzzentrum Berlin, Cardiothoracic and Vascular Surgery, Berlin, Germany;* [2]*Deutsches Herzzentrum Berlin, Cardiology, Berlin, Germany*

Purpose: Acute cellular rejection episodes are the main life threatening complications within the first year after heart transplantation [HTx]. This study tests the role of immunohistochemical evidence of B cells and macrophages in endomyocardial biopsies [EMB] without evidence of acute cellular rejection according to the Classification of the ISHLT.
Methods: Out of a total of 809 EMB with ISHLT grade 0 taken from 422 HTx patients (72 female, 350 male, mean age at HTx 46 years) with terminal heart failure (CAD=115, dCMP=274, others=33) 393 EMB without evidence of the Quilty phenomenon were divided into 5 time intervals [TI] after HTx (1st-4th month, N=70; 5th-12th month, N=48; >1st-2nd year, N=71; >2nd-4th year, N=78; >4th-10th year, N=126). In H&E stainings vascular reaction (endothelial cell swelling/vessel wall thickening) was graded and immunohistochemical reactions with antibodies directed against B cells (CD20cy, clone L26, Dako®) and macrophages (CD68, clone KP1, Dako®) were performed and evaluated semi-quantitatively by light microscopy (x200).
Results: 1. There was a positive reaction for B cells in 5.7% of EMB in TI I, in 14.6% in TI II, in 11.4% in TI III, in 11.8% in TI IV, and in 9.5% in TI V. 2. Immunohistochemical evidence of macrophages was found in 100.0% of EMB in TI I, in 93.7% in TI II, in 84.5% in TI III, in 83.3% in TI IV, and in 83.2% in TI V. 3. Distribution of positive reaction for B cells in males and females was as follows: male/female TI I 3.4/18.2%, TI II 11.9/33.3%, TI III 8.2/33.3%, TI IV 12.9/0.0%, TI V 11.1%/0.0%, and for macrophages: male/female TI I 100.0/100.0%, TI II 95.2/83.2%, TI III 83.9/88.9%, TI IV 83.3/83.3%, TI V 86.0%/66.7%. 4. There were no correlations between the immunohistochemical evidence of B cells and macrophages. 5. Severity of vascular reaction was independently of immunohistochemical evidence of B cells and macrophages.
Conclusions: 1. Evidence of activation of the humoral immunologic system and the unspecific immunologic system early after HTx is found in all HTx patients. 2. Evidence of humoral rejection is low in cases of absence of acute cellular rejection and increases within the 1st year after HTx. 3. Activation of the non-specific immunologic system plays a dominant role also in cases of absence of acute cellular rejection. 4. Activation of the humoral immunologic system during the first two years after HTx seems to be more pronounced in females. 5. Humoral immunologic reactions and non-specific immunologic reactions seem not to have an impact on the development of microvascular alterations after HTx.

P2320 Prognostic value of contrast stress echocardiography, myocardial stress scintigraphy and their combination in heart transplant recipients

P.H. Jung[1], M. Kung[1], C.H. Spes[2], S. Stoerk[1], J. Rieber[2], A. Koenig[2], C.E. Angermann[1]. [1]*University of Wuerzburg, Dpt. of Cardiology, Wuerzburg, Germany;* [2]*University of Munich, Dpt. of Cardiology, Kl. Innenstadt, Muenchen, Germany*

The diagnostic yield of dobutamine stress echocardiography (DSE) may be limited in heart transplant recipients (HTR) due to impaired image quality. As shown by our group, however, it can be improved by using both transpulmonary contrast agents and harmonic imaging. This study evaluates the prognostic value of contrast-DSE with harmonic imaging, of myocardial stress szintigraphy (SPECT) and of their combination.
Methods: 119 contrast-DSE and SPECT were performed in 81 HTR (66 male, aged 55±10,8 years) transplanted between 1985 and 1999. The contrast agent Optison® was injected intravenously as a bolus (0.3-1.0 ml) during rest and peak stress (dobutamine 5-40µg/kg/min). Regional wall motion was assessed offline by using the standard 16-segment model. SPECT was performed simultaneously (one day protocol) with application of the radiopharmacon (Tc99m-MIBI) at peak dobutamine stress. Any new or worsening wall motion or perfusion abnormalities were considered pathological.
Results: In 2 patients contrast-DSE, in 1 patient SPECT studies were not of diagnostic quality. No relevant side effects occurred. Within 12 months after the initial contrast-DSE 7 out of 23 patients with a pathological contrast DSE-result experienced cardiac events (6 x PTCA, 1x cardiac death; positive predictive value=PPV=30,4%) compared to 8 out of 50 patients with a pathological SPECT (7x PTCA, 1x cardiac death; PPV=16.0%). 7 out of 17 patients with both pathological contrast-DSE and pathological SPECT-results experienced cardiac events (6x PTCA, 1x cardiac death; PPV=41,2%). There was no siginificant difference between the negative predictive values for contrast-DSE, SPECT and their combination (95,7% vs. 95,4% vs. 96%, p= 0,68).
Conclusion: Contrast-DSE identifies patients with following cardiac events more precisely than SPECT, but the combination of both outmatches it. A normal contrast-DSE and/or SPECT appears to be a reliable marker for an eventless clinical course.

P2321 Mitochondrial permeability transition pore opening before cardiac graft acute rejection in rats

L. Gomez, O. Raisky, L. Chalabreysse, J. Ninet, O. Gateau-Roesch, J. Quash, M. Ovize. *Hôpital Cardiologique, Unité 81, Lyon, France*

We sought to determine whether mitochondrial permeability transition (MPT) pore opening might play a role in apoptosis during cardiac graft acute rejection. Seven to nine-week old male rats underwent an heterotopic (abdominal) cardiac transplantation that was either syngenic (Brown Norway/ Brown Norway, Syn group; n=10) or allogenic (Brown Norway/Lewis, Allo group; n=10). Transplanted hearts were harvested at day 3 or 5 following surgery. Mitochondria were isolated using differential centrifugations. Caspase 3 activity from the cytosolic fraction was assessed using a fluorimetric technique. Within the isolated mitochondria suspension, free Ca^{2+} concentration of the medium was measured by means of a specific microelectrode; MPT pore opening triggered by Ca^{2+} overload was defined as the brutal liberation of Ca^{2+} by the mitochondria. Cardiac graft rejection was evaluated using conventional histology grading. Acute rejection was detected in all Allo hearts at day 5, but was absent in Allo hearts at day 3. No rejection was detected in the Syn groups. At day 5, caspase 3 activity in Allo hearts averaged 41100 pmol/mg versus 3000 in the Syn hearts ($p<0.001$). At day 3, caspase 3 activity was normal in both Allo and Syn groups. The Ca^{2+} load that triggered MPT pore opening averaged 20 μM at day 5 in Allo versus 240μM in Syn ($p<0.001$). At day 3, Ca^{2+} load necessary to induce MPT pore opening averaged 240μM in Allo versus 320μM in Syn ($p<0.05$).

These data suggest an early sensitization to Ca^{2+} loading of the mitochondrial permeablity transition pore that occurs before the acute rejection and myocardial apoptosis following cardiac transplantation in the rat.

P2322 Long-term follow-up of combined heart and kidney transplantation. A single-center experience

M.G. Crespo-Leiro[1], M.J. Paniagua[1], L.F. Hermida[1], J.M. Herrera[1], J. Oliver[2], J.F. Gomez-Veiga[3], C. Rivera[2], A. Castro-Beiras[1]. *[1]Juan Canalejo, Cardiology, A Coruña, Spain; [2]Hospital Juan Canalejo, Nefrology, A Coruña, Spain; [3]Hospital Juan Canalejo, Urology, A Coruña, Spain*

Irreversible renal dysfunction is considered to be a contraindication for heart transplantation. However simultaneous heart and kidney transplantation (HKT) can be an acceptable option for these patients.

Purpose: To assess our experience in simultaneous heart and kidney transplantation from the same donor with particular attention to long-term follow-up.

Methods: Retrospective analysis of medical records of 11 HKT patients who underwent combined HKT from the same donor from 1995 to 2000. The variables recorded were age, sex, etiology of cardiac and renal diseases, immunosuppressive protocol, ischaemic time of both allografts, and follow-up data in terms of number of rejection episodes of boths allografts, kidney function and survival.

Results: All HKT patients were males, being the average age of 53 $\pm$ 9,3 years. Donor's average age was 34 $\pm$ 9,39 years. Etiology of the cardiopathy was dilated cardiomyopathy 23%, ischemic 61% and retransplantation 15,4%. Etiology of nefropathy was: glomerulosclerosis 9%, Wegener 9%, nefrotoxicity 18%, nefroangiosclerosis 18% and unidentifyed 36%. Cardiac allograft ischemic time was 187 $\pm$ 95 min, kidney allograft ischemic time was 412 $\pm$ 97 min. Immunosuppressive regimen was cyclosporine, azathioprine and steroids in 1 patient and in the other 10 patients, cyclosporine, mofetil-micophenolate and steroids; average of cardiac rejections/patient: 0,4 $\pm$ 0,97. No rejections were identifyed in renal allograft. Average creatinine at 1, 2 and 4 years was: 1.3 $\pm$ 0,24, 1.1 $\pm$ 0,2, and 1,2 $\pm$ 02 mg/dl respectively. One patient (9%) died in the postoperative period due to bleeding related to renal allograft surgery. The remaining 10 patients are alive and asymptomatic after an average follow-up of 44,5 $\pm$ 17,2 months with normal function of boths allografts.

Conclusions: Simultaneous heart and kidney transplant from the same donor is a therapeutic aproach suitable for patients with terminal cardiac and renal diseases. Apart from perioperative mortality, the long-term evolution is good with high survival, low rate of cardiac rejection episodes, no renal rejection episodes and normal function of boths allografts.

P2323 Influence of prolonged left ventricular assist device support on post transplantation acute rejection and survival

E. Birks[1], P.D. Tansley[1], C.T. Bowles[1], J. Smith[1], J.R. Pepper[2], N.R. Banner[3], A. Khaghani[1], M.H. Yacoub[1]. *[1]Harefield Hospital, Cardiothoracic Surgery Dept., Harefield, United Kingdom; [2]Royal Brompton Hospital, Cardiothoracic Surgery, London, United Kingdom; [3]Royal Brompton and Harefield Hospital, Department of Cardiology, London, United Kingdom*

Although left ventricular assist devices (LVADs) can be life saving in deteriorating patients and offer opportunities for prospective HLA matching, they modulate the cell mediated and humeral immune systems. These changes can potentially influence both early and mid term outcome after transplantation (Tx). To clarify these issues we prospectively followed eleven patients from 1995 who had LVAD support and subsequently received transplants at our institution, consisting of 10 heart & 1 heart and kidney transplants. Nine were males & 2 were females. Ages ranged from 15-59 (mean 43.2) yrs. Original disease was ischaemic heart disease (IHD) in 8, dilated cardiomyopathy in 2 and congenital heart disease in 1. Duration of support was 4-23(mean 10.8) mths. Only one patient developed HLA class II antibodies following LVAD implantation. Of all the other patients who survived more than 3 months after LVAD over the same time period and were not transplanted, HLA antibody formation only occurred in 1(4.5%) of 22. Prospective HLA matching was done in all patients and in 2 a 0DR and in 4 a 1DR mismatch was achieved. Pre-operative cross match was negative in all. There were no early deaths and two late deaths, one at 4 months due to donor heart dysfunction thought to be due to pre-existing donor hypertension and one at 6 years 3 months due to neurological disease predating transplantation. Follow up was up to 6 yrs 3 mths after Tx. The actuarial survival for the group was 88.9% at 1 and 88.9% at 5 yrs compared to 82.7% and 78.8% in the 256 non LVAD patients transplanted over the same time period. All 9 survivors are in NYHA Class I at latest follow up. There was a tendancy to lower rejection in this group. Angiographic follow up showed minimal disease in two patients. In conclusion this limited study has shown that LVADs are associated with no significant incidence of HLA antibody formation, possibly a low incidence of acute rejection presumably due to the reported apoptosis of T cells, may allow for prospective HLA matching and the mid term results are excellent.

P2324 Usefulness of plasmapheresis in the management of severe allograft dysfunction without cellular rejection after heart transplantation

M.G. Crespo-Leiro, M.J. Paniagua, C. Ramirez, P. Torres, F. Arnal, T. Tabuyo, A. Juffe, A. Castro-Beiras. *Juan Canalejo, Cardiology, A Coruña, Spain*

Severe allograft dysfunction without signs of cellular rejection on endomyocardial biopsy (EMB) is a major complication after heart trans-plantation (HT). The anatomopathologic diagnosis and treatment of this kind of rejection (also called humoral rejection) are a matter of debate, but it is generally considered to be mediated by antibodies and is more dangerous than cellular rejection. The treatment used in our centre for this complication consists of a steroid bolus, cyclophosphamide or mofetil mycophenolate, and plasma-pheresis

The aim is to assess the incidence of severe HT allograft dysfunction without EMB evidence of cellular rejection, and the effectiveness of our management protocol.

Methods: Retrospective analysis of medical records of HT patients who had severe allograft dysfunction (ejection fraction < 30% and need of i.v. inotropic support and/or intraaortic baloon pumping). Clinical suspicion of humoral rejection was required upon observation of severe allograft dysfunction and no lymphocytic infiltrates in EMB tissue. The variables recorded were age, sex, time post-HT of immunofluorescence (IF) studies of EMB tissue, number of plasmapheresis sessions, and follow-up data on allograft function and survival.

Results: Of a total of 386 HT patients, 12 patients (3.1%) gave rise to clinical suspicion of humoral rejection (11 males, mean age 55.0 $\pm$ 8.3 years). Time to onset after HT was 16.7 $\pm$ 21.8 months (range 2-72). The IF studies (C3, C4, c1q, fibrin, IgG, IgM and IgA) were mainly negative. The number of plasmapheresis sessions was 10.0 $\pm$ 3.9 (range 7-19). Evolution was satisfactory in 11 of the 12 patients (91.6%), who regained normal allograft function and were in NYHA functional class I after a mean follow-up period of 36 $\pm$ 18 months. Two of these patients died (after 24 and 36 months) from non-cardiac cause (abdominal aortic aneurism surgery and lower ischaemia surgery, respectively). The only patient who did not improve underwent heart retrans-plantation 3 months after detection of humoral rejection. Plasmapheresis gave rise to no serious complications.

Conclusions: Severe allograft dysfunction after HT without signs of cellular rejection on EMB is an infrequent but major complication. Our management protocol, which includes plasmapheresis, has generally been successful, allowing total recovery of allograft function in 90% of cases. Anatomopathologic diagnosis needs to be improved.

DIASTOLIC FUNCTION IN HEART FAILURE

P2325 Effect of atrial fibrillation on Doppler indexes of left ventricular diastolic function

R.R. Brandt, H.F. Pitschner, J. Sperzel, C.W. Hamm. *Kerckhoff Heart Center, Cardiology Dept., Bad Nauheim, Germany*

Doppler transmitral (M) and pulmonary vein (PV) flow velocity curves are generally used to describe left ventricular diastolic function. However, these indexes are dependent on several factors and are only defined for patients in sinus rhythm (SR). Atrial fibrillation (AF) is a common arrhythmia characterized by a lack of organized atrial mechanical activity and, thus, has a confounding influence on Doppler indexes. AF is often a consequence of diastolic dysfunction and both conditions frequently coexist making it difficult to assess the true effect of AF on Doppler indexes. Therefore, we have chosen the experimental approach to measure Doppler indexes first in SR and subsequently after induction of AF in 10 patients (6 men, 4 women, mean age 53±8 years) undergoing radiofrequency ablation of paroxysmal AF (circular insulation of PV). Four patients had a history of hypertension with mild left ventricular hypertrophy. Otherwise, none had signs of structural heart disease and everyone had normal or near normal diastolic function by Doppler echocardiography. Multiplane transesophageal echocardiography was performed in patients under general anesthesia at the beginning of the procedure to measure Doppler M (sample volume between leaflet tips) and left upper PV (sample volume 1 to 2 cm within the orifice) flow velocity curves. Measurements were first obtained in SR and during right atrial pacing (RAP) at 60, 80, and 100 ppm. AF was then successfully induced in all patients by high rate pacing (cycle length 140 to 180 ms) in the coronary sinus and measurements were repeated. Each patient served as his own control. Statistical analysis (paired t-test) was performed between measurements in AF and SR/RAP at comparable heart rates. Data shown in the table are mean±SD.

	HR (/min)	E-wave (cm/s)	A-wave (cm/s)	DT (ms)	PV TVI syst./diast.	PV Vmax syst./diast.
SR/RAP	78±10	57.3±19.1	46.6±20.9	256±29	1.17±0.26	1.61±0.87
AF	76±7	65.5±22.7		213±29	0.69±0.23	0.63±0.26
p	NS	<0.05		<0.01	<0.001	<0.01

HR = heart rate; DT = deceleration time; TVI = time velocity integral; Vmax = peak velocity

In summary, keeping other factors constant, AF by itself shortens deceleration time and decreases syst./diast. pulmonary flow ratios. These data may serve to define a "normal" range of Doppler indexes for patients in AF.

P2326 Is left ventricular dysfunction related to carotid atherosclerosis in hypertensives?

G. Parrinello, D. Colomba, P. Bologna, A. Licata, A. Pinto, R. Scaglione, S. Paterna, G. Licata. *Universita di Palermo, Dept. of Internal Medicine, Palermo, Italy*

This study has been designed to investigate the relationship between carotid atherosclerosis and diastolic dysfunction in hypertensives. The study population includes 142 hypertensive (HT) patients (64 females and 78 males) selected from a data base consisting of 3541 subjects who were referred to our ultrasound cardiovascular laboratory in the last five years (1995-2000) at the first diagnosis of mild to moderate (according to the WHO/ISH criteria) essential hypertension, younger than 55 years. Accurate evaluation of wall carotid artery and left ventricular function and structure were the main inclusion criteria. From the analysis were excluded all the subjects with other associate major cardiovascular risk factors. Examination of both common carotid arteries was detected by high-resolution vascular ultrasound to evaluate carotid Intima-Media Thickness (IMT) and M-B mode and Doppler ultrasonography examination was performed to evaluate left ventricular structure and function. Left ventricular diastolic filling was detected by peak early LV filling velocity/peak atrial filling velocity (E/A), deceleration time (DTE) and isovolumic relaxation time (IVRT). According to carotid IMT values all patients were sub-grouped as follows: group A consisting of 85 (59.9%) pts with IMT > 1 mm; group B consisting of 57 (40.1%) pts with carotid IMT < 1mm. Our results shows that IVRT, DTE and RWT were significantly ($p < 0.05$) higher in group A (IVRT 106 + 15.5 ms; DTE 237 + 51.3 ms; RWT 0.40 + 0.08) than in group B (IVRT 97.54 + 13.1 ms; DTE 203.3 + 27 ms; RWT 0.37 + 0.06). The prevalence of LVH was significantly ($p< 0.01$) higher in-group A (30/85; 35%) than in-group B (8/57; 14%). In all subjects with normal left ventricular geometry a positive correlation ($r = 0.33$; $p< 0.04$) between IMT and DTE was observed. The main new finding of the present study is the recognition of an association between higher levels of carotid arterial wall thickness and left ventricular diastolic dysfunction in newly diagnosed essential hypertensives. This association seems to be independent by the presence of left ventricular hypertrophy. These results are consistent with the indication that the evaluation of carotid wall morphology has to be recommended not only in hypertensive patients with LVH but also in those with alterations in left ventricular diastolic function. This approach might improve the prognostic stratification of hypertensive subjects and it might be suitable to recognize subset of patients at higher risk of cardiovascular disease or events.

P2327 Recruitment into a diastolic heart failure study – Few patients meet the criteria

J.E. Sanderson, A. Chan, S. Chan, W.H. Fung, G. Yip, J. Wong, W.Y. Ma, W. Chan. *The Chinese University of Hong Kong, Medicine & Therapeutics, Shatin, NT, Hong Kong*

Purpose: The Hong Kong Diastolic Heart Failure Study (HKDHF study) which started in 1999 is a multicentre trial comparing diuretic alone, diuretic plus ramipril or diuretic plus Irbesartan in patients with diastolic heart failure (DHF) on quality of life (QOL), exercise capacity, hospitalizations and mortality. Recruitment has been slow. We have investigated the reasons why.
Methods: The main inclusion criteria are: clinical History of heart failure within 2 months prior to screening including a chest X-ray demonstrating pulmonary congestion; NYHA Functional Class II - IV; left ventricular ejection fraction > 45% by echocardiography (M-mode/2D/AVP) or a radionucleotide technique and therapy with diuretics with stable dose > 14 days prior to the screening. After stabilization patients are randomized into one of the 3 treatment arms. A QOL questionnaire, 6min walk test, echocardiography and natruiretic peptides are measured at baseline, 3, 6 and 12 months.
Results: In the first 14 months 1400 subjects with a history of heart failure were screened in our centre (PWH). 847 were women and the average age was 77.5 yrs and 72.6 yrs for men (553). All had an echocardiogram. Of these 40 subjects (2.86%) were recruited into the study (currently 90). There were many reasons for rejection including administrative 102 (7.3%), CRF 217 (15.5%), Valvular HD 152 (10.9%), Haematology/other blood abnormality 228 (16.3), MI and/or long term ACEI 407 (29.1%), Dementia 40 (2.9%), Other medical reason 216 (15.4%)EF ≤ 45%, 16 (15.4%), Unstable angina 23 (1.6%), COAD (not HF) 16 (1.1%), Chest infection (not CHF) 9 (0.6%),Very ill 63 (4.5%), Frail 53 (3.8%), and Died before randomization 16 (1.1%).
Conclusions: Our experience indicates that a large scale DHF study will be difficult to conduct as many patients with DHF are very elderly, have significant co-morbidities, and many others do not have DHF on further investigation.

P2328 Reliability of exponential versus four-parametric logistic time constant estimated from different ventricular isovolumic pressure fall intervals

S F. Langer. *Free University Berlin, UKBF, Institute of Physiology, Berlin, Germany*

In left ventricular pressure (LVP) curves, the cut-off points of the isovolumic period are not clearly identified. A reliable method to estimate the time constant (tau) of this pressure fall has therefore to be robust against choosing different regression interval limits. This property was tested in the four-parametric logistic model P=Pinf+(P0-Pinf)/[g+(1-g)exp(t/tau)] and in the usual three-parametric exponential model (i.e. P with fixed g=0).
LVP curves were obtained from 36 isolated ejecting hearts (each 12 from rats, guinea pigs, and ferrets), working in an artificial circulation apparatus. Standard isovolumic pressure fall intervals (IPI) were taken from peak -dP/dt to the re-encountered end-diastolic pressure of the preceding beat. The start-point was then varied by ±5ms in ms-steps, thus forming 11 different IPI from which median tau and mean deviation from that median (MDM) were calculated by both of the compared models. This procedure was repeated by varying the end-point of IPI. The differences in MDM between exponential and logistic model were tested by Wilcoxon matched pair signed rank tests.
No species differences were notable; the results depend only on the actual logistic shape parameter, g (Table). By numerical reasons, g=0 turns the logistic model into the exponential, and the latter is numerically favorable at small g. However, most hearts present (a posteriori) with considerable g>0, where the logistic model is significantly more robust against IPI range changes.

Variability of time constant estimates

Subset	N	variable	ExpMED	ExpMDM	LogMED	LogMDM	Advantage Exp/Log	Wilcoxon
g<0.45	18	startpoint	24.5	0.7	16.5	2.2	12/6	p<0.01
		endpoint	23.9	0.6	15.4	2.1	15/3	p<0.01
g>0.45	18	startpoint	22.1	1.1	14.1	0.3	3/15	p<0.01
		endpoint	22.1	0.4	14.3	0.1	3/15	p<0.05

variable: variation of start- or end-point of IPI, respectively; Exp: 3-parametric exponential, Log: 4-parametric logistic model; MED: median time constant (ms); MDM: mean deviation from median (ms); Advantage: number of less MDM in exponential and in logistic fit, respectively.

In conclusion, the exponentially estimated tau is not only biased by model violation but significant additional error is caused by errors in determining the IPI; both disadvantages are overcome by the four-parametric logistic model.

P2329 Independent and additional prognostic value of left atrial enlargement in the elderly with dilated cardiomyopathy

F.L. Dini[1], R. Nuti[2], L. Barsotti[2], G. Micheli[2], S.M. De Tommasi[1]. *[1]Santa Chiara Hospital, Cardiovascular Diseases Unit 2, Pisa, Italy; [2]Villamarina Hospital, Cardiology Unit, Piombino, Italy*

Previous studies have shown that abnormal mitral flow patterns and left atrial (LA) enlargement are independently associated with survival in patients with left ventricular (LV) dysfunction. However, it is not known whether these outcome indicators can provide different information in patients of various age groups.

This study was designed to assess the prognostic value of restrictive mitral flow pattern (RMFP) and increased LA size in older and younger patients with LV dysfunction.

A series of 207 patients consecutively examined at our Doppler-echocardiographic laboratory and diagnosed with LV dysfunction (ejection fraction <45%) due to either ischemic or idiopathic dilated cardiomyopathy (DCM) was evaluated at the index Doppler echocardiogram. Patients were grouped into those ≤70 years (n=102; mean age: 61 years) and those >70 years (n=105; mean age: 78 years). All patients were subsequently followed-up for a mean period of 22±14 months.

In patients >70 years, indexed LA size (>26 mm/m^2) was the single best predictor of the fatal outcome (hazard ratio [HR]: 3.0, p=0.018) and emerged as the most important outcome variable of the combined end point (HR: 2.2, p=0.016) on multivariate analyses. In patients ≤70 years, RMFP, characterized by an early wave deceleration time (EDT) <140 msec, was independently associated with cardiac death or heart failure hospitalization (HR: 5.7, p=0.0013). When, demographics, clinical, echocardiographic and Doppler measures were analyzed in hierarchic order, indexed LA size yielded the most valuable contribution in predicting the combined end point in older patients (global chi-square from 11.5 to 18.7). RMFP was associated with the higher additional prognostic value in younger patients (global chi-square from 14.4 to 24.1).

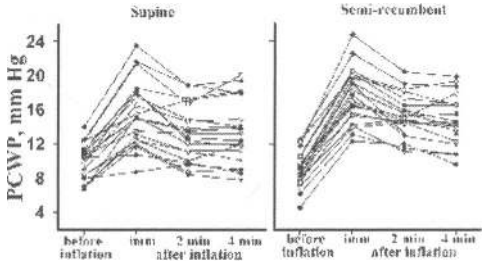
Increased indexed LA size had an independent and incremental prognostic value in patients aged >70 years with LV systolic dysfunction due to either ischemic or idiopathic DCM. Although RMFP can predict cardiac death and events in younger DCM patients, the more frequent blunting of early mitral flow and EDT prolongation with advancing age may decrease its value in the elderly. The prognostic relevance of LA enlargement is likely to descend from the impact of concomitant increases in LV filling pressure as well as significant mitral regurgitation.

P2330 Anti-G garment inflation: a suitable method to increase pulmonary capillary wedge pressure in healthy elderly subjects

J.J. Remmen[1], W.R.M. Aengevaeren[2], F.W.A. Verheugt[2], R.W.M.M. Jansen[3]. *[1]University Medical Center, Heartcenter, Department of Cardiology, Nijmegen, Netherlands; [2]University Medical Center, Heartcenter, Department of Cardiology, Nijmegen, Netherlands; [3]University Medical Center, Geriatric Medicine, Nijmegen, Netherlands*

Background: Non-invasive assessment of pulmonary capillary wedge pressure (PCWP) could facilitate treatment of heart failure in the elderly. Therefore, we want to study whether changes in PCWP can be assessed using the blood pressure (BP) response to the Valsalva maneuver. Initially, we investigated whether inflation of an anti-G garment was a suitable non-invasive method to increase PCWP temporarily in healthy elderly subjects.

Methods: In 20 subjects, before, immediately after, and at 2 and 4 minutes after anti-G garment inflation to 52 mmHg (1 psi), PCWP and continuous cardiac output (CCO) were measured with a CCO Swan-Ganz catheter and BP and heart rate with Finapres®, in supine and semi-recumbent position.



Results: The figure shows individual PCWP values. Immediately (imm) after inflation, group mean PCWP (mmHg±SD) increased from 9.9±2.1 to 15.5±3.9* in supine and from 8.9±2.0 to17.5±3.3* in semi-recumbent position (* p<0.01 vs. before inflation, paired t-test). After 4 minutes, PCWP was still significantly elevated. Cardiac output and heart rate did not change after inflation; mean BP slightly increased.

Conclusion: In healthy elderly subjects, anti-G garment inflation is a safe, non-invasive, method to induce an increase of PCWP in supine and semi-recumbent position. Our findings justify its application in future studies in which non-invasive temporary increase of PCWP is required.

P2331 Evaluation of post haemodialysis changes in left ventricular diastolic function by standard and load-independent echocardiographic parameters

E. Traversi, E. Colombo, A. Aldrovandi, C. Opasich, R. Tramarin. *Salvatore Maugeri Foundation, Cardiology, Pavia, Italy*

Background: Tissue Doppler imaging of the lateral mitral annulus (TDI) and intraventricular M-mode color inflow Doppler (Vp) have been described as theoretically load-independent indexes of left ventricular relaxation, while transmitral and pulmonary venous flows are strictly load dependent. Hemodialysis (HD) session in chronic renal failure patients leads to acute and significant left ventricular pre and after load changes.

Aim of the study: To evaluate the effective load indipendence of TDI and Vp.

Methods: Thirteen patients without history of heart disease, ECG changes or hypertension (7 male, age: 53±12 yrs, creatinine: 9.7±0.9 mg/dl, mean duration of dialitic treatment: 7.6±6.2 yrs, mean weight loss after HD: 2.8±0.6 Kg, duration of HD session: 4 hours) have been evaluated before (<30 min, PreD) and after (<30 min, PostD) HD. The following parameters have been evaluated: Left ventricular ejection fraction (EF), early diastolic transmitral flow velocity (E) and its deceleration time (DT), late diastolic transmitral flow velocity (A) and its duration (DA), Systolic (X) and diastolic (Y) pulmonary flow velocities and duration of the reverse pulmonary flow wave (DZ), iso-volumic relaxation time (IVRT), early (Ea) and late (Aa) diastolic TDI velocities and Vp calculated as the slope of the first aliasing of the proto diastolic left ventricular filling measured from the mitral plane to 4 cm into the left ventricle.

Results: Heart rate changed from 78±12 to 85±11 bpm (ns); the EF from 57±9 to 58±5% (ns). Changes of diastolic parameters are reported in the table.

	E cm/s	A cm/s	DT msec	Dz-Da msec	IVRT msec	X cm/s	Y cm/s	E' cm/s	A' cm/s	Vp cm/s^2
PreD	67(14)	84(15)	227(51)	-52(36)	84(17)	49(12)	35(5)	13(4)	15(3)	60(15)
PostD	56(16)	81(25)	195(58)	-28(30)	87(12)	49(17)	39(8)	12(5)	14(3)	65(20)
	p<.05	ns	p<.05	p<.05	ns	ns	ns	ns	ns	ns

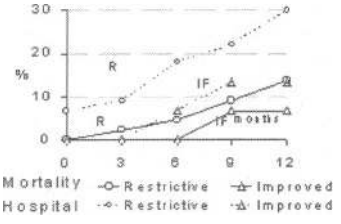
Conclusions: TDI and Vp seems to be independent from load changes due to HD treatment. The independence of TDI and Vp from load conditions support their use in the left ventricular diastolic functional evaluation as a more reliable alternative to transmitral and pulmonary venous flow Doppler parameters.

P2332 Response of the restrictive left ventricle diastolic filling to Valsalva manoeuvre is predictor of events in patients with systolic dysfunction

M. Pavlovic, M. Tomasevic. *University cardiovascular clinic, Nis, Yugoslavia*

The aim was to evaluate the prognostic value of the response of restrictive transmitral inflow pattern to standardized Valsalva manoeuvre, in patients with advanced left ventricle systolic dysfunction.

Methods Fifty nine patients with ischemic and dilated cardiomyopathy and EF<30% (mean 23±3), who showed restrictive left ventricle diastolic filling pattern (E/A >2, DT <150 msec), and had no evidence of mitral regurgitation greater than mild degree on Doppler assessment, were investigated. Mitral inflow velocities were recorded with sample volume positioned at the leaflet tips, first at the end of normal expiration and then during the strain phase of standarized Valsalva manoeuvre.



Results In 44 (75%) patients Valsalva manoeuvre induced decrease of both E and A velocity during straining phase, but the restrictive left ventricle diastolic filling pattern remained unchanged (Restrictive pattern). In the remaining 15 (25%) patients E velocity was decreased and A velocity was either increased (12 patients) or slightly decreased (3 patients) and diastolic filling pattern was changed (E/A<2) and pseudonormalized (improved filling pattern). Patients were followed up for 12.1±4.1 months. In patients who showed no reversion of the restrictive filling pattern during Valsalva manoeuvre there were 6 deaths (13.6%) and 13 hospitalization (30%) on account of heart failure worsening. In patients who showed improvement of the diastolic filling pattern there were 1 death (6.7%, NS) and only 2 hospitalization (13,3% P< 0.05).

Conclusion Restrictive filling pattern represents advanced left ventricular diastolic dysfunction. Unimprovement of the filling pattern in response to preload reduction by Valsalva manoeuvre can detect patients with more adverse outcome.

P2333 Role of hypoalbuminemia in pulmonary oedema associated with diastolic heart failure

S. Arques[1], P. Ambrosi[2], J.F. Aviérinos[2], R. Luccioni[2], G. Habib[2]. *[1]Hôpital d'Aubagne, Cardiology, Aubagne, France; [2]C.H.U. La Timone, Cardiology Dept., Marseille, France*

The main cause of pulmonary edema is a decrease in the gradient: serum colloid osmotic pressure (COP) - pulmonary artery wedge pressure (PAWP). The respective contributions of COP and PAWP abnormalities in pulmonary edema resulting from diastolic heart failure have not been previously evaluated. Therefore we measured COP and PAWP in 34 controls, in 26 pts with pulmonary edema and systolic heart failure (LVEF<50%: SHF) and in 37 pts with pulmonary edema and diastolic heart failure (LVEF>50%: DHF).

Methods: COP was estimated from albuminemia and protidemia. PAWP was estimated within the first hours following admission using Doppler-echocardiography, from isovolumetric relaxation time (IRT) and mitral flow propagation velocity with color M mode (Vp): PAWP= 4.5x 1000/(2xIRT+Vp)-9.

Results: Patients with DHF were older than pts with SHF (82±8 versus 75±14 years) and have more frequently marked hypoalbuminemia <30g/l (68% versus 38%, p<0.01).

	Albuminemia(g/l)	COP (mmHg)	PAWP (mmHg)	COP-PAWP
controls	35.1±5	25±3.7	11.1±2.5	13.6±5
SHF	31.1±5*	23.6±4	25.3±4*	-1.2±6*
DHF	24.9±7*°	19.7±5*°	19.6±8*°	0.0±6*

*p<0.01 DHF or SHF versus controls; °p<0.01 DHF versus SHF

Conclusions: PAWP was lower in DHF than in SHF. However the gradient COP-PAWP was similar in DHF and SHF since COP was lower in DHF. Thus our results suggest that low albuminemia (resulting in low COP) is a major determinant of pulmonary edema in patients with DHF.

PATHOPHYSIOLOGY OF HYPERTENSION

P2334 Hypertensive subjects with "non-dipping" circadian blood pressure profile have reduced baroreflex sensitivity

V. Melenovský[1], D. Wichterle[2], J. Widimsky[1], T. Zelinka[1], B. Strauch[1], J. Hradec[1]. *[1]General University Hospital (VFN), 3rd Department of Internal Medicine, Prague, Czech Republic; [2]St.George's Hospital Medical School, Department of Cardiological Sciences, London, United Kingdom*

Purpose: Subjects with attenuated or even absent nighttime blood pressure (BP) fall are at higher risk of hypertensive organ damage. The factors responsible for nocturnal BP decrease are not fully understood. An impairment of autonomic cardiovascular regulations has been suggested. The aim of study was to compare indices of baroreflex sensitivity and heart rate variability between hypertensive subjects with preserved (dippers) or absent (non-dippers) night BP fall.

Methods: The study investigated 121 hypertensive patients (61 essential hypertension, 37 primary aldosteronism, 7 pheochromocytoma, 16 undetermined). Ambulatory blood pressure monitoring (SpaceLabs 90207) was performed after washout from chronic medication (alfa and/or Ca blockers allowed only). Time-domain indices of heart rate variability (mean NN, SDNN, rMSSD) and baroreflex sensitivity (BRS) were assessed by cross-spectral analysis of simultaneous recordings of RR intervals (ECG) and continuous finger arterial pressure (Finapres) during spontaneous (SR, 5-min) and controlled respiration (CR, 3-min, 0.1 Hz). Non-dippers were defined as subjects with nighttime (22-06h) systolic and diastolic BP fall < 10% of average daytime (06-22h) BP.

Results: Dippers and non-dippers differed in age, mean 24h systolic and diastolic BP, and in baroreflex sensitivity. There was no difference in etiology or duration of hypertension, casual BP, body mass index, and time-domain indices of heart rate variability (see table).

Characteristics of dippers/non-dippers

Variable	Non-dippers (n=63)	Dippers (n=37)	p value (t-test)
Age (years)	49.0 ± 10.5	42.5 ± 11.7	0.005
24h SBP (mmHg)	148 ± 17.4	138 ± 22.4	0.014
24h DBP (mmHg)	94.3 ± 11.3	85.5 ± 14.4	0.001
Mean NN-SR (ms)	944 ± 129	932 ± 154	0.67
SDNN-SR (ms)	41.3 ± 19.4	49.6 ± 33.9	0.12
rMSSD-SR (ms)	27.8 ± 19.0	35.7 ± 29.2	0.11
BRS-CR (ms/mmHg)	10.9 ± 6.5	15.4 ± 11.1	0.014

Values are means ± SD.

Conclusions: Time-domain indices of heart rate variability are not significantly altered in non-dippers. The absence of sufficient nighttime BP decline is associated with reduced baroreflex sensitivity.

P2335 Nighttime blood pressure variability as a predictor of diurnal blood pressure pattern stability

I. Kotovskaia, Zh. Kobalava, A. Dmitriev, V. Moiseev. *Moscow, Russian Federation*

Objective: Detailed assessment of diurnal BP pattern stability.

Materials and Methods: Stability of diurnal BP pattern was analyzed on 48 h ABPM in 80 pts (27 men and 53 women, mean age 54,9+1,6 years). ABPM was performed in the hospital to provide standard daily activity of the pts during the both days of investigation. Pts with sleep disturbances during at least one night of the investigation were not included into analysis.

Results: According to diurnal index (DI) of systolic BP (SBP) as traditional criteria for BP diurnal pattern assessment (dippers or non-dippers) stable BP diurnal rhythm was observed in 75% pts (36% were stable dippers, 39% - stable non-dippers). In 25% pts diurnal BP pattern transformed during the second day of ABPM: in 9% pts from dipper to non-dipper, in 16% - from non-dipper to dipper. Due to wide intraindividual DI variations we tried to provide quantitative assessment of diurnal BP pattern stability. Using standard deviation (SD) of DI during the 1st and the 2nd day of ABMP the pts were divided to tertiles with cut off points 2,4 and 4,9. Highly stable diurnal BP rhythm (SD DI 0–2,4) was revealed in 44% pts, moderately stable (SD DI 2,5–4,9) - in 30%, unstable (SD DI >5%) – in 26%. When traditional criteria were used the groups were highly heterogeneous on nighttime BP variability but there was no significant difference between the group mean values. When quantitative assessment of diurnal BP pattern stability pts with unstable rhythm had the highest nighttime BP variability.

Diurnal BP pattern	SD nighttime SBP, mm Hg	SD nighttime DBP, mm Hg
Traditional criteria		
Stable dippers	6,03±0,74	3,89±0,54
Dippers-non-dippers	7,15±1,52	3,58±0,55
Non-dippers - dippers	7,27±2,76	4,50±1,72
Stable non-dippers	8,65±1,44	5,08±0,70
Quantitative criteria		
Highly stable	5,05±0,79	3,61±0,49
Moderately stable	5,82±0,87	3,54±0,42
Unstable	11,99±1,56*	6,15±0,87*

*p<0,05 to compare with both other groups

Conclusion: New quantitative criteria allowed to assess BP diurnal pattern stability more precisely than tradition ones. High nighttime BP variability may be a predictor of diurnal BP pattern unstability.

P2336 Ambulatory blood pressure load can predict arterial pressure waveform contour in patients with essential hypertension

C. Tsioufis, C. Stefanadis, I. Kallikazaros, K. Gianakopoulos, C. Pitsavos, G. Goumas, I. Papaioannou, P. Toutouzas. *Hippokration, University of Athens, Department of Cardiology, Melissia, Greece*

The magnitude and timing of wave reflections are major determinants of the arterial pressure wave (APW) contours. Whether the different components of the overall blood pressure (BP) load affect the APW shape in essential hypertension has not been well defined.

Methods: To assess this, in 104 untreated, newly diagnosed with stage I-II (JNC VI) essential hypertension patients (pts) (aged 54±10 years, office BP 154/97 mmHg), echocardiography and ambulatory 24-hour blood pressure (ABP) monitoring was performed. APW was recorded by carotid applanation tonometry and waveform shape was expressed by the augmentation index (AI) according to Murgo et al classification.

Results: In the entire study population, LVMI was 92 gr/m^2, RWT was 0.48, 24h-SBP was 137mmHg, 24h-DBP was 85 mmHg and AI was 0.11±0.25. Patients with with a dominant late systolic peak (62 pts, AI=0.16±0.2) compared to those with a dominant early systolic peak (42 pts, AI =-0.002±0.4) were older (49 vs 56 years) and had significantly increased LVMI (98 vs 82 gr/m^2), RWT (0.49 vs 0.45), 24h-SBP (140 vs 129 mmHg), 24h-DBP (87 vs 80 mmHg), 24h ambulatory pulse pressure (PP) (53 vs 48 mmHg), daytime SBP (142 vs 132 mmHg), daytime DBP (90 vs 84 mmHg), nighttime SBP (129 vs 120 mmHg), nighttime DBP (78 vs 72 mmHg), 24h systolic load (43% vs 24%) and 24h diastolic load (38% vs 28%). AI was positively correlated with age (r=0.38, p<0.05), office SBP (r=0.21, p<0.05), LVMI (r=0.44, p<0.001), 24h-SBP (r=0.33, p<0.05), 24h-DBP (r=0.24, p<0.05), 24h ambulatory PP(r=0.24, p<0.005) and 24h-SBP and DBP load (r=0.27, p<0.05 and r=0.0.23, p<0.05 respectively). For the pooled population, in a multivariate model including office BP and ABP parameters, only the daytime SBP was identified as an independent determinant of AI (beta=0.45, p<0.001).

Conclusion: Among the different components of the overall hypertensive burden, daytime SBP affects APW contour to a greater extent in pts with moderate essential hypertension.

P2337 Effect of the breathing pattern on autonomic cardiovascular function in Andean high-altitude natives with and without chronic mountain sickness

C. Keyl[1], A. Schneider[1], A. Gamboa[2], L. Spicuzza[3], N. Casiraghi[4], A. Mori[5], F. Leon-Velarde[2], L. Bernardi[4]. [1]*University Medical Center, Anesthesiology, Regensburg, Germany;* [2]*Universita Peruana Cayetano Heredia, laboratorio de transporte de oxygeno, Lima, Peru;* [3]*University of Catania, Respiratory Diseases, Catania, Italy;* [4]*IRCCS S.Matteo University of Pavia, Clinica Medica 1, Pavia, Italy;* [5]*IRCCS S.Matteo University of Pavia, Pathology, Pavia, Italy*

We evaluated the hypothesis that subjects with polycythemia and chronic mountain sickness (CMS) suffer from an impaired autonomic cardiovascular regulation, and tested the effect of different breathing patterns on arterial oxygen saturation (SaO2) and autonomic function.
Ten Andean natives with a hematocrit (Hct) >65%, and 10 natives with an Hct <55%, all living permanently at an altitude of 4300 m, were included into the study. Cardiovascular autonomic regulation was evaluated by spectral analysis of hemodynamic parameters and by computation of the spontaneous baroreflex sensitivity, while subjects breathed spontaneously or frequency-controlled at 6 or 15 breaths/min, respectively. The recordings were repeated after a one-hour administration of supplemental oxygen and after performing breathing at 6 breaths/min for one hour, respectively.
Subjects with Hct >65% showed an increased incidence of CMS compared to subjects with Hct <55%. Spontaneous baroreflex sensitivity was decreased in subjects with high Hct compared to the control group (repeated measurements at 2 subsequent days: 3.9 ± 2.1 and 5.9 ± 2.2 ms/mm Hg vs. 11.2 ± 8.5 and 11.1 ± 5.5 ms/mm Hg, $p<0.05$ between groups). The effects of supplemental oxygen or modification of the breathing pattern were: 1) Ventilation and SaO2 was significantly increased in all subjects after the administration of oxygen. 2) Blood pressure and heart rate decreased significantly after both maneuvers in both groups. 3) Baroreflex sensitivity increased significantly in subjects with high Hct and was not different from subjects with low Hct after administration of oxygen as well as after low-frequency breathing.
Temporary slow-frequency breathing provides a beneficial effect on the autonomic cardiovascular function in high-altitude natives with polycythemia and CMS.

P2338 Baroreflex sensitivity in normotensive subjects with a family history of hypertension: effect of tilting

J. Maver[1], M. Strucl[2], R. Accetto[3]. [1]*Franc Derganc General Hospital, Cardiology, Sempeter pri Gorici, Slovenia;* [2]*Institute of Physiology, Medical Faculty, Ljubljana, Slovenia;* [3]*Clinical Centre, Clinic of Hypertension, Ljubljana, Slovenia*

Developed hypertension is characterized by decreased baroreflex sensitivity. It is not completely clear whether changes in the baroreflex sensitivity precede hypertension development or they are secondary to high blood pressure. That is why we studied the baroreflex sensitivity at the pre-hypertensive stage of hypertension development.
Methods: Blood pressure and heart rate were monitored by finapres device in 59 normotensive subjects with a family history of hypertension (28.6 ± 0.5 years) and 46 normotensives without a family history of hypertension (25.7 ± 0.7 years). The baroreflex sensitivity was estimated by the sequence method in supine position and in consecutive half-a-minute intervals during ten-minute up-right tilting (65°). Multiple regression model was built with the baroreflex sensitivity in supine position as a dependent variable.
Results: In heart rate and diastolic pressure we did not find any significant differences between the two groups. Systolic blood pressure was significantly higher ($p = 0.011$) and baroreflex sensitivity in supine position significantly decreased ($p = 0.008$) in normotensives with a family history of hypertension as compared to those without a family history of hypertension. During the first and the second half-a-minute interval of up-right tilting the baroreflex sensitivity was also significantly decreased in normotensives with a family history of hypertension comparing to the subjects without a family history of hypertension ($p = 0.001$ and $p = 0.01$, respectively). During remaining half-a-minute intervals of ten-minute tilting the baroreflex sensitivity was not significantly different between the two groups. Multiple regression model showed that the baroreflex sensitivity in supine position was significantly influenced by heart rate ($p < 0.0001$), age ($p = 0.0016$) and a family history of hypertension ($p = 0.0367$).
Conclusions: We proved altered baroreflex sensitivity even in normotensive subjects with a family history of hypertension, what could be one of the earliest changes in essential hypertension development.

P2339 Plasma level of atrial and brain natriuretic peptide and left ventricular geometry in patients with essential hypertension

W. Kosmala, A. Spring. *Medical University, Cardiology, Wroclaw, Poland*

Natriuretic peptides, atrial (ANP) and brain (BNP) are known to be elevated in hypertensive patients (pts), especially in those with left ventricular hypertrophy and dysfunction, but their relation to different patterns of left ventricular geometry (LVG) is not clearly established.
The aim of the study was to estimate relation between plasma ANP and BNP levels and patterns of LVG in pts with hypertension.
Material and methods: Studied group consisted of 80 pts (37 males, 43 females) aged 52.5±12.6 yrs with mild, moderate and severe essential hypertension. Subjects with other diseases affecting structure and function of the heart were excluded. As control group (CG) served 19 healthy subjects aged 50.5±9.6 yrs In every patient plasma levels of ANP and BNP were estimated by radioimmunoassay and echocardiographic study was performed. According to echocardiographic measurements every patient was classified into one of four patterns of LVG: normal geometry (NG), concentric remodeling (CR), eccentric hypertrophy (EH) and concentric hypertrophy (CH).
Results: (table)

	CG (n = 19)	NG (n= 18)	CR (n = 21)	EH (n = 17)	CH (n = 24)
ANP [pg/ml]	94.2 ± 36.7	108.6 ± 46.4	134.5 ± 39.6*	131.2 ± 41.4*	164.8 ± 56.5#
BNP [pg/ml]	156.7 ± 52.1	169.3 ± 61.6	176.1 ± 70.8	181.2 ± 67.3	277.4 ± 79.7#

* - $p < 0.05$ vs CG and vs NG; # - $p < 0.01$ vs CG, vs NG, vs CR and vs EH

In conclusion: In hypertensive pts:
1. CH is accompanied by increased plasma levels of ANP and BNP, whereas CR and EH only by increased plasma level of ANP,
2. among all 4 patterns of LVG plasma levels of both ANP and BNP are the highest in group with CH,
3. plasma ANP level seems to be a good predictor of any change in LVG, while plasma level of BNP may be helpful in discrimination of CH.

P2340 Growth hormone prevents apoptosis in cardiomyocytes cultured in vitro

J.R. González-Juanatey, R. Piñeiro, M.J Iglesias, C. Alcaide, F. Lago. *Hospital Clínico Universitario, Unidad de Investigación, Santiago de Compostela, Spain*

Background: The use of growth hormone (GH) as a new therapy of heart failure has received considerable attention in recent years. However, the mechanisms by which GH influences cardiomyocyte cell function are largely unknown. In this paper we have tested the possibility that GH exerts a direct antiapoptotic effect on cardiomyocytes.
Methods and Results: Rat neonatal primary cultured cardiomyocytes (PC) were tested for GH receptor (GHR) expression. In HL-1 cardiomyocytes we performed GHR binding assays and western blot/immunoprecipitation studies to evidence expression and activation of GHR and classical downstream effectors induced by GH. Apoptosis was induced by serodeprivation or treatment with cytosine arabinoside (AraC) respectively. GH prevented apoptosis in serodeprivated (48h) PC, as assessed by DNA ladder electrophoresis, TUNEL assays (55.02±14.4% of control, $p<0.05$), and Hoechst dye staining (58.74±0.7% of control, $p=0.0102$). In HL-1 cells treated with GH+AraC, TUNEL revealed a decrease of apoptotic cells (24.64±0.35%) in comparison with those treated with AraC (44.87±3.25%; $p<0.001$). Anti-IGF-1 antibody treatment did not affect the antiapoptotic effect of the hormone. We used calcineurin phosphatase inhibitors cyclosporine (Cy) and FK-506 in order to dilucidate a possible role for this calcineurin phosphatase on GH effects on cardiomyocytes. By FACS analysis, HL-1 cells growing in normal medium displayed a 9.69% of apoptosis, AraC treatment increased apoptosis up to 21.09%, and GH reverted significantly this effect (13.9%). The combined treatment with AraC, GH and Cy/FK-506 increased newly the apoptosis rate to 21.46%. GH increased the percentage of cells in S/G2/M phase (52.83% vs 36.95% of AraC treated cells).
Conclusions: GH exerts an antiapoptotic effect on PC and HL-1 cells. Our data point to a direct effect of GH on cardiomyocytes not mediated by IGF-1, and this effect require the action of calcineurin phosphatase.

P2341 Procollagen peptides in essential hypertension and its relation to cardiac structure and functions before and after antihypertensive therapy

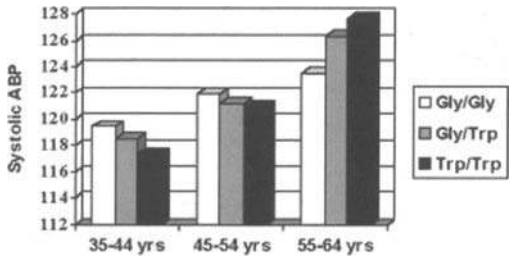
H. Kamal[1], A. El Hawary[1], T. El Serafy[2], F. Maklady[1]. [1]Ismailia, Egypt; [2]Suez Canal University, Biochemistry, Ismailia, Egypt

Background and Aim: A significant increase in fibrillar collagen content type I and III has been observed in the cardiac ventricles of both animals and humans with arterial hypertension. The serum concentration of procollagen type I carboxy terminal peptide (PIP) and procollagen type III amino terminal peptide (PIIIP) has been proposed as a useful markers of collagen types I and III synthesis. Therefore, the present study was conducted to evaluate fibrogenic activity in patients with essential hypertension by measuring serum PIP and PIIIP as biochemical markers of tissue synthesis of collagen type I and III, and its relation to parameters of left ventricular (LV) structure and functions in those patients.
Methods: The study included 79 hypertensive patients and 50 normotensive control subjects. Mean age was 47 year. After clinical evaluation, echocardiography (M-mode, 2D, and pulsed Doppler) was done to evaluate LV anatomy and function. Serum PIP and PIIIP were measured by radioimmunoassy. Echocardiography and biochemical studies were repeated for the hypertensive patients after 6-month treatment with captopril.
Results: Serum PIP and PIIIP were significantly higher in patients than in control (258±57 and 3.73±2.2 mg/L versus 167±70 and 1.9±1.4mg/L respectively). In addition PIP and PIIIP were significantly higher in patients with LV hypertrophy (LVH) than in those with normal LV mass. Moreover, PIP level was directly correlated with LV mass index (LVMI). On the other hand, PIIIP level was inversely correlated with VE/VA ratio.
After treatment with captopril for six months, significant echocardiographic and biochemical improvements were observed. LVH regressed in 13 out of 68 patients (19%), LVMI was normalized in 17 out of 58 patients (29%), and diastolic dysfunction was normalized in 10 out of 44 patients (23%). Serum PIP and PIIIP were significantly reduced in hypertensive patients.
Conclusion: Serum level of PIP and PIIIP are significantly increased in hypertensives. Such increment was more evident and correlated with LVH patients. These changes improved significantly after treatment with captopril. So, biochemical monitoring of collagen fibril turnover might provide a potential non-invasive method of assessing myocardial fibrosis. Circulating procollagen derived peptides may reflect ongoing myocardial fibrosis in essential hypertension. The renin-angiotensin-aldosterone system may participate in the excessive synthesis of collagen type I and type III in hypertension.

P2342 Age-dependency of alpha-adducin polymorphism modulation of blood pressure

M. Castellano[1], C. Barlassina[2], F. Rossi[1], M. Beschi[1], L. Tizzoni[2], D. Cusi[2], G. Bianchi[3], E. Agabiti Rosei[1]. [1]University of Brescia, Dip. Scienze Mediche e Chirurgiche, Brescia, Italy; [2]Univ. degli Studi, Dept. of Nephrology, Milan, Italy; [3]Univ. Vita e Salute, Milano, Italy

Considering that one large study from the HyperGEN Network suggested that alpha-adducin appears to be an important risk factor for hypertension particularly in older people, we decided to verify if our previous observation that a Gly-460-Trp polymorphism of the alpha-adducin gene is associated to blood pressure levels, in a sample of middle-age (50 to 65 years) general population, can be extended to younger individuals from the same population.
To evaluate if the relationship between a-adducin polymorphism and blood pressure may be influenced by the age of subjects.
We studied a randomly selected sample of the general population of an Italian town. Subjects were selected in the age range of 35 to 64. Blood pressure was measured by ambulatory monitoring (Spacelabs), with at least 60 measurements over a 24 hour period. In 414 Individuals phenotypic and genotypic data were available.
In the overall population sample, 24-hour ambulatory blood pressure (ABP) did not significantly differ among Gly-460-Trp genotypes. However, analysis of data after stratification by age (below vs. above median value, or according to tertiles of age) revealed a significant interaction (ANOVA, p=0.048) between classes of age and Gly-460-Trp genotypes on blood pressure, so that Trp460 is associated to blood pressure increase only in older subjects (> 55 years).



Our findings suggest that the association between the Trp460 allele and hypertension is influenced by age. It is hypothesizable that at older age, the pathogenetic effect of adducin mutation is more evident, possibly due to a reduced efficiency of compensatory mechanism(s). This observation underscores the necessity of taking into account an age-dependent effect when investigating genotype-phenotype interactions.

P2343 Neutral endopeptidase and angiotensin I converting enzyme insertion/deletion gene polymorphism in normotensive and hypertensive subjects

J. Jalil[1], C. Oliveri[2], M.P. Ocaranza[1], I. Godoy[1], S. Cordova[1], G. Chamorro[1], J.B. Michel[3], S. Lavandero[2]. [1]P Universidad Catolica de Chile, Cardiovascular Diseases, Santiago, Chile; [2]Chemical and Pharmaceutical Sciences, University of Chile, Santiago, Chile; [3]Remodelage Cardiovasculaire, INSERM, Unité 460, Paris, France

Background: Neutral endopeptidase (NEP) hydrolizes angiotensins (Ang) I and II and generates angiotensin-(1-7). Angiotensin I converting enzyme (ACE) may influence Ang II levels and regulate the vasculature tone. In humans, the insertion/deletion (I/D) ACE gene polymorphism determines plasma ACE levels by 50%. The D allele is associated with increased ACE activity. In rats with a similar ACE polymorphism, high plasma ACE is inversely related to circulating and tissue NEP activity (Oliveri et al. Hypertension 2001; 38: 650-654).
Aims: To evaluate the relationship between ACE expression and NEP activity in normotensive and hypertensive human subjects.
Methods: Plasma ACE and NEP activities were determined in 37 normotensive subjects and in 40 untreated patients with essential hypertension. Both groups were homozygous DD ACE (high plasma ACE) or II (low plasma ACE). Normotensive subjects and hypertensive patients were similar in terms of age and gender distribution. Genotypes were determined by PCR.
Results: Plasma ACE activity was elevated by 70% ($p < 0.001$) in both DD ACE homozygous groups (normotensives and hypertensives) compared with both II ACE homozygous groups and it was 20% higher ($p < 0.01$) in both hypertensive groups (II and DD ACE homozygous) compared with both normotensive homozygous groups. No interaction between ACE genotypes with blood pressure status on ACE activity was observed. In the normotensive homozygous DD subjects, plasma NEP activity was 0.30 ± 0.02 U/mL and it was 64% higher ($p < 0.001$) in the normotensive homozygous II subjects, with a significant negative linear correlation between ACE and NEP activities ($r = -0.56$, $p < 0.01$). In the hypertensive homozygous DD patients, plasma NEP activity was 0.47 ± 0.03 U/mL without difference with the hypertensive homozygous II patients. Using ANOVA with 2 factors, a significant effect of the ACE genotypes ($F \approx 4.7$, $p < 0.02$) and also an interaction effect between the ACE genotypes and the blood pressure status (normotensive or hypertensive) on plasma NEP activity were observed ($F = 13$, $p < 0.002$).
Conclusions: These results are consistent with a modulatory effect of the ACE polymorphism on NEP activity in normotensive humans. High ACE expression is associated with low circulating NEP activity (and vice versa). This inverse relationship between ACE expression and NEP activity is not observed in hypertension. These observations could explain some pathogenic mechanisms in hypertension and some effects associated with the presence of the D ACE allele.
Support: Fondecyt 1000576 and ECOS-Conicyt C99S01.

P2344 Microvascular disease and abnormal endothelium-dependant arterial dilatation in essential hypertension

M. Kelm[1], M. Preik[1], C. Rademacher[1], T. Lauer[1], D. Hafner[2], B E. Strauer[1]. *[1]Universitätsklinikum Düsseldorf, Kardiologie, Pneumologie, Angiologie, Düsseldorf, Germany; [2]Heinrich-Heine-Universität Düsseldorf, Department of Pharmacology, Düsseldorf, Germany*

Background: Arterial hypertension is a pivotal risk factor of endothelial dysfunction in conduit arteries representing a key trigger for atherosclerosis. A reduced flow reserve in resistance vessels is a hallmark of hypertensive microvascular disease. We hypothesized that microvascular abnormalities impair endothelium-dependent flow-mediated dilatation (FMD) in upstream conduit arteries in patients with essential hypertension.
Methods: Brachial artery endothelium-dependent FMD was measured in 43 hypertensive patients (HT) and 38 normotensive controls (NT) using high resolution ultrasound. Microvascular flow reserve (FR) in forearm resistance vessels was assessed by venous occlusion plethysmography.
Results: Brachial artery endothelium-dependent FMD was markedly impaired in HT (3.6±0.3%) as compared with NT (10.2±0.3%), whereas endothelium-independent dilatation was only slightly blunted. FMD was progressively impaired with increasing duration of hypertension. Microvascular flow reserve of forearm resistance vessels was significantly reduced in hypertensive patients (3.2 in HT versus 6.0 in NT). Brachial artery FMD was related to microvascular flow reserve in HT ($r=0.60$, $p<0.01$), but not in NT. Multiple stepwise regression analysis unmasked microvascular flow reserve as a strong independent variable determining the extent of brachial artery FMD ($r^2=0.45$, $p<0.01$). In hypertensive patients reversal of impairment in microvascular flow reserve improved brachial artery endothelium-dependent dilatation by more than 60%.
Conclusions: In essential hypertension microvascular disease may emerge as a novel, independent, and potentially reversible mechanism impairing flow mediated dilatation in conduit arteries. Microvascular abnormalities may thus become relevant to the pathogenesis and therapy of cardiovascular disease associated with arterial endothelial dysfunction.

P2345 The erythropoietin serum concentration in patients with essential arterial hypertension

M. Kobusiak-Prokopowicz, B. Jolda-Mydlowska. *Medical University, Cardiology Department, Wroclaw, Poland*

The role of erythropoietin (EPO) in the etiopathogenesis of essential hypertension (EH) is not univocally defined yet. EPO activates tissue RAAS, synthesis of endothelin and serotonin, exerts direct vasopressor effect and diminish influence of NO on the vascular smooth muscles. The aim of this study was to evaluate if endogenous EPO is a pathogenic factor in the EH.
Material and method: The study group consisted of 74 patients (pts) aged 17-79 years with EH, 43 women aged 20-79 years and 31 men aged 17-77 years. Control group consisted of 11 healthy volunteers, 4 women and 7 men, aged 20-71 years. The mild EH (by VI JNC standards) was noticed in 20 pts (MiEH), moderate EH in 34 pts (MdEH) and severe EH in 20 pts (SEH). The pts were also divided into 3 groups depending on the severity of organ damage (by WHO standards). 1st degree organ damage (dod) was observed in 13 pts (I group), 2nd dod in 49 pts (II group) and 3rd dod in 12 pts (III group). The blood samples for evaluation of EPO serum concentration was taken at baseline conditions and determined by the radioimmunological method using the Eritropoietine (Human) RIK no 6913 by Peninsula Laboratories INC. We also evaluated the echocardiographic parameters, renin plasma activity (ARO), plasma concentration of aldosterone, hematocrit, red blood cells count, creatinine concentration, creatinine clearance and 24-hours microalbuminuria.
Results: The baseline EPO was significantly higher in pts with SEH and 3rd dod than in control group (respectively 11.8±7.0 vs 6,9±4,3 ng/ml, $p<0.05$ and 12.5±8.9 vs 6,9±4,3 ng/ml, $p<0.05$). There was no statistically significant difference in baseline EPO between pts with MiEH, MdEH, 1st and 2nd dod and control group. In pts with MiEH EPO correlated positively with interventricular septum diameter ($r= 0.519$, $p<0.02$). In pts with MdEH and in pts with 2nd dod EPO correlated positively with ARO ($r= 0.424$, $p<0.01$ and $r= 0.288$, $p<0.04$). In pts with SEH EPO correlated positively with 24-hours microalbuminuria ($r= 0.574$, $p<0.01$). EPO correlated negatively with creatinine concentration ($r= -0.768$, $p<0.002$) and positively with creatinine clearance ($r= 0.769$, $p<0.002$) in pts with 1st dod. In pts with 2nd dod EPO correlated negatively with end-diastolic left ventricle diameter ($r= -0.291$, $p<0.04$).
Conclusions: We observed a significant elevation of EPO in pts with SEH and 3rd degree organ damage. EPO correlates also with different neurohumoral, biochemical and echocardiographic parameters. These findings suggest that EPO may contribute to development of the EH, what needs further investigations.

P2346 Abnormal ANP–type A-receptor – Dependent vasodilation in patients with essential hypertension: secondary to receptor downregulation?

D. Bulut[1], C. Hanefeld[1], M. Kuhn[2], A. Mügge[1]. *[1]St. Josef-Hospital, Medical Department II, Bochum, Germany; [2]Inst. of Pharmacology&Toxicology, Muenster, Germany*

Endothelial-mediated vasodilation is impaired in patients with essential hypertension (eHYP) whereas the endothelium-independent relaxation mediated by the soluble guanylatzyclase (GC) pathway appears to be preserved. Little is known about the particulare GC pathway which is stimulated by atrial natriuretic peptide (ANP). Recently, a deletion mutation in the 5' flanking region of the ANP-receptor has been observed in japanese patients with eHYP (Circ Res.2000;86:841) which reduces the promoter activity by 33%. It was the purpose of our study to investigate the ANP-receptor-mediated vasodilation in eHYP. We included 45 patients with eHYP and 17 normotensive subjects (control group). Blood flow was measured in the forearm circulation by venous occlusion plethysmography during i.a. infucions of ANP (50-400 ng/min), acetylcholine (ACh; 15-30 μg/min) and sodium-nitroprussid (SNP, 1.6-3.2 μg/min). The table summarizes the maximal increases in blood flow (D% baseline, mean ± SD) (*$p<0.05$vs. eHYP).

	eHYP	control
ACh max.	51,2 ± 28,1%	76,8 ± 25,7%*
SNP max.	95,2 ± 30,1%	100,4 ± 26,1%
ANP max.	45,8 ± 24,9%	69,4 ± 25,2%*

In the study group as well as in additional patients with eHYP (n=200) no deletion mutation in the 5' flanking region of the ANP receptor could be detected using polymerase chain reaction. Plasma-levels of pro-ANP as an indicator of cumulative ANP-production were significantly elevated in patients with eHYP (n=90) as compared to controls (n=45) (3.31 ± 1.48 vs. 1.94 ± 1.12 pmol/ml; $p<0.01$).
Conclusion: The ANP-receptor mediated vasodilation is impaired in patients with eHYP as compared to normotensive controls. This impairment is not caused by a deletion mutation in the 5' flanking region of the ANP-receptor. The elevated plasma levels of pro-ANP suggest that downregulation of ANP-receptors may participate to this phenomenon.

P2347 Polymorphism in intron 23 of the endothelial nitric oxide synthase gene (NOS3) is not associated with hypertension

N. Derebecka[1], M. Holysz[1], R. Dankowski[2], M. Wierzchowiecki[2], W. Trzeciak[1]. *[1]University of Medical Sciences, Dep. of Biochemistry and Mol. Biol., Poznan, Poland; [2]University of Medical Sciences, 2nd Department of Cardiology, Poznan, Poland*

Background: Impaired synthesis of NO due to mutations in the NOS3 gene is associated with hypertension. Several allelic variants of the NOS3 gene have been identified and evaluated for possible association with cardiovascular disease. The majority of NOS3 gene polymorphisms have been found in introns. The G11T polymorphism in intron 23 has not yet been widely investigated.
Aim: The purpose of our investigation was to determine the association of intron 23 polymorphism of the NOS3 gene with the incidence of hypertension.
Materials and methods: The study group consisted of 108 Caucasian patients (men-74, women-34) with arterial hypertension The patients ranged in age from 20 to 67 (median age 51). As a control group served 118 healthy individuals matched with sex and age. In our study we applied PCR-restriction fragments length polymorphism (PCR-RFLP) analysis with the use of restriction endonuclease NmuCI.
Results: The multitemperature single-stranded conformational polymorphism (MSSCP) analysis of the amplified fragment of the NOS3 gene showed three different banding patterns. Sequence analysis revealed three corresponding variants of G11T polymorphism in intron 23. Following PCR-RFLP analysis all the patients and the controls were divided into three groups: G/G, G/T and T/T, according to their genotype (table).

Group	Group size	Homozygotes T/T n (%)	Heterozygotes G/T n(%)	Homozygotes G/G n(%)	Allele frequencies (%) T—G
Patients	108	16(14,81)	52(48,15)	40(37,04)	39—61
Control	118	13(11.02)	55(46.61)	50(42,37)	34,3—65,7

Allelic Frequencies [patients vs control] $p = 0.31$ (X2 test) Genotype Distribution [patients vs control] $p = 0.32$ (U-test)

Conclusions: No major differences in the distribution of G11T polymorphism in the affected individuals and control groups were found (p=0.32). The present work shows that the G11T polymorphism of the NOS3 gene is not associated with hypertension.

ENDOTHELIAL FUNCTION

P2348 At the level of which vessels does flow-mediated dilation of the brachial artery correlate with coronary endothelial function?

H. Teragawa, K. Matsuda, Y. Fukuda, K. Ueda, H. Hirao, T. Yamagata, H. Matsuura, K. Chayama. *Hiroshima Univ. School of Medicine, First dept. of Internal Medicine, Hiroshima, Japan*

Background: Flow-mediated dilation (FMD) of the brachial artery has been widely used as an index of peripheral endothelial function. However, only a few studies have shown that the FMD of the brachial artery correlates with the endothelial function of coronary arteries. Furthermore, the vessel level at which the FMD of the brachial artery correlates with coronary endothelial function remains to be clarified. Therefore, we investigated whether the FMD of the brachial artery correlatesdwith coronary endothelial function at the level of conduit and/or resistance vessels. Methods: Thirty-nine patients (mean age: 62 yrs; 22 men and 17 women) with normal coronary arteries were enrolled for this study. Patients with myocardial infarction, heart failure, or other serious diseases were not included in the study. Changes in brachial artery diameter in response to hyperemic flow (FMD) were measured by high resolution ultrasound (10MHz) before coronary angiography. On coronary angiography, acetylcholine (Ach, 3 μg/min and 30 μg/min) was infused into the left coronary ostium over 2 min. The diameter of proximal and distal segments of the left anterior descending coronary artery was quantitatively measured and coronary blood flow (CBF) was calculated by quantitative angiography and Doppler flow velocity measurements. The changes in coronary artery diameter and CBF in response to Ach infusion were expressed as percent changes from baseline values. Results: FMD (4.8±0.6%) did not correlate with any changes in the coronary diameter induced by Ach at the proximal (Ach 3 μg/min: 0.8±1.0%, Ach 30 μg/min: -2.9±1.7%, both NS) nor at the distal segment (Ach 3 μg/min: -2.1±1.1%, Ach 30 μg/min: -4.8±2.2%, both NS). On the other hand, the FMD showed significant correlations with the increase in CBF induced by Ach at 3 μg/min (49±8%, r = 0.367, p = 0.0209) and 30 μg/min (86±16%, r = 0.357, p = 0.0271) dose levels. Conclusions: These results suggest that FMD of the brachial artery correlates with coronary endothelial function at the level of resistance vessels but not at that of conduit vessels. Interestingly, FMD of the brachial artery may be a useful index of coronary endothelial function at the level of resistance vessels.

P2349 Elevated serum C-reactive protein levels and early arterial changes in healthy children

M.J. Jarvisalo[1], A. Harmoinen[2], M. Hakanen[3], U. Paakkunainen[3], J.S.A. Viikari[4], T. Lehtimäki[1], O. Simell[3], O.T. Raitakari[5]. *[1]Turku University, Department of Clinical Physiology, Turku, Finland; [2]University of Tampere, Department of Clinical Chemistry, Tampere, Finland; [3]University of Turku, Turku, Finland; [4]University of Turku, Department of Medicine, Turku, Finland; [5]Turku University Central Hospital, Turku PET Centre, Turku, Finland*

Background: Elevated serum concentration of C-reactive protein (CRP) predicts cardiovascular events in adults. As atherosclerosis begins in childhood, we undertook a study to determine whether changes in brachial artery reactivity and the thickness of the carotid intima-media complex, two markers of early atherosclerosis, are related to CRP levels in healthy children.

Methods and Results: Using high-resolution ultrasound, we measured brachial artery flow-mediated dilatation (FMD) and carotid artery intima-media thickness (IMT) in 79 children (age 10.5±1.1 years). As compared to the children with CRP levels under the detection limit (<0.1 mg/L, N=40, Group 1), the children with higher CRP (Group 2: 0.1 mg/L=< CRP < 0.7 mg/L, n=20; Group 3: CRP>0.7 mg/L, n=19) had lower brachial artery flow mediated dilatation (9.0±4.4 vs 7.8±3.3 vs 6.5±2.6%; univariate p=0.015 for trend) and greater carotid artery intima-media thickness (0.45±0.03 vs 0.46±0.04 vs 0.49±0.06 mm; univariate p=0.006 for trend). CRP level remained a statistically significant independent predictor for both brachial artery flow-mediated dilation and carotid artery intima-media thickness in multivariate analyses including age, sex, body size, serum lipids, blood pressure and intercellular adhesion molecule-1 concentration, as covariates (table).

	CRP-groups			p-value (trend)
	<0.1 mg/L	0.1-0.7 mg/L	>0.7 mg/L	
peak FMD, %	9.0 (4.4)	7.8 (3.3)	6.4 (2.6)	0.018
mean IMT, mm	0.41 (0.03)	0.42 (0.04)	0.44 (0.04)	0.012
max IMT, mm	0.45 (0.03)	0.46 (0.04)	0.49 (0.06)	0.014

The associations between CRP groups and the ultrasonic measures of arterial function and structure. Values are mean (SD). P-values from multivariate linear regression adjusted for age, sex, body mass index, mean blood pressure, total cholesterol, HDL-C, ICAM-1 and baseline arterial diameter (brachial or carotid).

Conclusions: These data suggest that CRP directly affects the arteries of healthy children by disturbing endothelial function and promoting intima-media thickening. The findings support the hypothesis that CRP has an important role in the pathogenesis of atherosclerosis.

P2350 Impact of physical activity on phosphorylation of endothelial nitric oxide synthase in patients with coronary artery disease

R. Hambrecht[1], V. Adams[1], S. Erbs[1], K. Lenk[1], N. Kränkel[1], J. Gummert[2], F.W. Mohr[2], G. Schuler[1]. *[1]University of Leipzig - Heart Center, Dept. of Cardiology, Leipzig, Germany; [2]Dept. of Cardiothoracic Surgery, University of Leipzig - Heart Center, Leipzig, Germany*

Background: Regular physical exercise training (ET) is associated with a correction of endothelial dysfunction in patients (pts) with coronary artery disease (CAD). The molecular basis for this beneficial training effect, however is still unclear. Aim of this study was to assess the effects of ET on the expression and phosphorylation of endothelial nitric oxide synthase (ecNOS) in the endothelium of the left internal mammarial artery (LIMA) in pts with symptomatic CAD scheduled for elective bypass surgery (CABG).

Methods: Thirty-five pts with CAD were randomly assigned to either a training (T) or an inactive control (C) group. At study begin (B) and after 4 weeks (4 wks) endothelial-dependent vasodilation (eVD) in response to different dosages of acetylcholine (Ach) was assessed invasively with the help of a Doppler flow wire. The mRNA expression of eNOS was measured by real-time PCR in LIMA tissue not used for bypass grafting; the amount of phosphorylated ecNOS (serine 1177) (p-ecNOS) and phosphorylated protein kinase B (p-Akt) was quantified by Western Blot analysis.

Results: Acetylcholine-mediated (7.2 μg/min) average peak velocity (APV) (vs. 0.9% saline) increased significantly from 50±8 at B to 99±11% after 4 wks of ET (p<0.05 vs. C).The training group differed significantly from the C group with regard of ecNOS expression (6.1±1.2 vs. 3.1±0.6 rel. amounts; p<0.05 vs. C), p-ecNOS (serine 1177)(1.18±0.22 vs. 0.28±0.06 rel. amounts; p<0.01 vs. C), and p-Akt (1.31±.24 vs. 0.65±.1 rel. amounts; p<0.05 vs. C). The ecNOSmRNA/p-ecNOS ratio was significantly lower in T as compared to C (5.2±1.3 vs. 16.6±4.8; p<0.05).

There was a correlation between p-ecNOS and p-Akt (r=0.77, p<0.001) and between change in APV and p-ecNOS (r=0.56, p<0.002).

Conclusions: In patients with symptomatic CAD regular exercise training leads to a considerable improvement of agonist-mediated vasodilation of the LIMA. This beneficial training effect might on the cellular level be associated with a shear-stress induced/Akt-dependent increase in ecNOS phosphorylation.

P2351 Effect of pravastatin and chronic physical exercise on forearm blood flow in patients with coronary artery disease and average cholesterol levels

S. Eyer, N. Kartal, H. Saner, C. Vetter, S.M. Stengel, D. Pfiffner, O.M. Hess, Y. Allemann. *Swiss Cardiovascular Center Bern, Cardiology Dept., Bern, Switzerland*

Background: Improvement of forearm blood flow (FBF) by chronic exercise has been demonstrated in healthy volunteers, but studies in patients with coronary artery disease (CAD) are scarce. The purpose of this study was to investigate whether a 10-week (wk) treatment with pravastatin in patients with CAD and average cholesterol levels improves the endothelium-mediated vasodilatation of forearm arteries and whether this effect can be enhanced by physical exercise training.

Methods: 22 male patients with CAD and average cholesterol levels (<6,2 mmol/L) were randomised in three groups and investigated at baseline and after 10 wks. Group 1: 7 subjects received 40 mg pravastatin daily and did not change their lifestyle and recreational physical activity. Group 2 and 3: 15 subjects performed a structured endurance exercise program and were randomised in a double-blind trial to receive placebo (n=7) or 40 mg pravastatin (n=8). FBF changes were accessed with strain-gauge plethysmography.

Results: Sodium nitroprusside (SNP) and acetylcholine (Ach) caused a dose-dependent increase of the FBF that remained unchanged after pravastatin treatment and/or physical exercise training. In group 3, but not 1 and 2, the N-monomethyl-L-arginine (L-NMMA)-induced vasoconstriction was significantly greater at follow-up (0.72% (0.54-0.95) vs. 0.59% (0.38-0.70), p=0.03, baseline vs. follow-up).

Conclusion: Our observations indicate that a 10-wk therapy with 40 mg pravastatin combined with moderate endurance training improves the endothelial basal NO dilatator reserve in patients with CAD and average cholesterol levels. This is not achieved by either pravastatin therapy or exercise training alone. Concurrently, the stimulated NO release and the endothelium-independent vasodilatation remain unaltered.

P2352 Endothelial function is related to oxidized LDL and insulin resistance in healthy young men

H. Matsui, T. Mizuno, K. Okumura. *Nagoya University School of Medicine, Internal Medicine 2, Nagoya, Japan*

Background: Endothelial dysfunction is regarded as an early step in the development of atherosclerosis. Both LDL oxidation and insulin resistance play important roles in the pathogenesis of atherosclerosis. Furthermore, recent studies have suggested that there is a significant link between oxidized LDL (oxLDL) level and insulin resistance. In this study, we investigated the relationship between these factors and endothelial function in healthy young men.
Methods: Thirty-three men (aged 28.0±2.5 years), who had no history of atherosclerotic diseases, were enrolled in this study. Insulin sensitivity was estimated by homeostasis model assessment insulin resistance (HOMA-IR) and these subjects were divided into two subgroups according to HOMA-IR (insulin-resistant group with a HOMA-IR>=2.5, n=15; and insulin-sensitive group with a HOMA-IR<2.5, n=18). HOMA-beta-cell function was used to assess pancreatic insulin function. We evaluated endothelial function estimated by flow-mediated vasodilation during reactive hyperemia, using high-resolution ultrasound Doppler echocardiography. We also measured serum oxLDL level by a sandwich ELISA method.
Results: In the insulin-resistant group, body mass index, fasting glucose and insulin levels, HOMA-IR, and HOMA-beta-cell function were significantly higher and HDL-cholesterol level was significantly lower than those in the insulin-sensitive group ($p<0.01$, respectively). The serum oxLDL level was also significantly higher in the insulin-resistant group than in the insulin-sensitive group (133±42 vs. 105±34 U/L, $p<0.05$). Furthermore, the serum oxLDL level and HOMA-beta-cell function were significantly correlated with endothelium-dependent vasodilation (r=-0.568 and -0.521, $p<0.05$; respectively) in the insulin-resistant group. A stepwise multiple regression analysis in the insulin-resistant group showed that the serum oxLDL and fasting insulin levels were determinants of endothelium-dependent vasodilation (R^2=0.503). In contrast, the insulin-sensitive group showed no significant relationship between these parameters and endothelium-dependent vasodilation. There was no significant relationship between these parameters and endothelium-independent vasodilation induced by sublingual nitroglycerin in both groups.
Conclusion: These results suggest the possibility that LDL oxidation may be accelerated under the existence of insulin resistance and thus impair endothelial function in healthy young men.

P2353 Effects of vitamins C and E on thrombosis/fibrinolysis system in chronic smokers

K. Marinou, D. Tousoulis, C. Antoniades, C. Vasiliadou, M. Toutouza, G. Goumas, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, Cardiology Unit, Athens University, Athens, Greece*

Background: Smoking is implicated in coronary artery disease and acute coronary thrombosis. Purpose of this study was to investigate the effect of antioxidant vitamins C and E on endothelial function and simultaneously on blood levels of plasminogen activator inhibitor (PAI-1) von Willebrand factor (vWF), tissue plasminogen activator (tPA) and factor VII (fVII) in smokers.
Methods: 43 healthy young smokers (23 males 20 females aged 36±2 years) were enrolled in this double blind placebo controlled study. Subjects were divided into 4 groups receiving vitamin C 2g/day (n=10) (group A), vitamin C 2g/day and vitamin E 400IU/day (n=12) (group B), vitamin C 2g/day and vitamin E 800IU/day (n=10) (group C) or placebo (n=11) (group D), for 4 weeks. Forearm blood flow was measured using venous occlusion strain-gauge plethysmography. Endothelium dependent flow mediated vasodilation (FMD) was expressed as the % change from baseline to post reactive hyperemia blood flow. Endothelium independent % change flow (NTG%) was assessed after sublingual nitroglycerin administration. Plasma levels of PAI-1(ng/ml), vWf(%), tPA(IU/ML), and fVII(%) were determined by enzyme linked immunosorbent assay. All values are expressed as mean ± SEM.
Results: Blood pressure, heart rate, body weight, basal forearm blood flow and NTG% remained unchanged before and after treatment. FMD was significantly increased in group B (48.4±5.3 to 72.3±8.5%, $p<0.05$) and C (41.2±3.7 to 73.6±4.1%, $p<0.001$), while remained unaffected in groups A and D. Plasma levels of PAI-1 and vWF were decreased in group C (from 19.3±2.4 and 81.0±4.5 to 12.8±1.2 ng/ml and 68.5±3.1% respectively, $p<0.05$ for both), while remained unaffected in groups A, B, and D. Plasma levels of tPA and fVII did not change in none of the groups.
Conclusions: Combined administration of vitamin C 2g/day and vitamin E 800IU/day improves endothelial function and reduces blood levels of PAI-1 and vWF. These findings provide evidence that combined administration of vitamins C and E may affect thrombosis/fibrinolysis system in chronic smokers

P2354 Nitric oxide and prostaglandins mediate vascular effects of estrogen

T. Hövelborn[1], G. Yu[1], H.M. Hoffmeister[2], M.E. Beyer[1]. *[1]Medizinische Universitaetsklinik, Abt. III, Tuebingen, Germany; [2]Staedtisches Klinikum, Cardiology, Solingen, Germany*

Estrogen has atheroprotective and vasodilative effects. The mechanisms of these effects are unknown. Nitric oxide (NO) and prostaglandins (PG) like prostacyclin (PGI2) are endogenous vasodilators and both are released from endothelial cells in response to similar stimuli. Thus they may be involved in the mentioned estrogen-effects. This study examined, whether inhibition of NO-synthesis by L-NAME or inhibition of PG-synthesis by indometacin (INDO) modulates the vascular effects of 17beta-estradiol (17b-E) in vivo.
Methods: The effects of 200 ng/kg 17b-E were compared with NaCl-controls in open-chest female rats without and after pretreatment with 100 mg/kg L-NAME or 5 mg/kg INDO or after pretreatment with L-NAME and INDO. To quantify myocardial contractility isovolumic measurements (i. dP/dtmax) were performed. Additionally plasma levels of 6-keto PGF1a,the stabile metabolite of PGI2, were determined before and after infusion of 17b-E.
Results: 17b-E increases cardiac output and ejection fraction due to a reduction of the afterload. This effect is significantly reduced by INDO and completely abolished by L-NAME or by combined pretreatment. 17b-E has no inotropic effect. Infusion of 17b-E causes an increase of the 6-keto PGF1a plasma level from 2.9±0.5 ng/ml to 3.4±0.5 ng/ml.

	CO	EF	TPR	i. dP/dtmax
17b-E	167±10¶	127±3¶	71±3¶	97±4
NaCl	108±5	98±3	96±4	102±3
L-NAME + 17b-E	109±2	104±3	93±2	101±1
L-NAME + NaCl	113±2	106±5	92±3	98±2
INDO + 17b-E	135±5¶	114±5*	81±2*	98±2
INDO + NaCl	100±2	99±1	100±2	101±2
L-NAME + INDO + 17b-E	116±3	109±3	92±3	99±3
L-NAME + INDO + NaCl	115±4	111±4	89±3	96±3

Mean ± SEM in % of preinfusion values before 17b-E- or NaCl-infusion; *=p<0.01, ¶=p<0.001.

Conclusions: The estrogen-induced vasodilation is caused by NO-release since this effect is completely prevented by L-NAME. A part of the effect is mediated by PG. The combined pretreatment also completely prevents the vasodilation by 17b-E. Thus it seems possible that NO, which is released by 17b-E, itself releases PG.

P2355 Relationship between endothelial nitric oxide synthase gene polymorphisms and coronary vascular function among subjects with CHD

J. Muntwyler[1], M.S. Nauck[2], P. Helbling[3], W. Marz[2], T.F. Luscher[4] on behalf of ENCORE I Investigators. *[1]University Hospital, Internal Medicine Dept., Zurich, Switzerland; [2]University Hospital, Clinical Chemistry, Freiburg, Germany; [3]University Hospital, Intercornet, Zurich, Switzerland; [4]University Hospital, Cardiology, Zurich, Switzerland*

Background: Nitric oxide has an important role in endothelial function and integrity. There is evidence for a relationship between endothelial nitric oxide synthase (eNOS) gene polymorphisms and vascular function, but results are inconsistent.
Methods: This study was performed among 316 subjects enrolled in the ENCORE I study (mean age 58+10, 81% male). Inclusion criteria for the ENCORE I study were presence of CHD and pathological response to acetylcholine. With QCA, mean segment vessel diameter was determined at baseline and in response to acetylcholine (0.36, 3.6 and 18 µg/ml), adenosin (1.2 mg/ml) and nitroglycerin (200 µg). The eNOS gene polymorphism T-786C of the promotor region and the polymorphism G894T (Glu298Asp) in exon 7 were determined using PCR. The association of polymorphisms with QCA was tested with ANCOVA, adjusting for assessed segments, age and sex.
Results: CC homozygosity for T-786C was associated with a reduced baseline mean segment diameter (1.71 vs. 1.88 mm, p=0.02), and TT (G894T) carriers also had a non-significant reduction in segment diameter (1.79 vs. 1.86, p=0.40). Response to acetylcholine was similar among homozygotes compared to the remainder (CC vs TT/TC: mean response -23% vs. -20%, p=0.43; TT vs GG/GT: -20% vs. -20%, p=0.95; homozygosity for both variants, -25% vs -20%, p=0.44). Patients with the CC (T-786C) genotype tended to have an elevated response to nitroglycerin (21% vs 17%, p=0.16) and adenosin (18% vs 14%, p=0.18). In subjects who carried both the CC and TT variant response to nitroglycerin was significantly elevated (28% vs. 19%, p=0.04).
Conclusion: Our findings are compatible with a reduced basal endothelial NO production among CC and TT homozygotes of the T-786C and G786T eNOS gene polymorphisms supporting the hypothesis that these gene variants may be functional.

P2356 Cardiovascular events in patients with normal coronary angiogram but endothelial dysfunction of epicardial artery

T.H. Schindler[1], P.T. Buser[1], M. Olschewski[2], U. Solzbach[3], M. Pfisterer[1], H. Just[3]. *[1]Universitätskliniken Basel, Kantonsspital, Kardiologie, Basel, Switzerland; [2]Statistics and Biometry, University of Freiburg, Freiburg, Germany; [3]Kardiologie, University of Freiburg, Freiburg, Germany*

Little information is available to prove the relation between impaired endothelial-dependent vasomotion and cardiovascular events in long-term. We aimed to determine prospectively the prognostic impact of abnormal endothelial-dependent vasoreactivity of epicardial coronary artery in response to cold pressor testing (CPT) in patients with risk factors for atherosclerosis but normal coronary angiogram.

Method: In 141 patients with normal coronary angiogram, endothelial-dependent vasoreactivity in response to CPT and dilation of epicardial artery to intracoronary application of nitroglycerin was assessed quantitatively (%change of luminal area: delta LA%). Cardiovascular events (cardiovascular death, unstable angina pectoris, myocardial infarction, percutaneous transluminal coronary angioplasty, coronary bypass grafting, ischemic stroke, or peripheral revascularisation) were assessed as clinical outcome parameters over a median follow-up period of 45±7 months. Patients were assigned on the basis of their endothelial-dependent vascular responses to CPT into 3 groups: group 1 (delta LA:>0%; n=25), patients with normal endothelial-dependent vasodilation; group 2 (delta LA:0% to -15%; n=51), patients with moderate endothelial-dependent vasoconstriction; and group 3 (delta LA:<-15%; n=65), patients with severe endothelial-dependent vasoconstriction.

Results: None of the patients from group 1 had cardiac events. However, in group 2 six (11%) and group 3 thirty-two (49%) cardiovascular events occurred ($p<0.05$ versus group 1, respectively). Patients suffering from cardiovascular events during the follow-up (group 2 and 3) had significantly increased flow-mediated vasoconstriction to CPT as compared to group 1 (mean delta LA:-14±5% versus 15±13%;$p<0.03$), but normal endothelial-independent vascular responses to intracoronary apllication of nitroglycerin (P=NS). Impaired endothelial-dependent epicardial coronary reactivity in group 2 and 3 was associated with a significantly higher incidence of cardiovascular events by Kaplan-Meier analysis ($P<0.0001$).

Conclusion: Abnormal endothelial-dependent vasoreactivity of epicardial coronary artery is associated with increased cardiovascular events. These findings suggest that assessment of endothelial-dependent vasomotion of epicardial coronary artery in response to cold pressor testing may provide valuable diagnostic and prognostic information during routine coronary angiography.

P2357 Increased serum soluble heat shock protein 60 levels are associated with endothelial dysfunction in patients with coronary artery disease

V. Mwansa, E. Zouridakis, F. Davidson, Q. Xu, J.C. Kaski. *St George's Hospital Medical School, Cardiological Sciences Dept., London, United Kingdom*

Background: Recent clinical and experimental studies have suggested a significant role of soluble heat shock protein 60 (sHSP60) in inflammation and immune activation underlying atherosclerotic disease. Endothelial dysfunction is also considered to be one of the earliest events in the atherogenic process. The aim of our study was to investigate whether an association exists between sHSP60 and endothelial function in patients with coronary artery disease (CAD).

Methods: We examined 55 men (mean age 68±9yrs) with angiographically documented CAD (34 pts had multivessel disease). In all patients endothelial function was assessed by measuring flow mediated dilatation (FMD) of the brachial artery using high resolution ultrasound and standard methods. sHSP60 was measured by use of a sandwich enzyme-linked immunosorbent assay (ELISA)

Results: FMD of the brachial artery in these patients was 2.87±2.05%. The median [interquartile range] of sHSP60 was 458[131-935.6]ng/ml. sHSP60 had a skewed distribution and was logarithmically transformed before analysis. Univariate analysis showed a significant inverse relation between FMD and sHSP60 levels (beta=-1.90, $R^2=0.39$, $P<0.005$) indicating that endothelial dysfunction was more prominent in patients with higher sHSP60 concentrations. Multivariate analysis revealed that this association remained significant even after adjustment for other variables such as age, smoking, history of diabetes and hypertension, and lipid levels (P=0.002).

Conclusions: Our results showed that high levels of sHSP60 are associated with impaired endothelial function in patients with CAD. These findings indicate that this protein may play an important pathogenic role in the development of atherosclerotic heart disease.

P2358 Endothelial nitric oxide synthase and angiotensin-converting enzyme gene polymorphisms and the indices of arterial structure and function

D. Czarnecka[1], K. Kawecka-Jaszcz[1], A. Olszancka[1], K. Stolarz[1], A. Jabrocka[2], A. Dembinska-Kiec[2]. *[1]Collegium Medicum, I Cardiac Department, Krakow, Poland; [2]Collegium Medicum UJ, Department of Clinical Biochemistry, Krakow, Poland*

Endothelial nitric oxide exerts important effects on the regulation of vascular tone and structure. Genes regulating nitric oxide release have been suggested as a candidate genes involved in the development of hypertension.The ACE gene polymorphism is regarded to be a distinct heritable cardiovascular risk factor.

The aim of this study was to assess the contribution of two polymorphisms of the endothelial nitric oxide synthase (eNOS) gene and ACE gene polymorphism to aortic stiffness and carotid intima-media thickness in normotensive and hypertensive patients.

Material and methods: We studied 81 untreated hypertensive patients and 56 normotensive subjects. ABPM (SpaceLabs 90207) was performed in all subjects. Pulse wave velocity (PWV) between the carotid and femoral arteries was used as an index of arterial compliance (Complior device) and carotid intima media thickness (IMT) measured by carotid ultrasound was used as an index of arterial structure. The two eNOS gene polymorphisms: a biallelic variable number of tandem repeats (VNRT) in intron 4 and an exon 7 variant (G894T) that leads to Glu298Asp change were genotyped by PCR. The insertion/deletion(I/D) polymorphism for ACE gene was detected using polymerase chain reaction technigue.

Results: The distribution of genotypes and allele prevalence of eNOS polymorphisms among hypertensive and normotensive subjects were similar.The ACE genotype freguency was at Hardy-Weinberg eguilibrium. There was no association between Glu28Asp and VNRT polymorphism with blood pressure. No evidence of genetic influence was found in respect to pulse wave velocity. However, we observed that patients carrying T allele of Glu298Asp polymorphism had higher IMT (GG - 0.71 ± 0.1 mm, TG 0.95 ± 0.06 mm, TT - 1.32 ± 0.1 mm, $p<0.03$).No influence of ACE polymorphism on the indices of arterial structure and function was not observed.

Conclusion: These results indicate that the Glu28Asp polymorphism of eNOS identifies patients with increased carotid intima media thickness.

P2359 Effect of angiotensin-converting enzyme inhibition and AT1-receptor antagonism on myocardial perfusion in patients with endothelial dysfunction

B. Hornig[1], D. Hausmann[1], A. Börner[2], J. Klocke[1], S. Jategaonkar[1], N. Engberding[1], W. Knapp[2], H. Drexler[1]. *[1]Medizinische Hochschule, Abt. Kardiologie und Angiologie, Hannover, Germany; [2]Medizinische Hochschule, Abt. Nuklearmedizin, Hannover, Germany*

Background: It has been shown that statins improve myocardial perfusion in patients with hypercholesterolemia, possibly by improving endothelial function. Both ACE-inhibitors and AT1-receptor-antagonists have been shown to improve impaired endothelium-mediated vasodilation, i.e. long term quinapril therapy improved coronary endothelial function in the TREND trial. It is unclear, however, whether this beneficial effect on endothelial function is translated into improved myocardial perfusion or coronary flow reserve in normocholesterolemic patients with endothelial dysfunction.

Methods and Results: To test this hypothesis, we randomized 18 normocholesterolemic patients with typical anginal chest pain without significant coronary artery stenoses and with abnormal endothelial function (epicardial vasoconstriction and impaired coronary flow response to intracoronary acetylcholine infusion) to a 3 month therapy with quinapril (40 mg/d; n=11) or losartan (100mg/d; n=7). Myocardial perfusion at rest and after adenosin (140 µg/kg/min i.v.) was assessed using positron emission tomography (PET; C11-acetate) before and after therapy. Regional coronary flow reserve (CFR) was calculated from maximal myocardial blood flow after adenosin and blood flow under resting conditions. In patients treated with quinapril myocardial perfusion at rest was unchanged after therapy. However, maximal perfusion after adenosin was improved in every patient with 3 month quinapril, leading to restoration of regional CFR (from: 2.3 ± 0.3 to 3.5 ± 0.5; $p<0.05$). In patients treated with losartan, however, myocardial perfusion at rest, after adenosine and CFR was not significantly changed after 3 month therapy.

Conclusion: Longterm-ACE-inhibition restores regional coronary flow reserve in patients with endothelial dysfunction in the coronary circulation. Conceivably, this beneficial effect of long-term ACE-inhibition may be related to the documented improvement of quinapril on coronary endothelial function in this patient population.

P2360 Characterization of L-selectin-dependent adhesion to human microvascular cardiac endothelial cells

M. Gräfe[1], U. Thanabalasingam[1], D. Stibenz[1], S. Goetze[1], R. Pregla[2], E. Fleck[1]. [1]Deutsches Herzzentrum Berlin, Internal Medicine/Cardiology, Berlin, Germany; [2]Deutsches Herzzentrum Berlin, Cardiothoraxic and Vascular Surgery, Berlin, Germany

L-selectin ligands are heavily glycosolated proteins and characterized by o-linked sugars and the MECA79 epitope. L-selectin is constitutively expressed on nearly all leukocytes and plays an important role for recruitment of leukocytes into inflamed tissues. Functional data suggest that - apart from the MECA79 epitope - additional adhesion receptors for L-selectin are of importance. Aim of the present study was to characterize endothelial cells with regard to sugar moieties which mediate L-selectin-dependent adhesion of leukocytes to endothelial cells. Endothelial cells from the microvasculature of human hearts (MEC) were isolated from explanted human hearts by enzymatic treatment of the heart tissue and further purified with ulex europaeus-linked paramagnetic beads. Upon confluence MEC were stimulated with TNF alpha (4 hours, 500 U/ml). L-selectin-dependent adhesion was quantified at different shear stress levels (0.6-2.6 dyn/cm^2) in a flow chamber using NALM6 cells stably transfected with L-selectin (NALM6-L). In addition, leukocyte rolling velocities (V) were measured at 1.5 dyn/cm^2. NALM6-L adhered shear stress-dependent to TNF-stimulated MEC but not to unstimulated MEC. V were reduced from 2.3-5 mm/s (median 3.7) on unstimulated MEC to 1.8-4 mm/s (median 2.7) on TNF-stimulated MECs. Inactivation of o-linked sugar moieties on MECs with O-sialoglycoprotein peptidase had no influence on adhesion and V. Inhibition of N-glycosilation with tunicamycin (10 μg/ml) inhibited adhesion and increased V of NALM6-L on MECs. MECA79 was neither expressed on unstimulated nor on TNF-stimulated MECs as judged from flow cytometry. The results suggest that - in contrast to lymphatic endothelium - N-glycosolation of L-selectin ligands are of importance on vascular endothelial cells while O-linked sugar moieties and the MECA79 epitope are functionally not relevant.

P2361 Decrease of CRP serum levels determines the extent of Statin induced improvement in endothelial dysfunction

S. Fichtlscherer, S. Breuer, C. Badorff, M. Vasa, M.R. Langenfeld, S. Dimmeler, A.M. Zeiher. *Johann W. Goethe University, Dep. of Cardiology, Frankfurt, Germany*

Statin therapy is associated with improved endothelial vasodilator function. Recent studies suggest that the beneficial effects of statins on atherosclerosis disease progression are most prominent in patients with elevated inflammatory markers. Since endothelial dysfunction importantly contributes to atherosclerotic disease progression, we investigated whether the antiinflammtory effects (as measured by CRP serum levels) of statins correlate with improved endothelial function in patients with CAD. Systemic vasoreactivity was assessed in 20 consecutive patients with documented coronary artery disease measuring endothelium-dependent (acetylcholine, ACH, 10-50μg/min) and endothelium-independent (sodium-nitroprusside, SNP, 2-8μg/min) forearm blood flow (FBF) responses by venous occlusion plethysmography, before and after initiation of a therapy with 20 mg atorvastatin daily.

Results: Atorvastatin treatment resulted in a significant and profound reduction of LDL-cholesterol levels by 48.1 ± 3.6% ($p<0.05$) and CRP serum levels from 1.8 ± 0.6 to 0.6 ± 0.4 mg/dl ($p<0.05$). ACH induced FBF responses increased significantly after 4 weeks of atorvastatin therapy (+414.9 ± 179.7%). There was a close significant inverse correlation of increase in FBF responses to ACH with reduced CRP levels ($r=-0.6; p<0.05$), but not with the decrease of LDL-cholesterol levels. A decrease in CRP serum levels was the most important independent predictor of improved endothelial vasodilator function.

Conclusion: Atorvastatin induced improvement in endothelial dysfunction is closely associated with its antiinflammatory effects as measured by CRP, but independent of cholesterol lowering in patients with CAD. These results further support the importance of pleiotropic mechanisms to mediate vasciloprotective effects of statins.

P2362 Obesity and waist/hip ratio predict endothelium-dependent coronary vasoreactivity in postmenopausal women

C. Duvernoy[1], J. Martin[1], K. Briesmiester[1], J. Bae[2], A. Bargardi[3], O. Muzik[4], L. Mosca[5]. [1]University of Michigan, Division of Cardiology, Ann Arbor, Michigan, United States of America; [2]University of Michigan, Internal Medicine, Ann Arbor, Michigan, United States of America; [3]Veterans Affairs Medical Center, Cardiology Section, Ann Arbor, Michigan, United States of America; [4]Wayne State University PET Center, Nuclear Medicine, Detroit, Michigan, United States of America; [5]Columbia University, Preventive Cardiology, New York, New York, United States of America

Background: Obesity and body fat distribution have both been shown to be predictors of coronary heart disease (CHD). There is also an association between obesity and body fat distribution with impaired endothelium-dependent vasodilation in the peripheral as well as the coronary circulation.

Methods: We sought to noninvasively determine both endothelium-dependent and -independent measures of coronary vasoreactivity using dynamic N-13 ammonia positron emission tomography (PET). Myocardial blood flow (MBF) and myocardial flow reserve (MFR) were measured in 17 postmenopausal women (60±6 yrs) at risk for coronary heart disease. Mean body mass index (BMI) was 29.3±4.3 kg/m^2; mean waist-hip ratio (W/H) was 0.85±0.05. All subjects had elevated total and LDL cholesterol levels, as well as at least one additional CHD risk factor, and were not using hormone replacement therapy. All had negative dobutamine echocardiograms. MBF was measured using a three-compartment model at rest, in response to sympathetic stimulation with the cold-pressor-test (CPT), and to intravenous adenosine infusion, in order to determine baseline, endothelium-dependent, and endothelium-independent measurements, respectively. MFR was measured as the ratio between MBF during adenosine to MBF at rest. MBF and MBF normalized to the pressure rate product (PRP) were analyzed.

Results: There was a significant inverse correlation between BMI and normalized CPT MBF ($R= -0.605$, $p=0.010$). We also noted a significant inverse correlation between W/H ratio and CPT MBF ($R= -0.574$, $p=0.016$). There was a strong trend towards an inverse correlation between W/H and normalized CPT MBF ($R= -0.467$, $p=0.059$). No relationship was found between W/H or BMI and endothelium-independent flow, as assessed by maximal MBF after adenosine, or between W/H or BMI and MFR.

Conclusions: Both degree of obesity and visceral adiposity in postmenopausal women predict impaired endothelium-dependent coronary vasomotor responsiveness, as measured noninvasively by CPT PET.

P2363 Endothelial function in patients with severe coronary artery disease treated with enhanced external counterpulsation therapy (ECPT)

M. Shechter, S. Matetzky, M.S. Feinberg, P. Chouraqui, Z. Rotstein, H. Hod. *Sheba Medical Center, The Heart Institute, Tel Hashomer, Israel*

Background: Enhanced external counterpulsation therapy (ECPT) reduces angina and improves exercise tolerance in patients with coronary artery disease (CAD). Vascular endothelium plays a key role in circulatory homeostasis. In CAD patients the vascular endothelium is usually impaired, and it has been suggested that modification or reversal of endothelial dysfunction may be of significant therapeutic benefit in the treatment of CAD patients. However, the impact of short-term ECPT on flow-mediated dilation (FMD) in CAD patients has not yet been assessed.

Methods: We prospectively assessed endothelial function in CAD patients with severe stable angina pectoris [Canadian Cardiovascular Society Classification (CCSC) III or IV] unsuitable for coronary revascularization (either coronary artery bypass grafting operation or percutaneous coronary intervention), before and after ECPT. Endothelium-dependent brachial artery FMD and endothelium-independent nitroglycerin-mediated vasodilation (NTG) were assessed using high resolution (16 MHz) linear array ultrasound in 10 consecutive severe CAD patients (mean age 66±11 years, mean left ventricular ejection fraction 47±9%, mean body mass index 28±3 kg/m^2), in an ongoing, single center trial. All patients completed a full 35-hour treatment course.

Results: See table.

	%FMD	%NTG	No. SL NTG/day	CCSC
Before ECPT	3.5±5.0	7.5±2.4	4.7±2.9	3.3±0.4
Post ECPT	8.2±3.5	8.7±4.6	0.4±0.5	2.0±0.4
p-value	0.03	0.55	<0.01	<0.01

Values are expressed as mean±SD; %FMD, %NTG = % change from baseline in brachial artery diameter caused by FMD and NTG, respectively; SL NTG=number of sublingual nitrates pills per day; CCSC = Canadian Cardiovascular Society Classification.

Conclusion: CAD patients with severe anginal syndrome unsuitable for coronary revascularization suffer from impaired brachial artery endothelium-dependent, flow-mediated vasodilation, suggesting the presence of endothelial dysfunction. ECPT significantly improves vascular endothelial function, thereby suggesting that such a mechanism could improve anginal and heart failure symptoms.

P2364 Effects of exercise on the expression of NAD(P)H-oxidase and angiotensin-II receptors in the LIMA of patients with coronary artery disease

V. adams[1], S. Erbs[2], Y. Shu[2], S. Krabbes[2], J.F. Gummert[3], F.W. Mohr[3], R. Hambrecht[2], G. Schuler[2]. [1]heart-center Leipzig, Cardiology, Leipzig, Germany; [2]University Leipzig, Heart-Center Leipz, Cardiology, Leipzig, Germany; [3]University Leipzig, Heart Center, Cardiac Surgery, Leipzig, Germany

Introduction: In patients (pts) with coronary artery disease (CAD) physical activity (PA) has the potential to improve endothelial dysfunction. Several studies demonstrated that free oxygen radicals reduced the bioavailability of nitric oxide, a potent regulator of endothelial function. The aim of this study was to analyze the impact of PA on the expression of NAD(P)H-oxidase and angiotensin-II receptors (Ang-IIR) in the left mammarial artery (LIMA) of pts with CAD.
Methods: Thirty-five pts with the indication for a bypass surgery were randomized into either a training (T) or inactive control group (C). After 4-weeks the acetylcholine (ACH) mediated vasodilation of LIMA-rings in an organ bath and the expression of NAD(P)H-oxidase (subunit gp91phox and p22phox) and Ang-IIR (subtype 1 and 2) by real time PCR were analyzed.
Results: To induce a 50% relaxation (ED50) of phenylephrine-preconstricted LIMA-rings a significant lower concentration of ACH was necessary in T (7.6±0.3 [-log molar ACH]) as compared to C (6.9±0.2 [-log molar ACH]; $p<0.05$). The molecular analysis revealed that the expression of gp91phox (T: 0.36±0.12 vs. C: 2.06±0.62; $p<0.05$) and of p22phox (T: 1.67±0.47 vs. C: 4.79±1.5; $p<0.05$) was significantly reduced in T as compared to C. Additionally under the influence of PA a significant reduction of Ang-IIR subtype-1 (T: 3.6±0.79 vs. C: 16.6±5.7; $p<0.05$) and a significant increase of Ang-IIR subtype-2 (T: 2.6±0.61 vs. C: 0.48±0.21; $p<0.001$) was detected.
Conclusion: The results of this study demonstrate that also in the LIMA PA leads to an improvement of endothelial mediated vasodilation. At the molecular level this improvement may be due to a reduced expression of ANG-IIR subtype-1 and NAD(P)H-oxidase.

P2365 Chemokines (MCP-1, MIP-1a and RANTES) activation in acute myocardial infarction

J. Orzeszko[1], M. Kobusiak-Prokopowicz[1], G. Mazur[2], T. Wróbel[2]. [1]Medical University, Cardiology Department, Wroclaw, Poland; [2]Medical University, Hematology Department, Wroclaw, Poland

C-C chemokines are major factors in the recruitment and activation of monocytes and neutrophiles from the circulation into inflammed tissue and may play a role in acute myocardial infarction (AMI). The aim of this study was to assess the kinetics of three chemokines: Monocyte Chemoattractant Protein-1 (MCP-1), Macrophage Inflammatory Protein-1a (MIP-1a) and Regulated on Activation Normal T cell Expressed and Secreted (RANTES) serum level in patients with AMI.
Material and method: The study group consisted of 20 patients (pts) aged 43-79 (mean age 63,3) with AMI, 8 women and 12 men. Control group consisted of 10 healthy, sex- and age-matched volunteers. The blood samples for evaluation of MCP-1, MIP-1a and RANTES serum level was taken at the admission to the hospital, 3 hours (h) after thrombolytic therapy was started, then 24, 48 and 72 h and 7 days after admission. All chemokines serum level was determined by ELISA. In all pts we also measured serially during the first week of hospitalization serum creatinine kinase (CPK), serum creatinine kinase MB isoenzyme (CKMB), troponine I (TnI), white blood cells count and on the 3rd day after admission the echocardiography was made.
Results: The baseline MCP-1 and RANTES serum level was significantly higher in pts with AMI than in control group (MCP-1 836,1 vs 128,8 pg/ml $p<0,001$; RANTES 78,6 vs 31,3 pg/ml $p<0,01$). In pts with AMI there was a significant increase MCP-1, MIP-1a and RANTES serum level 3 h after thrombolytic therapy (MCP-1 1400,3 vs 836,1 pg/ml $p<0,01$; MIP-1a 70,4 vs 15,1 pg/ml $p<0,005$; RANTES 156,3 vs 78,6 pg/ml $p<0,01$). The MCP-1 and MIP-1a peak levels were 24 h after admission (MCP-1 1458,7 vs 836,1 pg/ml $p<0,01$; MIP-1a 91,9 vs 15,2 pg/ml $p<0,001$) and RANTES peak serum level was 3 h after thrombolytic therapy (156,3 vs 78,6 pg/ml $p<0,01$). MCP-1, MIP-1a and RANTES serum level was higher in pts with AMI also untill 7 days after admission. On the 3rd day the echocardiography examination was made and ejection fraction (EF) correlated negatively with chemokines, especially with MCP-1 ($r=-0.66$, $p<0.05$). Conclusions. In this preliminary report we detected a significant elevation of MCP-1, MIP-1a and RANTES serum level in pts with AMI during the 7 days of observation. The chemokines serum level correlated with cardiac marker proteins and statistically significant negative correlation with ejection fraction was found. These findings suggest that enhanced immune processes in AMI are connected with disease-related endothelial damage and may contribute to its pathophysiology, what needs further investigations.

P2366 -786C/T Gene polymorphism of endothelial nitric oxide synthase as a risk factor for coronary heart disease

M. Cattaruzza[1], W. Slodowski[2], A. Pelvan[1], J. Becker[3], M. Halle[4], A.B. Buchwald[4], M. Hecker[1]. [1]University of Goettingen, Cardiovascular Physiology, Goettingen, Germany; [2]Jagiellonian Univ Medical College, Department of Anesthesiology, Krakow, Poland; [3]Clinics NeuBethlehem, Cardiology Division, Goettingen, Germany; [4]University of Goettingen, Cardiology and Pneumology, Goettingen, Germany

Background: Coronary heart disease (CHD), ultimately leading to myocardial infarction or heart failure, is based on the development of atherosclerosis in one or more coronary arteries. Shear stress-dependent endothelial nitric oxide release not only contributes to local blood pressure control but also helps to retard atherosclerosis. Functionally relevant polymorphisms in the endothelial nitric oxide synthase (NOS-3) gene may thus contribute to the development of CHD.
Methods: To verify this hypothesis, genomic DNA was isolated from the blood of patients undergoing coronary angiography and genotyped for the -786C/T polymorphism of the NOS-3 gene by restriction fragment length polymorphism analysis. In addition, shear stress-induced NOS-3 expression in endothelial cells isolated from genotyped umbilical cords was determined at the mRNA and protein level.
Results: Shear stress-induced NOS-3 expression was detected in -786T/T and -786C/T but not -786C/C genotype endothelial cells. Moreover, in patients below 65 years of age with angiographically proven CHD, the -786C/C genotype was significantly more frequent (19%) than in patients without CHD (2.5%, $P<0.0001$). The primary CHD risk factor profile, on the other hand, was the same in all patients irrespective of the genotype.
Conclusions: The -786C/T polymorphism of the NOS-3 gene, namely the -786C/C genotype, may thus constitute an independent risk factor for the development of CHD, presumably due to an alteration of the shear stress-responsiveness of the C-type promoter.

P2367 Determinants of plasma homocysteine levels in coronary patients

M. Qiao, P. Chook, P.Y.K. Poon, G.N. Thomas, K.S. Woo. The Chinese University of Hong Kong, Dept of Medicine & Therapeutics, NT, Hong Kong

Background: Hyperhomocysteinemia is an emerging coronary risk factor. This study aimed to evaluate the major plasma determinants of plasma homocysteine in patients with coronary artery disease.
Methods: We studied 636 patients with angiographically documented coronary disease (CAD). Fasting (>12hours) total plasma homocysteine (tHcy) taken at time of angiography were measured by fluorescence polarization immunoassay (IMx, Abbott Laboratories), methylenetetrahydrofolate (MTHFR, C677T) gene status was determined by polymerase chain reaction-restriction fragment length polymorphism and folate and vitamin B-12 by dualcount solid phase no boil assay (Diagnostic Products Corporation).
Results: Mean tHcy of the CAD group is 10.2±1.4mmol/l, being lowest in patients with CC genotype and normal folate levels (9.6mmol/l), and highest in patients with TT or CT genotype and folate deficiency (13.1mmol/l). The frequency of CC, CT and TT MTHFR polymorphisms were 59%, 35.8% and 5.2% respectively. On multivariate linear regression, age, plasma creatinine, folate, vitamin B-12 and TT genotype were independently correlated with tHcy levels (model $R=0.64$; F value=62.6; $p<0.001$), with significant interaction between plasma folate and TT genotype.

Clinical Paremeter of CAD Patients

	Standardized Coefficients	p-Value
Age	0.13	<0.001
Plasma creatinine	0.37	<0.001
Plasma vitamin B-12	-0.38	<0.001
Plasma folate	-0.14	<0.001
TT genotype	0.83	<0.001
TT plus plasma folate	-0.66	0.001

Conclusion: Plasma folate and vitamin B-12 levels, renal function and MTHFR genotype are major determinants of tHcy; folate profile is particularly determinative in TT genotyp

P2368 Different significance of soluble VCAM-1 and ICAM-1 in patients with acute versus chronic coronary syndromes

M. Rugolotto[1], E. De Fanti[2], E. Visentin[1], C. Marchi[1], R. Schiavon[2], G. Rigatelli[1], R. De Caterina[3]. *[1]Legnago General Hospital, Cardiovascular Department, Legnago, Italy; [2]Legnago General Hospital, Laboratory Medicine, Legnago (VR), Italy; [3]The Chieti University, Cardiology, Chieti, Italy*

Background: Soluble vascular cell adhesion molecule (sVCAM-1) and intercellular adhesion molecule (sICAM-1) are likely to reflect surface levels of molecules mediating adhesion and transmigration of leukocytes to the vascular endothelial wall and promoting plaque growth and instability.
Aim: To assess whether sVCAM-1 and sICAM-1 are increased in patients (pts) with coronary artery disease and whether they are differently regulated in acute versus chronic coronary syndromes.
Methods: We obtained plasma samples from 76 pts. 27 pts had acute coronary syndromes (ACS; 14 unstable angina, Braunwald IIIb, 3 nonSTEMI and 10 STEMI). Diagnosis of myocardial infarction was based on clinical data, modifications of the ECG and of the markers of myocardial damage (troponin, myoglobin). 37 pts had chronic coronary syndromes (CCS); in 12 of them, with positive exercise stress test, plasma samples were also collected before and after an exercise stress test (ST pre and ST post). 12 were control non-coronary patients. Quantitative determination of sVCAM-1 and sICAM-1 was performed by ELISA. C-reactive protein (CRP) and von Willebrandt factor (vWF) were also assessed by immunonephelometric and immunoenzimatic methods, respectively.
Results: See table.

	No. pts	sVCAM-1 (ng/ml)	sICAM-1 (ng/ml)	VWF (U/dL)	CRP (mg/dL)
ACS	27	749 (563-831)(**) (°°)	311 (251-370)(**)	196 (152-228)(**)	1.02 (0.56-1.71)(*)(°)
CCS	37	389(360-500)	309(260-352)(**)	127(94-160)(*)	0.41(0.25-0.50)
ST pre	12	461 (354-555)	352(340-370)	139(87-150)	0.46(0.25-0.50)
ST post	12	523(427-681)	416(378-447) (¶¶)	145(90-154)	0.44(0.26-0.55)
Controls	12	415(381-452)	204(188-230)	98(85-112)	0.31(0.05-0.52)

For abbreviations see text. Values are expressed as median (interquartile range). (**): p<.01 vs controls. (*): p<.05 vs controls. (°°): p<.01 vs CCS. (°): p<.05 vs CCS. (¶¶): p<.01 vs ST pre.

Conclusions: 1)sICAM-1 was significantly increased both in ACS and in CCS compared to controls, as well as after stress induced ischemia. 2)sVCAM-1 was significantly increased in ACS compared to CCS and controls; no significant difference was observed between CCS and controls. While sICAM-1 may be considered a marker of chronic coronary disease, sVCAM-1 appears more related to disease instability.

P2369 Association between multiple cardiovascular risk factors and endothelium dysfunction with myocardial infarction before 40 years of age

D. Assanelli[1], A. Bonanome[2], M. Grassi[3], L. Brentana[4], N. Mollichelli[5], N. Akkawi[6], F. Visioli[7], P. Monari[4]. *[1]cardiologia, brescia, Italy; [2]University of Studies, Internal Medicine, Padova, Italy; [3]University of Pavia, Statistics, Pavia, Italy; [4]University of Brescia, Cardiology, brescia, Italy; [5]University of Padova, Internal Medicine, Padova, Italy; [6]University of Brescia, Neurology, Brescia, Italy; [7]University of Milan, Pharmacology Institute, Milan, Italy*

Cardiovascular disease (CD) is a multifactorial disorder. Between 2 –6% of myocardial infarctions occur in subjects younger than 40. Althought traditional risk factors, such as hypertension, dyslipidemia, overweight, are significantly associated with CD, a significant number of coronary events remain of unknown ethiology. There is evidence that the younger the age of occurrence the greater the impact that genetic factors play on CD incidence. CD in youth is related to monovasal or to widespread atherosclerotic lesions, none of which of significant severity in its own right. Also, impairment of endothelial function is thought to trigger acute coronary events. We performed a case-control study for a through assessment of the risk profile in young coronary patients and we aimed at correlating it with changes in their endothelium-dependent vasodilatation and with the presence of atherosclerotic lesions, both in coronary and in carotid arteries.
Methods: 48 subjects with previous myocardial infarction and younger than 41 years of age, from the same geographical area. Patients were matched 1:1 with random sample controls, according to age and sex. We evaluated serum concentrations of total, HDL, and LDL cholesterol, triglycerides, fibrinogen, homocysteine, folic acid, vitamin B12, vitamin E, antioxidant capacity, uric acid, and Helicobacter pylori, and we searched for C667T and T1298C genetic mutations for MTHFR and CBS genes. Post-ischemic vasodilatation of the brachial artery was studied as index of endothelial function and all patient underwent an echo-color-doppler study of common and internal carotid arteries for the measurement of intima-media thickness (IMT).
Results and Discussion: Education, BMI, smoking habits, familiarity, apoE4 genotype, MTHFR genotype, dyslipidemia, HDL, sistolic and diastolic pressure, fibrinogen, vitamin E level, antioxidant capacity, vasodilatation (evaluated both as actual dilation and percent increase over controls), and IMT were significantly different between cases and controls. Through a statistical multivariate comparison among block variables, we noted that smoking, apoE genotype, dyslipidemia, plasma fibrinogen and vitamin E concentrations, and IMT are important predictors, exhibiting an accuracy of 91%. Such premature occurrence of acute coronary event warrants the screening of siblings for the assessment of their risk profile.

P2370 Modulation of endothelial function as assessed by magnetic resonance imaging of the forearm

M.G. Friedrich[1], W. Utz[1], T. Niendorf[2], J. Schulz-Menger[1], R. Dietz[1]. *[1]Franz-Volhard-Klinik, Cardiology, Charite Campus Buch, Berlin, Germany; [2]GE Medical Systems, Leipzig, Germany*

Background Endothelial function plays a key role in atherosclerotic disease. None of the currently available techniques, however, is able to visualize changes on a capillary level. T2*-weighted magnetic resonance imaging (MRI) detects changes of tissue perfusion by exploiting the BOLD (Blood-Oxygen-Level Dependent) effect. We assessed the sensitivity of BOLD-sensitive MRI in the detection of endothelium-dependent perfusion changes.
Subjects and Methods
In six healthy male volunteers (age 29±3y.) we applied a T2*-sensitive echo planar imaging (EPI) sequence (TE 17,4ms). Image data (between 3000 and 3500 images/protocol) were obtained using a pulse-trigger (TR = RR). The signal intensity changes in the forearm were assessed before, during, and after intraarterial administration of acetylcholine (Ach, 16 and 64 μg/min.) with or without previous application of L-NMMA (5mg/min.). Furthermore, Sodium-Nitroprusside was administered with a stepwise increase of the dosage from 2 to 6μg/min for 5min each. For signal intensity analysis, the contralateral arm was included as an internal reference.
Results The basal signal scatter was less than 0.2%. During acetylcholine there was a significant transient signal intensity increase at both dosages ($p<0.05$ and $p<0.01$, respectively) in the muscular tissue. In contrast, the administration of L-NMMA was associated with a significant decrease of the signal intensity ($p<0.001$). The signal increase during the ACh dose of 16μg/min. was completely blocked by previous administration of L-NMMA, whereas this effect was only partially present when applying 64μg/min. of ACh.
Application of Sodium-Nitroprusside resulted in a similar, dose-dependent, but more plateau-like vasodilatory response.
We also observed systemic variations of the signal intensity, which involved the contralateral arm, were independent of the time of pharmacological interventions in 3 of six subjects, and more pronounced related to an uncomfortable body position.
Conclusion We conclude that BOLD-MRI is well suitable for the noninvasive assessment of vasodilatory endothelial function. The advantages over established techniques may be important for future research.

P2371 Regional findings of endothelial function in the forearm as assessed by high-field BOLD-MRI

W. Utz[1], J. HubaÁek[2], N. Filipchuk[3], R. Frayne[4], H. Banijamali[3], T. Anderson[2], M.G. Friedrich[1]. *[1]Franz-Volhard-Klinik, Cardiology, Charite Campus Buch, Berlin, Germany; [2]Foothills Hosp., University of Calgary, Cardiology, Calgary, Canada; [3]Foothills Hosp., University of Calgary, Nuclear Medicine, Calgary, Canada; [4]Seaman Family MR center, Univ. of Calg, MR Physics, Calgary, Canada*

Background Vascular endothelial dysfunction is a hallmark of atherosclerosis and its risk factors. BOLD-MRI is known to reflect changes of tissue perfusion due to the relation of the signal intensity to the ratio of oxy-hemoglobin to deoxy-hemoglobine. Since this phenomenon, the BOLD effect, is positively correlated to the magnetic field strength, measurements at high field strength seem to be advantageous. We addressed the question whether BOLD-MRI in a high-field system provides accurate and reproducible data on alterations of endothelial function.

Subjects and Methods

17 volunteers (34±4 years) were studied using a 3 T MRI system (Signa, GE Medical Systems, Milwaukee, USA). The subjects were placed in a supine position with one of the forearms lifted and put into the head coil. A two-shot gradient-echo/EPI sequence was applied (TE 20ms, effective TR 2000ms, slice thickness 10mm, field of view 160x160mm, matrix 256x256) to generate T2*-sensitive images. The signal was continuously obtained before, during and after the following interventions on tissue perfusion:

Ischemia was induced by inflation of a blood pressure cuff to at least 50mmHg above systolic blood pressure for 3 minutes with a rapid release. RH measurements were repeated twice.

ACh (30μg/min.) was continuously applied for 3 minutes into the brachial artery. In the BOLD-MRI images, the signal difference between baseline and maximum was calculated. In a subset of volunteers we assessed regional signal intensity changes in different groups of the skeletal muscle.

Results Image quality was good to excellent in all cases. RH experiments revealed a marked SI decrease (see fig. 1, middle panel) with a trend towards reaching a plateau during the last portion of the ischemic period and a steep SI increase with a significant overshoot (3.8±0.2%SE). ACh infusion led to a plateau-like SI increase, when the analysis was performed for the entire cross-sectional view. The evaluation of single muscle groups, however, showed different curve shapes with different patterns, even within the same subject in repeat studies.

Conclusion BOLD-MRI at 3 T detects pharmacological interventions on endothelial function. The finding of a regionally different, inhomogeneous regulation of skeletal muscular perfusion is surprising and requires a more detailed investigation.

P2372 TIMI frame count index successfully identifies the patients with endothelial dysfunction

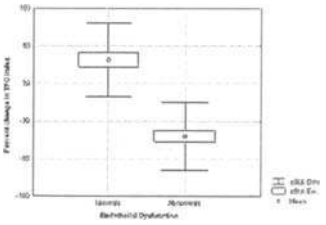
C. Barcin, A.E. Denktas, K.N. Garratt, S.T. Higano, D.R. Holmes, A. Lerman. *Mayo Clinic, Division of Cardiology, Rochester, United States of America*

Background: Endothelial dysfunction impairs microvascular blood flow and correlates with an increased risk of vascular events. We sought to determine if a new TIMI frame count index(TFCI) could identify the patients with endothelium-dependent coronary endothelial dysfunction.

Methods: 57 consecutive patients (18 males) without obstructive coronary artery disease underwent coronary physiologic study in the Mayo Clinic were involved in the study. Coronary flow parameters were assessed using coronary angiography and a Doppler guidewire at baseline and after 0.182, 1.82 and 18.2 microgram/mL concentrations of acetylcholine (Ach) infusion. An increase in coronary blood flow >50% above baseline after 18.2 microgram/mL Ach infusion was considered to represent normal coronary endothelium dependent function. In each patient a distal landmark was defined and TFC (number of frames required for the contrast to travel from the ostium to the distal landmark) at baseline and after 18.2 microgram/mL of Ach were assessed. TFCI was defined as the vessel area divided by TFC. Percent change in the TFCI from baseline was then calculated.

Results: The mean change in TFCI was -36.1±35.7% in patients with endothelial dysfunction (n=32) and 44.6±39.3% in patients with normal endothelial function (n=25)(p<0.0001)(Figure 1). ROC curve analysis showed that a cut off value of less than 0.5% decrease in TFCI would have a specificity of 88% and a sensitivity of 87% in determining coronary endothelial dysfunction. A significant correlation was observed between the percent change in TFCI and the percent change in coronary blood flow (r=0.88, p< 0.0001).

Conclusion: Changes in TFCI in response to Ach may be used as a simple and inexpensive method for detecting coronary endothelial dysfunction.



BIOMARKERS IN ISCHAEMIA/INFARCTION

P2373 Pregnancy associated plasma protein-A levels are elevated in patients with unstable angina

A.E. Denktas[1], P.J.M. Best[1], J.E. Woodrum[1], M.T. Overgaard[2], C. Oxvig[2], D.R. Holmes[1], C.A. Conover[3], A. Lerman[1]. *[1]Mayo Clinic, Division of Cardiology, Rochester MN, United States of America; [2]University of Aarhus, Dept. of Molecular and Structural Biol, Aarhus, Denmark; [3]Mayo Clinic, Endocrine Research Unit, Rochester, MN, United States of America*

Background: Pregnancy-associated plasma protein A (PAPP-A), recently identified as an insulin like growth factor (IGF) binding protein proteinase, is a high molecular weight zinc binding metalloproteinase secreted by vascular smooth muscle cells. Increased PAPP-A activity leads to enhanced IGF bioactivity and may contribute to the progression of atherosclerosis. Thus, the current study was designed to test the hypothesis that circulating PAPP-A levels are elevated in patients (pts) with unstable angina (UA).

Methods: Blood samples were taken from 335 pts undergoing cardiac catheterization at the Mayo Clinic. PAPP-A levels were analyzed using a biotin-tyramide-amplified enzyme immunoassay. UA was defined as the new onset of anginal symptoms (<6 weeks), rest pain, or post infarction angina (within 3 weeks of infarction). Control pts were those who had coronary disease and did not meet the requirements for UA or were undergoing routine cardiac catheterization for preoperative cardiac surgery such as valve repair/replacement. Thirty-two pts with UA were identified and the circulating levels of PAPP-A were compared to the remaining pts. Clinical characteristics were identified through patient interview and chart review. Coronary angiograms were reviewed for the extent of the disease, which was defined as the number of major vessels with >70% stenosis.

Results: The study group consisted of 335 pts, 224 (67%) were males, mean age 64±11. There were no differences in the age, gender, presence of diabetes, hypertension, family history, cholesterol levels, smoking history of the pts with or without UA. The PAPP-A levels in the UA pts were significantly higher than in the pts without UA (7.1 ± 4.0 vs. 5.5 ± 3.4 mIU/L, p= 0.01, two sided p=0.036). PAPP-A levels were associated with older age (p<0.001), male gender (p=0.005) and lower levels of high-density lipoprotein (p=0.002). PAPP-A levels were not associated with the extent of the coronary artery disease.

	UA (N=32)	Control (N=303)	p value
PAPP-A level (mIU/L)	7.1 ± 4.0	5.5 ± 3.4	0.036

PAPP-A levels in unstable angina (UA) and control groups.

Conclusion: Patients with unstable angina have higher levels of circulating PAPP-A than patients without unstable angina. PAPP-A may be marker for plaque instability.

P2374 Is C-reactive protein level a useful marker of severity and infarct size in patients with acute ST elevation myocardial infarction?

M. Suleiman[1], Y. Levy[2], D. Aronson[1], A. Roguin[1], H. Halabi[1], M. Kapeliovich[3], H. Hammerman[3]. [1]*Rambam Medical Center, Cardiology, Haifa, Israel;* [2]*Rambam Medical Center, Internal Medicine D, Haifa, Israel;* [3]*Rambam Medical Center, Intensive Coronary Care Unit, Haifa, Israel*

Background: Elevated C-reactive protein (CRP), a marker of chronic inflammation and an acute phase reactant, has been shown to correlate with higher risk for coronary events in patients with unstable angina. Our aim was to assess the value of CRP levels as a marker of infarct severity in the setting of acute ST-segment elevation myocardial infarction (STEMI).
Methods: Ninty-nine consecutive patients (mean age 62 ± 13, 68% men) with first acute STEMI were prospectively enrolled in the study. CRP levels were measured within 24 hours of symptoms onset by a highly-sensitive assay. Infarct size was assessed by peak creatine kinase (CK) levels and two-dimensional echocardiographic examination performed on day 2 or 3. The patients were divided into 2 groups according to their CRP levels.
Results: Patients with elevated CRP levels (>3.4 mg/dL) had more anterior infarcts, larger infarct size, worse left ventricular systolic function, higher wall motion score index, and worse Killip classification. In addition, in-hospital mortality was significantly higher in patients with elevated CRP levels (table).

Variable	CRP<3.4 mg/dL (n=72)	CRP>3.4 mg/dL (n=27)	P value
Age, y (mean±SD)	59 ± 12	69 ± 11	0.05
Men (%)	53 (73)	17 (63)	NS
Anterior MI (%)	29 (40)	17 (63)	<0.001
Killip 3-4 (%)	3 (4)	12 (44)	<0.001
Reperfusion therapy (%)	50 (70)	18 (66)	NS
Peak CK (U/l)	1792± 214	3152 ± 491	0.004
LV systolic function			
Moderately reduced (%)	9 (12)	10 (37)	0.005
Severely reduced (%)	3 (4)	6 (22)	0.005
WMS index	1.51± 0.3	1.78 ± 0.3	<0.001
In-hospital mortality (%)	1 (1)	5 (19)	0.002

MI=myocardial infarction, CK=creatine kinase, WMS= wall motion score

Conclusion: In patients with STEMI, CRP levels on admission correlate with infarct size, reduction in left ventricular systolic function, the development of clinical heart failure, and with increased in-hospital mortality.

P2375 B-type and atrial natriuretic peptide in acute myocardial infarction – impact of left ventricular function and systemic inflammatory response

R. Witthaut, D. Stoevesandt, R. Prondzinsky, I. Stabenow, K. Werdan. *Klinikum Kroellwitz, Med.Klinik III, Halle, Germany*

Background: Elevated plasma levels of interleukin-6 (IL-6), B-type (BNP) and atrial natriuretic peptide (ANP) are associated with an increased risk for recurrent non-fatal myocardial infarction or fatal cardiovascular event in patients with acute myocardial infarction (MI). Volume expansion or pressure overload have been postulated to be responsible for BNP and ANP secretion in MI. Also members of the interleukin-6 family are able to induce ANP expression and secretion. The purpose of this study was to assess whether the natriuretic peptide system in MI is activated in response to impaired left ventricular (LV) systolic function and systemic inflammation in MI.
Methods: In a prospective study, 45 consecutive patients presenting with MI (age 58±3 years, mean±SD) undergoing emergency angioplasty (PTCA) and 20 patients who underwent elective angioplasty (controls, age 57±4 years)were enrolled. The study design allows for a discrimination of procedural effects from MI sequelae. Plasma-BNP and -ANP was analysed for up to 7 days post MI. White blood cells (WBC)were counted. IL-6, C-reactive protein (CRP)and fibrinogen (FN) gave evidence of systemic inflammation. Creatine kinase (CK-MB) and troponin I (T) detected myocardial injury. Left ventricular systolic function (LVEF) were determined by levokardiography in standard projections (LAO 30°, RAO 60°) and left ventricular enddiastolic pressure (LVEDP) was measured.
Results: Compared to controls, BNP ($p<0.05$) and ANP ($p<0.01$) were increased in MI pre coronary intervention. BNP was negatively correlated to LVEF at any time point ($p<0.05$). ANP rose correlated to LVEDP ($p<0.05$) 4 h following PTCA ($p<0.01$) and went down to baseline by 24 hours. This increase of ANP was paralleled by a rise of IL-6. IL-6 was positively correlated with WBC ($p<0.05$), CK-MB ($p<0.05$) and T ($p<0.05$). While IL-6 went down to baseline by 48 hours, ANP rose again ($p<0.05$ vs baseline). This second peak of ANP showed a positive correlation to CRP and FN (both $p<0.01$), while there was no significant correlation between ANP and LVEDP or LVEF.
Conclusion: BNP levels measured in patients presenting with MI are related to the degree of impaired LV systolic function. The delayed increase of ANP independent of procedural effects suggest a modulation of this hormone by IL-6 in MI.

P2376 Infarct size-dependent elevation of matrix metalloproteinase 9 in the early phase of myocardial infarction

J.J. Kaden[1], I. Kugler[2], P. Gaudron[2], C. Liebetrau[1], C.E. Dempfle[1], M. Borggrefe[1]. [1]*University Hospital of Mannheim, 1st Department of Medicine, Mannheim, Germany;* [2]*Krankenhaus St. Georg, Department of Cardiology, Bad Pyrmont, Germany*

Background: Acute myocardial infarction (MI) leads to an early inflammatory response in the myocardium that enhances tissue repair. Recent animal studies have proposed that the matrix metalloproteinases MMP-2 and MMP-9, two enzymes capable of degrading damaged extracellular matrix, are involved in this process. The role of MMP-2 and MMP-9 during myocardial infarction in humans is not known.
Methods: In a prospective study, 20 patients (pts) with proven acute MI underwent coronary angiography and thrombolysis (n=7) or transluminal angioplasty (n=13) within 6 hours after onset of symptoms. Coronary angiography after 1 week showed successful reperfusion in all pts. MI size was determined as percentage of the akinetic/dyskinetic segment of the LV circumference by levocardiography (ADS) after 1 week. Patients were grouped as large MI (ADS>25%) and moderate MI (ADS<or=25%). The plasma concentrations of MMP-2, MMP-9, and the endogenous tissue inhibitor of metalloproteinases (TIMP)-1 were determined by enzyme immunoassay on admission and after 24 hours, 48 hours, 1 week, 4 weeks, 3 months, and 6 months.
Results: MI size groups were equal in age, gender, MI localisation, and reperfusion method. MMP-2 levels remained unchanged over time in both groups. On admission, the concentration of MMP-9 was elevated significantly in large MI compared to moderate MI (195±190 ng/ml vs 78±63 ng/ml, mean±standard deviation, $P<0.01$, t-test), and returned to baseline (large MI: 18±16 ng/ml, moderate MI: 16±17 ng/ml) by 1 week after MI ($P<0.05$, ANOVA). The plasma concentrations of TIMP-1 were elevated in large MI, and remained unchanged over time. The MMP-9/TIMP-1 ratio was significantly increased on admission in both size groups (large MI: 0,24±0,24, moderate MI: 0,17±0,16) and returned to baseline (large MI: 0,05±0,03, moderate MI: 0,06±0,06) by 48 hours ($P<0.05$ for both groups, ANOVA).
Conclusion: This study shows a transient elevation of MMP-9 plasma concentration during acute MI that is dependent on MI size and returns to baseline by 1 week. Also, the MMP-9/TIMP-1 ratio is elevated in acute MI suggesting an increased enzymatic activity of MMP-9. These data suggest a pathophysiologic role of MMP-9 during the early phase of acute MI.

P2377 Heat shock protein 60 homologues in unstable angina atheroma – correlation with markers of inflammation and apoptosis

R. Andrié[1], P. Braun[2], B. Lüderitz[1], G. Bauriedel[1]. [1]*University of Bonn, Med. Univ. Klinik und Poliklinik II, Bonn, Germany;* [2]*Heart Center, Duisburg, Germany*

Background: Recent studies provide evidence that infection, inflammation, immunological reactions and apoptotic events play an important role in the acuity/progression of atherosclerosis. In this respect, a chronic persistent Chlamydia pneumoniae infection, indicated by the presence of chlamydial heat shock protein 60 (cHSP 60), endogeneous human (h) HSP 60, that serves as a target for autoimmune reactions, C-reactive protein (CRP), a systemic inflammatory marker with predictive significance, and caspase 3, a cell death effector, are focused.
Methods: Coronary atherectomy specimens retrieved from 30 primary target lesions of patients with unstable angina (UA; n=15) or stable angina (SA; n=15) were assessed immunohistochemically for the presence of cHSP 60, hHSP 60, CRP and caspase 3. These data were correlated with plaque morphology and assessed for prevalence in either UA or SA lesion group.
Results: Coronary plaques revealed immunoreactive cHSP 60 in 64%, hHSP 60 in 80%, CRP in 58% and caspase 3 in 89% of the lesions vs. none of 20 undiseased control samples. Intimal predilection sites were regions with macrophages/foam cell accumulation, inflammatory infiltrates and sparse cellularity. Mean expressions were 6.6% for cHSP 60, 6.5% for hHSP 60, 1.8% for CRP and 7.8% for caspase 3. As the central finding of the present study, the expression of all four proteins was significantly ($p<0.05$) higher in UA lesions compared to SA lesions (8.7% vs. 3.0%, 8.7% vs. 2.0%, 2.3% vs. 1.1%, 10.8% vs. 3.7%). Moreover, we found positive correlations between cHSP 60/hHSP 60 ($r=0.44$; $p<0.01$), cHSP 60/caspase 3 ($r=0.43$; $p<0.01$), hHSP 60/CRP ($r=0.45$; $p<0.01$), hHSP 60/caspase 3 ($r=0.69$; $p<0.01$) and CRP/caspase 3 ($r=0.46$; $p<0.01$). Interestingly, some correlations were observed only in the UA and not SA subgroup: cHSP/hHSP 60 ($r=0.35$; $p<0.05$), hHSP 60/CRP ($r=0.34$; $p<0.05$) and hHSP 60/caspase 3 ($r=0.64$; $p<0.01$).
Conclusions: cHSP 60, hHSP 60, CRP and caspase 3 are partially colocalized within coronary primary atheroma, the most in lesions associated with UA. Thus, our data suggest a role of all four proteins as intimal determinants implicated in human coronary plaque instability.

P2378 Diagnostic implications of elevated brain natriuretic peptide levels in patients with non-ST-segment elevation myocardial infarction

H. Kriatselis, S. Helbig, K. Göhl, T. Falke, M. Gottwik. *Klinikum Nürnberg Süd, Med. Klinik II8/Kardiologie, Nürnberg, Germany*

Background: Brain natriuretic peptide (BNP) reflects both ventricular stretch and neurohumoral activation and is a reliable biochemical marker in patients with heart failure, correlating strongly with haemodynamic parameters and clinical signs. The diagnostic and prognostic value of BNP in patients with non-ST elevation myocardial infarction (NSTEMI) is not known.
Methods: 98 patients (age 63 ±20 yrs, 38 females) with NSTEMI were included according to the following criteria: i. angina pectoris in the last 48 h, ii. ST-segment depression (>0.5mm) and/or negative T-waves in at least 3 leads on surface ECG, iii. positive troponin T (>0.1 ng/ml). BNP was measured with a point-of-care device at hospital admission. All patients underwent coronary angiography within 72 h and angioplasty was performed as indicated.
Results: A mean time of 8±6 hours elapsed between beginning of angina and BNP measurement. BNP levels ranged between 5-1256 pg/ml with a mean value of 127 ± 196 pg/ml. BNP levels correlated moderately with left ventricular ejection fraction (r= -0.36, p=0.01). In 58 patients BNP exceeded 80 pg/ml. 52 of these patients (89%) had at least one haemodynamic significant (>70%) stenosis of the left anterior descending artery (LAD) and/or right coronary artery (RCA) or 3 vessel coronary artery disease (CAD). Among 40 patients with BNP<80 pg/ml only 10 patients (25%) were found to have significant LAD/RCA stenosis or 3 vessel CAD. A strong association existed between BNP level and Killip-class (table).

Killip class	I	II	III	IV
BNP> 80 pg/ml	19	18	15	6
BNP< 80 pg/ml	33	7	0	0

BNP levels and Killip class

Conclusion: In patients with NSTEMI high levels of BNP (>80 pg/ml) associate strongly with haemodynamic significant stenosis of LAD/RCA or 3 vessel CAD and signs of left ventricular dysfunction.

P2379 Inflammatory markers correlate with coronary lesion morphology in patients with unstable angina

C. Heeschen[1], M.J. van den Brand[2], C.W. Hamm[3], E. Boersma[2], M.L. Simoons[2] on behalf of the CAPTURE study. [1]*Molecular Cardiology, Frankfurt, Germany;* [2]*Erasmus University, Thoraxcenter, Rotterdam, Netherlands;* [3]*Kerckhoff Heart Clinic, Div. of Cardiology, Bad Nauheim, Germany*

Increasing evidence suggests that atherosclerosis is an inflammatory disease and that elevated inflammatory markers predict the risk for cardiovascular events. We sought to assess the relation between inflammatory markers and angiographic features of target coronary lesions in patients with unstable angina enrolled in the CAPTURE trial (n=853). Angiograms were evaluated by a blinded Angiographic Committee.
Results: At baseline, neopterin levels > 10 nmol/L were found in 47.3% and CRP levels > 15 mg/L were found in 41.4% of the patients. There was no correlation between neopterin and CRP concentrations (r=0.12; P=0.21). Both neopterin and CRP did not predict the presence of thrombus formation and TIMI flow at baseline. However, we observed a significant correlation between complex lesion characteristics and inflammatory marker concentrations (neopterin: r=0.85; P<0.0001; CRP: r=0.64; P<0.001). Multivariate analysis including troponin T measurements demonstrated that only neopterin was independently associated with complex lesion characteristics (P<0.001), PCI-related complications (P=0.003), and patients' short-term prognosis (death or MI at 30-day follow-up; P=0.002). At discharge, neopterin was elevated in 52.5% with a significant difference between the abciximab and the placebo group (40.3% vs. 64.7%; P<0.001). Patients with discharge neopterin concentrations < 10.0 nmol/L had a more favorable prognosis (adjusted hazard ratio 0.73 [95%CI 0.58-0.95] whereas discharge CRP levels < 15 mg/L did not predict a better outcome (adjusted hazard ratio 0.98 [95%CI 0.58-1.50].
Conclusions: Serum concentrations of neopterin and CRP, respectively, were associated with the presence of complex target lesion characteristics in patients with unstable angina. Neopterin, a marker for macrophage activity, was the more powerful predictor of patients' short-term risk and neopterin levels were reduced by abciximab treatment. Our findings suggest that neopterin may be regarded as a novel marker of plaque instabiliy.

P2380 Strong and independent association between serum interleukin 1 receptor antagonist and future cardiovascular events

E. Lubos[1], H.J. Rupprecht[1], S. Blankenberg[1], C. Bickel[1], L. Tiret[2], J. Meyer[1] on behalf of AtheroGene Group. [1]*Johannes Gutenberg-Universität, Department of Medicine II, Mainz, Germany;* [2]*Institute for Cardiovascular Genetics, INSERM U525, Paris, France*

Background: Inflammatory mechanisms play a crucial role in the development and progression of atherosclerosis and plaque vulnerability. C-recactive protein (hs-CRP) is being discussed as a marker of future cardiac events. Interleukin (IL)-1 as a central cytokine is responsible for activiation of a variety of proatherogenic features andacute phase responses. We evaluated the impact of IL-1 receptor antagonist (ra) on future cardiovascular events in patients (pts) with coronary artery disease (CAD).
Methods: In 1339 pts with documented CAD inflammatory markers such as hs-CRP [mg/l], fibrinogen [mg/dl], and IL-1ra [pg/ml] were determined. 1336 pts (99.9%) had a follow up (f/u) after 4.1 (maximum 5.2) years.
Results: During the f/u 103 pts died because fo cardiac reasons, 51 pts suffered from non-fatal myocardial infarction (MI). Univariate predictors (p<0.05) for the combined endpoint were age, diabetes, HDL-cholesterol, statin treatment, interventional strategy, ejection fraction as well as serum level of hs-CRP and fibrinogen. The relative risk (RR) for increasing IL-1ra per quartile was 1.3 (95%CI 1.1-1.6) in a fully adjusted model (for adjustment see Table). hs-CRP and fibrinogen lost their predictive impact after inclusion of IL-1ra in the multivariate model.

Risk Ratios Acording to IL-1ra

	Q1	Q2	Q3	Q4
range [pg/ml]	<167.9	167.9 - 300.1	>300.1 - 505.2	>505.2
% cv event	5.4	11.0	12.7	17.1
Relative Risk	1	2.4	2.4	2.7
95% CI	–	1.7 - 4.7	1.2 - 4.6	1.4 - 5.2
P value	–	0.008	0.01	0.004

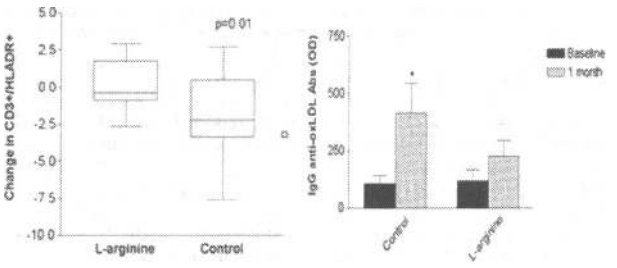
Adjusted for age, sex, bmi, classical risk factors, clinical (acute coronary syncrome, history of MI, extent of vessel disease, ejection fraction) and therapeutical (statin, betablocker, and interventional therapy) features.

Conclusion: IL-1ra is a strong and independent predictor of future cv events in documented CAD. Most interestingly, in this large prospective cohort of CAD pts IL-1ra appears superior to hs-CRP and fibrinogen.

P2381 L-arginine attenuates lymphocyte activation and anti-oxidized LDL antibody levels in unstable angina

H.I. Miller, J. George, S. BenShmuel, I. Hertz, L. Heifets, S. Israelov, V. Deutch, G. Keren. *Tel-Aviv Medical Center, Tel-Aviv, Israel*

Background: Pts with acute coronary syndromes (ACS) exhibit evidence of peripheral T lymphocyte activation, elevated acute phase proteins and enhanced oxidative stress. L-arginine (Arg), a NO donor, ameliorates experimental atherosclerosis and restenosis as well as endothelial dysfunction. We studied the effect of Arg on lymphocyte activation and anti-oxLDL antibodies in pts with unstable angina (UA) undergoing PCI with stent placement.
Methods: Pts with UA were randomized to treatment with Arg (10 gm/daily; n=13) or none (n=16) for 1 month starting on day of stent deployment. Lymphocyte activation was assayed by FACS employing double staining with a common lymphocyte marker (CD3) and an activation marker HLA-DR, on the day of the procedure and 1 mth later. Anti-oxLDL antibodies were assayed by ELISA.
Results: Patients with unstable angina not receiving L-arginine exhibited a 43% rise in the percentage of activated peripheral T lymphocytes 1 month after stent deployment. Patients treated with Arg exhibited a fall in the fraction of peripheral lymphocytes bearing the activation marker. Antibodies to oxLDL rose significantly between baseline and 1 month follow up. Arg treatment significantly attenuated the rise in anti-oxLDL antibody levels.



Conclusion: Arg attenuates the systemic rise in peripheral lymphocyte activation and oxidative stress markers induced by vessel wall injury following PCI. These effects may contribute to a favorable effect of the drug in pts with ACS undergoing PCI.

P2382 Clinical significance of matrix metalloproteinases activity in acute myocardial infarction patients

D. Papadopoulos[1], K.I Kapetanios[2], E.V Economoy[2], P.K Toutouzas[2].
[1]Laiko, Cardiology, Athens, Greece; [2]University of Athens, Cardiology Athens Medical School, Grecce, Greece

Matrix Metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) are key enzymes in myocardial fibrillar collagen degradation. We investigate the effect of increased MMP-1 and their TIMP-1 activation on the left ventricular (LV) remodeling in-patients (pts) with acute myocardial infarction (AMI).
Methods: We measured MMP-1 and TIMP-1 plasma levels in 24 pts (mean age 58,46±13,9yrs) with first attack of AMI and classified in two groups. Pts with a third Heart Sound (S3) Ejection Fraction (EF)<45% and End Diastolic Diameter (EDD) of LV.>47,5mm were included in group A. In group B were pts without S3 with EF>45%and EDD<47,5mm. Plasma blood samples were collected at the time of admission in the hospital (0h) as well as, 3h, 6h, 9h, 12h, 18h, 24h, 36h, 48h, 3days, 4d, 5d, 7d, 15d,30d, thereafter and measured by relevant ELISA kits. All patients did not have previous history of any other disease. For statistical analysis ANOVA rp.m.a and unpaired t-test was used. Data are expressed as mean values SEM in ng/ml. $p<0,05$ was considered statistically significant.
Results a) The mean blood values of MMP-1 were found higher in-group (A) average by 30% for total time points compared to mean blood values of MMP-1 in-group (B). Additionally on several time points mean blood values difference of MMP-1 between the two groups were statistically significant $0,005<p<0,008$ b). The mean blood values of TIMP-1 in-group (A) were higher in average by 10% for total time points compared to mean values of group (B).
Conclusions: Thus the degree of collagenolysis in pts with AMI expressed by higher MMP-1 and lower TIMP-1 may be related to the infarct expansion and to late process of post-MI remodeling.

P2383 Circulating matrix metalloproteinase 2 and tissue inhibitor of metalloproteinases 1 after severe and minor acute myocardial infarction

E.V. Economou, C.P. Pitsavos, A. Masourou, A. Zervoudaki, M.G. Toutouza, K.I. Kapetanios, C.I. Stefanadis, P.K. Toutouzas. University of Athens, Hippokration Hospital, Dept. of Cardiology, Athens, Greece

Background: Acute myocardial infarction (AMI) induces upregulation of vascular remodeling mechanisms subserving angiogenesis. Matrix metalloproteinase 2 (MMP-2) which promotes angiogenesis by new basement membrane deposition, as well as tissue inhibitor of metalloproteinases 1 (TIMP-1) which inhibits angiogenesis by inhibiting matrix formation, both regulate angiogenesis. Aim of this study was to compare the time-dependent alterations of both MMP-2 and TIMP-1 in a thirty day assessment following severe and minor AMI.
Methods: In 29 patients (pts) with first attack of AMI, no evidence of any other disease, divided in 2 age- and sex-matched groups, group A: pts with severe AMI, large infarct size, ejection fraction <45% and subsequent heart failure and group B: pts with minor AMI, ejection fraction >45% and normal LV function, plasma levels of MMP-2 and TIMP-1 were determined on hospital admission [mean latency from the onset of chest pain: 2±1 hours (h)] before thrombolysis (0h) and subsequently 3h, 6h, 9h, 12h, 18h, 24h, 36h, 48h, 72h, 4 days (d), 5d, 7d, 15d and 30d and compared to respective values of 20 age- and sex-matched healthy controls (HS).
Results: In group A, at 0h, MMP-2 and TIMP-1 levels were lower than those of HS (MMP-2: 603±43 vs 885±40 ng/mL, p=0.02 and TIMP-1: 582±74 vs 710±24 ng/mL, $p<0.04$). MMP-2 levels negatively peaked twice, at 24h (511±41 ng/mL) and on 5d (524±45 ng/mL) (in both cases $p<0.05$ compared to the respective values at 0h). TIMP-1 levels increased sharply at 6h (780±40 ng/mL), peaked at 36h (763±46 ng/mL) (in both cases $p<0.001$ in comparison to the respective levels at 0h) and declined to normal values, reaching them on 5d (672±37 ng/mL). In group B, at 0h, MMP-2 and TIMP-1 levels were also lower than those of HS (790±68 vs 885±40 ng/mL, $p<0.02$ and TIMP-1: 471±89 vs 710±24 ng/mL, $p<0.01$). MMP-2 levels negatively peaked twice, at 6h (489±29 ng/mL) and on 5d (464±63 ng/mL) (in both cases $p<0.05$ compared to the respective values at 0h). TIMP-1 levels gradually increased, peaked on 5d (928±26 ng/mL) ($p<0.02$ in comparison to the respective levels at 0h) and sharply declined thereafter to normal values, reaching them on 15d (719±60 ng/mL)
Conclusions: Later alterations in MMP-2 levels and earlier elevation in TIMP-1 levels, observed in severe AMI, compared to those observed in minor AMI, may reflect delayed extracellular matrix-associated angiogenesis. Since this process is vital to initiate wound healing and could limit tissue damage, such a delayed angiogenesis may reduce myocardial salvage in the border zone after a severe AMI.

P2384 The clinical significance of circulating levels of granulocyte/macrophage-colony stimulating factor in acute myocardial infarction patients

K.I Kapetanios, C.E Pitsavos, S. Kastelanos, G.P. Vyssoulis, D.B. Panagiotakos, M.G. Toutouza, C.I. Stefanadis, P.K. Toutouzas. Univ. of Athens Medical School, Cardiology Dept., Athens, Greece

Despite recent advances in our understanding of ischemia-induced angiogenic process, the occurrence of vasculogenesis, i.e. the in situ formation of blood vessels from circulating endothelial progenitor cells or hemangioblasts, due to ischemia, remains an unsettled issue. Therefore, we investigated the role of granulocyte/macrophage- colony stimulating factor (GM-CSF), a hemopoietic agent with vasculogenic properties, in acute myocardial infarction (AMI) patients.
Methods: 29 pts with first attack of AMI admitted and thrombolysed during the acute phase,and no previous history of any other disease, were examined for plasma levels of GM-CSF, measured by ELISA, and compared to corresponding levels of 20 normal controls (NC) with mean values:3,1 ± 0,28 pg/ml. All pts were divided in 2 sex and age-matched groups. Group A: 15 pts with minor AMI, EF>45% and no subsequent LV dysfunction. Group B: 14 pts with large infarct size, EF<45% and residual heart failure.Plasma samples were collected at the time of hospital admission (0 hours) and 3h, 6h, 9h, 12h, 18h, 24h, 36h, 48h, 3 days, 4d, 5d, 7d, 15d and 30d thereafter.
Results: Data is expressed as mean values±SEM in pg/ml. For the statistical analysis the Wilcoxon test was used with a statistical significance of $p<0,05$ compared to corresponding values of: a) NC(*), b) the relevant lowest plasma value at 24h(°). Group A exhibited a slight non significant GM-CSF increase (3,92±0,83) on admission, followed by a gradual decrease reaching the lowest plasma value at 24h (2,87±0,42) which is reversed leading to a late significant peak at 5 days (10,72±1,93*°). In contrast, group B developed a significant initial peak (8,56±1,44*°) succeeded by a gradual decrease reaching a nadir at 24h (2,98±0,32) followed by a slight non significant peak at 7 days (4,08±1,25).
Conclusions: Both groups developed high initial GM-CSF levels but only in group B this increase was significant compared to NC and the lowest plasma value at 24h. This early increase in group B may account for macrophage recruitment leading to macrophage- induced LV dysfunction in the early post- AMI period and is later reversed in both groups. A late GM-CSF rebound at 5d is significant only in group A probably implying that vasculogenesis is enhanced, thus preserving LV function and exerting a cardioprotective potential in these pts, while it remains practically absent in those pts with extensive AMI, thus resulting in LV decompensation. This study provides an important proof of concept for the key role of GM-CSF in the short-term LV remodeling following AMI.

P2385 Validation of a novel blood test for ischaemia during percutaneous coronary intervention

I.F. Purcell[1], A. Gomma[1], K. Bainbridge[2], D. Gaze[2], K. Fox[1], P. Collinson[2].
[1]Royal Brompton Hospital, Department of Cardiology, London, United Kingdom; [2]St George's Hospital, Clinical Chemistry, London, United Kingdom

Introduction: N terminal modification of albumin has been proposed as a biochemical test for the detection of ischaemia which can be used in combination with myocyte necrosis markers such as troponins. Validation of this test is difficult as there is no gold standard for ischaemia and animal models are of limited value.
Objective: We have examined dynamic changes in N terminal albumin, assessed by the ischaemia modified albumin (IMA) test in patients with induced ischaemia during percutaneous coronary intervention (PCI).
Methods: 60 patients with stable angina undergoing PCI with elective stenting (48 male, age range 38-76, median 57 years) and 28 controls with stable angina undergoing diagnostic coronary angiography (21 male, age range 38-81, median 58 years) were studied. Blood samples were taken pre-procedure, immediately post procedure, at 6 hours post procedure and 24 hours post procedure. Serum was separated and stored frozen at -80°C prior to analysis. Samples were defrosted and analysed for N terminal albumin content by cobalt binding (IMA test, Ischaemia Technologies) and for cardiac troponin I (cTnI) by a reformulated sensitive technique (ACCESS Accu cTnI, Beckman-Coulter). Baseline values were compared with post procedure, 6 hour and 24 hour values (Wilcoxon).
Results: There was no difference in IMA value at baseline between the PCI group and control (angiography only) group. In the immediate post procedure samples, values were slightly elevated in the control group (P=0.04) but markedly elevated in the PCI group (P=0.0002)compared with baseline. At 6 hours, the elevation remained significant in the PCI group (P=0.004). IMA values returned to baseline 24 hours following PCI. This pattern was observed even in patients without any evidence of peri-procedural myocyte necrosis indicated by undetectable cTnI at 24 hours. PCI to the left anterior descending artery (LAD) produced a significantly larger immediate rise in IMA than circumflex or right coronary artery PCI (P=0.01). This result may reflect the greater myocardial mass subtended by the LAD.
Conclusion: Myocardial ischaemia induced by PCI can be detected by the IMA test.

P2386 Implementation of diagnoses and outcome by chest pain unit management in the emergency department of Florence

A. Conti[1], B. Paladini[2], M. Zanobetti[2], L. Di Felice[3], S. Grifoni[3], G. Bini[3], C. Francois[3], G. Berni[3]. [1]Chest Pain Unit, Emergency Department, Florence, Italy; [2]Careggi Hospital, Chest Pain Unit, Florence, Italy; [3]Careggi Hospital, Emergency Department, Florence, Italy

Background: Chest Pain Unit (CPU)-management is a valuable tool for recognizing patients (pts) with chest pain (CP) at "high-intermediate-risk" from those at "low-risk" of cardiac events (CE). However, in welfare health systems, the feasibility and potential benefits of such management in the Emergency Department (ED) require further investigation. Methods and Results. A total of 13,762 consecutive pts with CP were screened during 1998-2000. "High-intermediate-risk" pts (n=9,335) were triaged as follows: 2,420 pts with acute myocardial infarction (25,9%; 10.6% in-hospital mortality), 3,764 pts with unstable angina (40,3%; 1.1% mortality), 129 pts with aortic arch dissection (1.4%, 23,3% mortality), and 408 pts with pulmonary embolism (4,4%; 27,6% mortality); moreover 268 pts had pneumothorax (2,9%; 1,1% mortality); 90 pts had acute pericarditis (1.0%; no deaths); and 2,256 pts showed chronic coronary artery disease (CAD) associated to other conditions of clinical instability (24,2%; 5,2 mortality). "Low-risk" pts (n=4,427) were triaged as follows: 885 pts (20%) were recognized as having CAD (1.1% mortality) by observation and/or serial ECG or stress-tests in CPU; 2,672 pts (60%) were discharged <6 hours after a negative first-line evaluation, including ECG, troponins and echocardiogram (echo), (0.2% no fatal CAD at 6 month follow-up); 870 pts (20%) were discharged <24 hours after further negative investigation, including serial ECG, echo, myocardial scintigraphy, exercise tolerance test; none of these pts had fatal/non fatal CAD at follow-up. Among these low-risk pts in whom CAD was excluded, 52% were diagnosed as having anxiety or gastroesophageal disorders as follows: 27% had active gastroesophageal disorders (17% peptic ulcer and 10% esophageal reflux or spasm), and 25% had anxiety (9% panic). Conclusions. An effective screening program with an observation area (CPU) inside the ED was successfully implemented in a public health environment and contributed significantly to reduce admissions (80% early discharge from the CPU-ED), and in "low-risk" pts, to recognize CAD in 20% of pts avoiding inadvertent discharge. Moreover, in one half of "low-risk" pts CPU management allowed recognition of alternative causes of chest pain.

P2387 Early risk stratification in ST-segment elevation myocardial infarction with admission troponin T and ST-segment resolution

E. Björklund[1], B. Lindahl[2], T. Jernberg[2], P. Johansson[3], A.M. Svensson[3], M. Dellborg[3], P. Venge[4], L. Wallentin[2]. [1]Kardiologkliniken, Uppsala, Sweden; [2]Uppsala University Hospital, Dept. of Cardiology, Uppsala, Sweden; [3]Sahlgrenska University Hospital/Östra, Clinical Experimental Research Lab., Gothenburg, Sweden; [4]Uppsala University Hospital, Dept of Clinical Chemistry, Uppsala, Sweden

The prognostic value of admission troponin T (tnT) levels and the resolution of the ST-segment elevation in ST-elevation myocardial infarction (STEMI) is well established. However, the combination of these two early available markers for predicting risk has not been evaluated. The aim of this study was to evaluate the combination of admission tnT and ST-segment resolution (ST res.) for early risk stratification in STEMI patients treated with thrombolysis.

Methods: Plasma-tnT was determined on admission with the third gen. assay on an Elecsys in 881 patients with STEMI from the Assent 2 and Assent plus studies. ST-segment monitoring for analysis of ST res. was performed in 752 patients from the same studies. 516 patients had both admission tnT and ST-segment monitoring. All patients were followed for one month regarding mortality. We used a prospectively defined cut-off value of tnT of <0.1 μg/L or >=0.1 μg/L. For ST res., <50% or >=50% measured after 60 minutes was used as cut-off.

Combining these two markers a profound difference in risk (R.R. 22.7, 95%CI 3.0-174.2) was observed between the high (tnT >=0.1 μg/L and ST res.<50%) and low (tnT<0.1 μg/L and ST res. >=50%) risk groups.

Results:

Results:	tnT			ST res.		
	<0.1ug/L n=400	≥0.1ug/L n=116	p-value	≥50% n=215	<50% n=301	p-value
Death 30 days	2.0%	9.5%	<0.001	0.9%	5.6%	0.005

Death 30 days	tnT<0.1ug/L	tnT ≥0.1ug/L	p-value
ST res.≥50%	0.6% (n=177)	2.6% (n=38)	for trend
ST res.<50%	3.1% (n=223)	12.8% (n=78)	<0.001

Conclusion: Especially elevated tnT (>=0.1 μg/L), but also no ST res. (<50%), were associated with an increased 30 day mortality. ST res. (>=50%) identified a large low risk group of patients. The combination of these two markers gave additive early information about prognosis and further improved the risk stratification.

P2388 Prognosis in patients with troponin positive acute coronary syndrome without electrocardiographic abnormalities

G A. Large[1], D. Gray[2], J R. Hampton[2]. [1]University Hospital Nottingham, Department of Cardiovascular Medicine, Nottingham, United Kingdom; [2]University Hospital Nottingham, Department of Cardiovascular Medicine, Nottingham, United Kingdom

Background: Prognosis in unstable angina (UA) and myocardial infarction (MI) correlates well with the extent of cardiac troponin release into peripheral blood in the hours and days following hospital admission. This is additive to the prognostic information available from electrocardiography (ECG). Little is known about the significance or otherwise of troponin positivity in the context of normal electrocardiographic appearances. We performed a prospective, observational, outcome study of patients admitted to our hospital with chest pain associated with an elevation in serum cardiac troponin I but normal ECGs.

Methods: All cases of admission to our acute cardiac and coronary care units over a 1-year period because of suspected MI or UA were identified and followed for the course of their admission. The only inclusion criterion for further follow-up was an elevation of serum troponin during hospital stay. Patients whose ECGs were abnormal and who had been enrolled previously were excluded.

Results: Out of 2098 patients screened, 102 (4.9%) satisfied the study entry criteria. The 30-day mortality and non-fatal MI rates were 1.0% and 2.0% respectively. At one year, these had increased to 3.0% and 3.0%. All 3 deaths at one year were from non-cardiac causes.

Conclusion: In this relatively small study population, troponin positivity, in patients admitted with suspected UA or MI, in the presence of normal serial ECGs was not associated with adverse cardiovascular outcome. Larger studies are warranted.

P2389 Markers of myocardial injury following coronary artery bypass surgery

R. Kovacevic[1], N. Majkic-Singh[2], S. Ignjatovic[2], P. Otasevic[3], R. Obrenovic[2], I. Jovanovic[4]. [1]Dedinje Cardiovascular Institute, Biochemistry Lab, Belgrade, Yugoslavia; [2]Clinical Center of Serbia, Clinical Lab, Belgrade, Yugoslavia; [3]Dedinje Cardiovascular Institute, Cardiovascular Research Center, Belgrade, Yugoslavia; [4]Children's Hospital, Department of cardiology, Belgrade, Yugoslavia

Aim: To assess the clinical significance of serum cardiac troponinT (cTnT) assay in detection of perioperative myocardial infarction (PMI) after coronary artery bypass grafting (CABG).

Methods: The clinical utility of cTnT was compared to that of total CK, CKMB mass, CKMB activity and myoglobin. Serial venous blood samples were obtained before surgery and 4, 8, 16, 24, 48 and 72 hours after aortic unclamping (AU) in 42 patients who underwent CABG. We had 6 PMI patients, 24 patients with minor myocardial damage (MMD) and 12 without ischemic myocardial changes (no IMC).

Results: In discriminating no IMC from PMI, diagnostic sensitivity, specificity and predictive values of cTnT was superior to that of CKMB mass, CKMB activity, myoglobin and total CK during 72 hours after AU. However, in discriminating MMD from PMI the diagnostic performances for CKMB mass and CKMB activity was superior to that of cTnT during first 24 hours. After 24 hours diagnostic performances for cTnT was improved, but began to decline for CKMB isoenzymes. Discriminator power of myoglobin measurements was lower than that of cTnT and CKMB mass.

Conclusions: Our results indicate that the troponin T is an accurate marker for detection and monitoring of perioperative myocardial damage, especially 24 hours after AU.

P2390 Short-term outcome and its predictors in patients with acute chest pain and normal troponin I levels

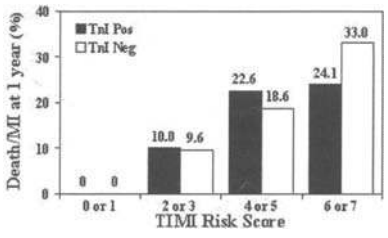
J. Sanchis, V. Bodi, A. Llácer, A. Roselló, E. Plancha, J. Núñez, L. Facila, F.J. Chorro. *University Clinic Hospital, Cardiology, Valencia, Spain*

Background: The benign prognosis of patients with acute chest pain and normal Troponin levels is controversial.
Method: The study group consisted of 301 consecutive patients evaluated in the emergency room for acute chest pain with normal troponin I levels (determined upon arrival, and 8 and 12 hours after pain onset). Clinical (chest pain score and risk factors) and ECG data were collected. Sixty-eight patients were discharged early (<24h) after exercise testing and followed-up 10 days later. Outcomes (recurrent angina (RA), acute myocardial infarction (AMI) and cardiac death (CD)) were recorded in all patients during hospital admission or on an ambulatory basis in patients discharged early.
Results: Cardiac ischemia (abnormal exercise testing or angiogram) was seen in 93 (31%) patients, RA in 34 (11%), AMI in 7 (2.3%), CD in 4 (1.3%) and major events (AMI or CD) in 10 (3.3%). By multivariate analysis, the predictors of a diagnosis of cardiac ischemia were: male sex (OR=2.7; CI=1.3-5.6; p=.006), age ^{3}64 (OR=2.5; CI=1.3-4.9; p=.008), at least 2 concomitant major risk factors (OR=2.8; CI=1.4-5.4; p=.003), and chest pain score >10 points(OR=3.5;CI=1.8-6.7; p=.0002). RA was associated to insulin-dependent diabetes (OR=3.5; CI=1.1-12.2; p=.04), coronary by-pass surgery (OR=6.0; CI=1.5-25; p=.01), chest pain score >10 points (OR=9.9; CI=2.3-44; p=.003) and ST segmentdepression (OR=3.3; CI=1.3-8.4; p=.01); AMI to insulin-dependent diabetes (OR=12;CI=2.5-59; p=.008); CD to age >72 (OR=3.1; CI=2.7-3.7; p=.01); and major events to insulin-dependent diabetes (OR=11.4; CI=2.9-45; p=.002).
Conclusions: In troponin-negative chest pain, cardiac ischemia can be evidenced in at least one-third of patients, and the rate of cardiac events is not negligible. Clinical and electrocardiographic data should be carefully evaluated in this population.

P2391 Value of cardiac troponin I as a sole marker of risk in acute coronary syndromes

J. Ferreira[1], C. Aguiar[2], R. Teles[2], P. Araujo Goncalves[2], J. Figueira[2], R. Seabra-Gomes[2]. [1]*LINDA-A-VELHA, Portugal;* [2]*Hospital Santa Cruz, Cardiology, Carnaxide, Portugal*

Background: Cardiac-specific troponins (Tn) were shown to be powerful independent predictors of future cardiac events in patients (Pts) with non-ST segment elevation acute coronary syndromes (ACS). Nevertheless, its prognostic value is sometimes overestimated.
Objective: We sought to evaluate the prognostic value of TnI, as a sole marker of prognosis, in Pts with ACS, using the TIMI Risk Score (RS) in Pts with elevated (TnI Pos) and normal (TnI Neg) levels of TnI.
Methods: We studied 433 consecutive Pts admitted to our Coronary Unit with ACS (mean age 63 ± 11 years, 21% female). Pts were classified according to the highest level of TnI measured during the first 24 h, using the cut-off value of > 0.1 ng/ml for TnI Pos. The 7 variables of the TIMI RS were applied at admission and the study endpoint was the combination of death or myocardial infarction (MI) at 1 year.
Results: TnI Pos was found in 239 Pts (55.2%). The incidence of death or MI at 1 year was 16.7% in Pts with TnI Pos and 11.3% in TnI Neg (p=0.053). The incidence of death or MI at 1 year, according to the TIMI RS in Pts with TnI Pos and Neg were as follows:
In Pts with TnI Pos the incidence of death or MI at 1 year was 8.2% in Pts with a TIMI RS < or=3 and 20.57% in Pts with a TIMI RS>3 (p<0.05). In Pts with TnI Neg the incidence of the study endpoint was 7.6% in Pts with a TIMI RS < or =3 and 15.7% in Pts with a TIMI RS>3 (p<0.05).



Death or MI according TIMI risk score.

Conclusion: Troponin I should not be relied on as the sole marker for risk stratification in patients with ACS, because either patients with positive or negative troponin I levels presented a wide range of risk of death or MI at 1 year. In clinical practice, multiple variables should be integrated into a global assessment of risk.

P2392 The kinetic properties of troponin I release during small myocardial infarctions

M. Cassin[1], F. Macor[1], E. Cervesato[1], E. Dell'Armellina[1], C. Pitzorno[1], F. Antonini Canterin[1], P. Cappelletti[2], G.L. Nicolosi[1]. [1]*Cardiology Dept., Italy;* [2]*Clinical Pathology, A.O. S. Maria degli Angeli, Pordenone, Italy*

Rationale: Cardiac troponins are nowadays considered the preferred markers for the diagnosis of myocardial infarction, according to the new definition (ESC/ACC). The kinetic of their blood release during classical myocardial infarctions is characterized by a relatively early appearance after chest pain onset and a rather long persistence in the blood (days-weeks). On the contrary, little information is available on the kinetic properties of the release of these markers during small or minimal ischaemic damage. This may have clinical impact on the correct planning and timing of marker-based protocols for chest pain evaluation in the emergency departments.
Methods: According to the methodology approved by the ESC/ACC joining group, the decisional level for troponin I in our hospital was set at 0.13 ng/ml. Small myocardial infarctions were defined as those with peak troponin I blood level between 0.13 and 0.1 ng/ml. The diagnosis for myocardial infarction comprised also chest pain characteristics and/or ECG changes according to the classical WHO criteria.
Results: In the year 2000 troponin I was measured consecutively in 2657 patients with suspected acute coronary syndrome. This has been confirmed in 760 patients (28.6%). After exclusion of patients with inadequate or incomplete values of cardiac markers (less than 3 measurements and immediate decrease values) we evaluated 134 patients, 120 of whom with a peak value less or equal to 0.1 ng/ml (group A) and 14 with peak values greater than 0.1 ng/ml (group B). The average time to peak was 7.4(4.1) hours in the group A and 8.8(4.9) hours in the group B (p=0.01). The normalization time was 18.5(14.5) hours in group A and 144.9(73.3) hours in group B (p<0.001). In the group A the normalization was achieved after 12 hours in 49 patients (40.8%), after 18 hours in 42 patients (35%), after 24 hours in 21 patients (17.5%) and after 48 hours in 8 patients (6.7%).
Conclusions: the kinetic properties of troponin I blood release after myocardial infarction is variable, particularly in relation to the ischaemic extent. This finding has to be taken into account in the planning of diagnostic protocols for rapid triage of patients coming to the emergency department for chest pain

P2393 A multimarker strategy for the risk stratification of unstable angina using C-reactive protein, troponin T and myoglobin

O. Bazzino[1], B.O.T.T.O. F[2], J.L. Navarro Estrada[1], J. Fuselli[3], M.I. Sosa Liprandi[4], S. Ahuad[5], J. Santopinto[6], R. De Miguel[1] on behalf of PACS group of investigators. [1]*Hospital Italiano de Buenos Aires, CCU, Capital Federal;* [2]*ICBA, Cardiology, Buenos Aires;* [3]*CEMIC, Cardiology, Buenos Aires;* [4]*Sanatorio Mitre, Cardiology, Buenos Aires;* [5]*Sanatorios Antartida, Cardiology, Buenos Aires;* [6]*L Lucero, Cardiology, Bahia Blanca, Argentina*

Background: Cardiac markers have different release characteristics and varying sensitivity/specificity. A multi-marker strategy testing for several prognostic markers may improve risk stratification in patients with non-ST-elevation acute coronary syndromes.
Methods: This prospective multicenter cohort study included derivation(n=1000) and validation sets (n=500) of consecutive patients admitted with non-ST-elevation acute coronary syndromes. Single assays of 3rd generation troponin T(TnT),high sensitivity C-reactive protein (CRP)and myoglobin (Myo) were performed after a median time of 9 hours from symptom onset.All results were kept blinded until the conclusion of the study. The association between all markers and 180-day events was examined by chi-square and Cox regresion analyses. The primary endpoint was the 180-day incidence of the composite of death or myocardial infarction(D/AMI).
Results: D/AMI occurred in 9.5% of patients at 180 days. Cox multivariate analysis identified the following independent variables (see Table). The addition of CRP,Myo and TnT values to the clinical model increased the area of the receiver-operator (ROC)curve from 0.66±0.03, to 0.67±0.03, 0.67±0.03 and 0.72±0.03, respectively. When all three markers were added, the ROC area increased to 0.745±0.03(p<0.03).This results were confirmed in the validation set(area of the ROC curve 0.72±0.03, p=0.43)

	chi-square	Hazard Ratio	95% CI	p
TnT>0.1 ng/ml	30.2	2.31	1.50-3.60	0.0001
Age(per year)	28.9	1.03	1.01-1.05	0.003
CRP >3 mg/L	8.6	1.97	1.23-3.16	0.005
ST segment depression>1mm	7.7	1.71	1.09-2.70	0.009
Prior angina	5.4	1.71	1.13-2.60	0.024
Myo > 80 ng/ml	5.3	1.70	1.09-2.80	0.037

Conclusions: In a non selected population of non-ST elevation acute coronary syndromes, a model including 3 cardiac markers enhanced the predictive performance of clinical predictors.A combination of these markers may assist to the identification of patients at increased risk of future events.

NURSING ROLES IN HEART FAILURE MANAGEMENT: MEETING THE NEEDS OF PATIENT AND CARERS

P2394 Factors causing hospitalisation due to heart failure

A. Strömberg[1], J. Mårtensson[2], B. Fridlund[3], U. Dahlström[4]. [1]Department of Cardiology, Linköping, Sweden; [2]County Hospital Ryhov, Department of Cardiology, Jönköping, Sweden; [3]Halmstad University, School of Social and Health Sciences, Halmstad, Sweden; [4]University Hospital, Department of Cardiology, Linköping, Sweden

Aim: to determine delay time and factors causing hospitalisation in patients with heart failure and to assess the levels of knowledge and self-care behaviour.
Material and method: A consecutive sample of patients with chronic heart failure in NYHA II-IV, hospitalised at one university and one county hospital in Sweden were included in the study. Data were collected through structured, standardised interviews with the patients and through chart review.
Results: Of the 163 patients surveyed, mean age was 78 years, 47% were females, 69% suffered from ischemic heart disease and 27% had diabetes. At time of admission 58% of the patients were in NYHA III-IV, 47% had atrial fibrillation, 58% received an ACE-inhibitor, 81% diuretics and 55% beta-blockers. The most common symptoms at admission were dyspnea (92%), fatigue (67%), ortopnea (50%), leg or abdominal oedema (48%) and chest pain (30%).
The initiative to seek care came from the patient in 36% of the cases, from the family in 22% and 27% were referred by their GP. Delay in seeking medical assistance was analysed showing that 19% of the patients sought care during the same day as their symptoms first occurred, 33% within one week, and almost half of the patients delayed more than 1 week.
The most common reason for the deterioration of heart failure was myocardial infarction or acute anginal chest pain causing 28% of the hospital admissions. Not optimal treatment was the primary cause of hospitalisation in 21,5% and noncompliance, infections and arrhythmias in 12% respectively.
Approximately 60% of the patients did not know the rationale for weighing themselves daily and only 23% performed daily weighing. Half of the patients did not plan to take any action if they noted signs of fluid retention and only 26% had knowledge on flexible diuretic intake. Half of the patient recognised the importance of fluid restriction, but only one third restricted their fluid intake. Half of the patients exercised regularly and 90% took an influenza immunisation every year.
Conclusion: Treatment-seeking delays for heart failure symptoms are high with one third of the patients waiting for more than 2 weeks after symptom onset. Most common factor causing hospitalisation were myocardial infarction or angina. Optimised heart failure treatment and improved compliance may prevent one third of the hospitalisations. Knowledge and self-care were insufficient. Patient education and other interventions in order to improve knowledge and self-care behaviour need to be improved.

P2395 Searching for underlying mechanisms in nurse led heart failure management

T. Jaarsma, D.J. van Veldhuisen. *University Hospital Groningen, Department of Cardiology, Groningen, Netherlands*

Background There is an increasing body of knowledge on non pharmacological nurse led heart failure (HF) management programs. In addition to the effectiveness of these programs, it is vital to know what the mechanisms of effects are, e.g. improved patient compliance, early recognitions of deterioration or/and improved self-control of patients.
To determine the role of underlying mechanisms of a non pharmacological nurse led HF management program, a multicenter study recently started. (Coordinating study evaluating Outcomes of Advising and Counselling in Heart Failure: COACH).
In this study 1050 patients with advanced HF, older then 18 years of age will be randomised into 1) care-as usual or 2) a low intensity HF management program or 3) a high intensity HF management program. Patients will be recruited from 10 centres in the Netherlands and patients will be interviewed at their initial admission to the hospital, and at 1, 6, 12 and 18 months after discharge. In addition to the main study on mortality, readmission, costs and quality of life, 4 projects are initiated to look at underlying mechanisms
1. What is the reason for readmission of patients. Data of all readmitted patients and their partners (if available) in the study will be collected from medical chart, interview and data from health care providers. A profile of high risk patients for readmission will be produced.
2. What are the knowledge, attitude and skills of patients with or without a HF management program? (Questionnaires)
3. How do patients from the three groups take are for themselves? (European HF Self-care Behaviour Scale).
4. How do patients from the three groups comply with the regimen? Compliance will be assessed by using a microprocessor-based medication monitoring (medication container with a microprocessor) self-report, diaries and blood-samples. Qualitative data will be collected on in a subsample on perception of a complex medical regimen
The study started in January 2002 and is planned be completed in 2005. Data on mechanisms underlying effectiveness of nurse led HF management can help to improve HF care and adapt existing or develop new programs for HF patients.

P2396 A study of medication self management during heart failure: the importance of support for both patient and carer

A.M. Clark[1], M.E. Reid[1], C.E. Morrison[2], D.L. Murrdoch[3], S. Capewell[4], J. McMurray[5]. [1]University of Glasgow, Department of Public Health, GLASGOW, United Kingdom; [2]Greater Glasgow Health Board, GLASGOW, United Kingdom; [3]Southern General Hospital, Department of Cardiology, GLASGOW, United Kingdom; [4]University of Liverpool, Dept. of Public Health, LIVERPOOL, United Kingdom; [5]University of Glasgow, CRI in Heart Failure, GLASGOW, United Kingdom

Introduction: Patients with heart failure (HF) should take a range of medications that can reduce mortality, morbidity and the need for re-hospitalisation. Though compliance with prescribed treatments is vital to realise the benefits of these drugs, comparatively little is known about how those with HF approach medication management when at home nor the roles that carers have in management.
Method and Results: A qualitative interview approach was used to examine medication management in 50 patients with NYHA class II & III HF (33 males, average age 68 years; 17 females, average age 67 years) and 30 of their carers. Patients were recruited from the out patient clinics of two large hospitals in an urban area of Scotland. HF patients took a mean of 9 different medications per day (SD 4.3, range 4-21). Drugs taken most commonly included loop diuretics (n=38), ACE Inhibitors (n=38), beta blockers (n=17) and Warfarin (n=14). 28 (93%) of the 30 carers reported being involved daily in managing the medication. This assistance ranged from reminding individuals to take their medications occasionally to organising all aspects of medication provision and management. Carers involvement in management also tended to increase with patients in class III HF. Those with HF and the carers saw the medication as being important but both groups had very limited knowledge of why this was case or the specific purpose of each drug. Both groups reported receiving little support from health professionals in relation to medication management. Despite these limitations, carers and patients collaborated to develop sophisticated ways of coping with the dangers they associated with the medications. To lessen these dangers, they utilised home made pill-boxes (33%), commercial boxes (33%) or the medications' original containers (33%). Each method was selected based on the perceived capabilities of those with HF, the dangers associated with medications and the need that was perceived to live a normal life.
Conclusion: Knowledge of the medications and their management was poor in both those with HF and their carers. Carers played a pivotal role in the management of HF medications. Though both parties received little support from health professionals, they collaborated to develop ways of managing the medications. In addition to providing greater support to those with HF, health professionals should involve carers in education and support related to the management of HF and work in partnership with both parties to identify the best means to manage medication-taking effectively.

P2397 Six first months of a new heart failure unit: nurse evaluation of patients

B. González, J. Lupon Roses, A. Urrutia, T. Parajón, S. Altimir, R. Coll, M. Prats, V. Valle. *H. Universitari Germans Trias i Pujol, Unitat Insuficiència Cardíaca, Badalona, Spain*

Knowledge about heart performance, heart failure (HF) and treatment (T) can help patients (P) to be more compliant and have better self care (diet, weight control, smoking or alcohol habits, etc). In order to know how much P know about their disease and their T, and how compliant they are, we designed a short nurse questionnaire, composed of 14 items addressed to several aspects of knowledge and understanding of heart performance and HF, treatment, weight and blood pressure control, diet, physical activities and smoking and drinking habits.

Results: 173 P (mean age 65.6 years) have been evaluated since august-2001 at the first visit to the HF unit. Only 63 P (36%) know and understand the performance of the heart. Only 62 P (36%) understand the disease. 145 P (84%) know more than 3 alarm signs of worsening. Only 74 P (43%) know all the names of the pills they are receiving, although 122 (70%) know at least about 3/4 parts of them. Only 52 P (30%) know the action of all the pills they are receiving, although 118 (68%) know at least the action of 3/4 parts of them. 94% of P say they are taking all the medication prescribed. 162 P (94%) carry on always their written prescription and only 2% never do this. 56% of P control weight only at the medical visit and only 19% control weight more than once a week. Only 31 P (18%) control blood pressure more than once a week and 45% of P control blood pressure only at the medical visit. Only 76 P (44%) say to always follow a restricted sodium diet, although 80% of P say to follow it always or almost always. While only 9 P (5%) do some kind of physical exercise, the majority of P (83%) do walking and daily life activities. 94 out of 107 P with ischemic heart disease (88%) know how to use sublingual nitroglicerin. The great majority of P never smokes (91%) and never or only very rarely drinks alcohol beverages (87%).

When analysed by age (>69 versus <70 years) we found statistical significant differences in only 4 items: knowledge and understanding of heart performance and HF, knowledge of action of the pills they are receiving and physical activities.

Conclusion: there is a lot of work to do in nurse-guided education of P with HF, although T compliance, alarm signs, use of nitroglicerin and abstinence of smoking and alcohol intake seems to be initially quite assumed by the majority of our P. Results do not differ in the majority of items among elderly and younger P, except in several aspects of knowledge and understanding of disease and treatment, and in physical activities.

P2398 Delivering evidence-based care to patients with heart failure: impact of a nurse-delivered programme in 9 UK centres

M. Cowie[1], H. McIntyre[2] on behalf of The OMADA Investigators. [1]*National heart & Lung Institute, Cardiac Medicine, London, United Kingdom;* [2]*Conquest Hospital, Hastings, United Kingdom*

The evidence base for the management of heart failure is well established but implementation of the evidence into routine practice is often slow and variable across the health service. Consequently, heart failure has been identified by the UK Government as a target area for service improvement. OMADA is a unique secondary-care based nurse-delivered patient-management programme designed to improve the delivery of evidence-based care (including patient education, lifestyle advice and drug therapy). We describe the impact of this programme on the prescription of drug therapy known to improve prognosis in nine UK centres. Methods: Trained specialist nurses were appointed in the 9 hospitals in 1999. Heart failuire patients were identified from local disease registers, an audit, and new referrals. These patients were managed by the nurses according to an agreed protocol supported by an electronic disease management database. 1118 patients were enrolled over an 18 month period (mean age 67 years, 73% male, 62% NYHA Class II or III), and data were entered at the time of each patient contact. These data include all the audit points recommended by the UK Health Department. Results: At entry into the programme 80% of patients were taking an ACE inhibitor but only 34% of these were taking the dosage used in clinical trials. This rose to 47% after completion of the programme ($P<0.001$). 24% of patients were taking a beta-blocker at entry to the programme (usually because of co-existent CAD). The nurses introduced beta-blockade therapy to all patients who were eligible. Carvedilol accounted for the majority of prescriptions: 29% reached the optimal dose of 25mg bd, 29% stopped the drug because of side effects, and the remainder are currently in the process of titration. Conclusions: A nurse-delivered protocol-driven heart failure management programme has been demonstrated to improve the delivery of evidence-based care (including drugs known to improve prognosis) to heart failure patients in a range of secondary care settings in the UK. This may prove a useful model for other countries.

P2399 The importance of a heart failure nurse in tailoring medication for CHF-patients

G.V.J. Cleuren, C. Lucas. *Rijnland Hospital, cardiology, Leiderdorp, Netherlands*

Background: The importance of optimal medical therapy for CHF-patients has been well demonstrated. This includes high dosing of ACE-inhibitors and the institution of beta-blockade. Optimizing this medication involves intensified follow-up and guidance of these patients. A specialized heart failure nurse can play an important role in this.

Methods: During 2000 and 2001 a heart failure nurse has been involved in the care of all CHF-patients being admitted at the cardiology department of the Rijnland Hospital. Apart from giving extensive information to patients and family about their disease and its practical consequences, the nurse was used to guide medical therapy. During this time-interval characteristics of all admitted CHF-patients were collected. Furthermore both medication on admission and discharge were noted and compared.

Results: Totally 313 patients were admitted at least once in 2000 and 2001. Of the first admission 51% were men, mean age was 75 years. Mean LVEF was 42%. In 61% an ischemic cause for heart failure was present. Admission medication included an ACE-inhibitor in 38% and a betablocking agent in 22%. On discharge 44% received a betablocking agent and 72% an ACE-inhibitor. mean dose of respective medication is shown in the table.

Medication	Mean admission	Mean discharge
ACE-inhibitor		
enalapril	15mgr (n=42)	24 mgr (n=39)
captopril	48 mgr (n=44)	67 mgr (n=113)
quinapril	15 mgr (n=10)	23 mgr (n=37)
Betablocking agent		
carvedilol	15 mgr (n=15)	15 mgr (n=68)
metoprolol	85 mgr (n=12)	69 mgr (n=17)
metoprolol oros	117 mgr (n=27)	88 mgr (n=32)

Conclusion: Optimal medication for CHF-patienst has been shown to be an important contributing factor to prevent mortality and readmissions. However optimal dosing of this medication presumes intensive guidance. As shown a heart failure nurse can play a role in installing essential therapy in giving ACE-inhibitors and betablocking agents in this group as demonstrated by majority of patients receiving this medication in optimal dose.

P2400 Nurse specialist participation in a Portuguese heart failure clinic: cost evaluation

I. Rodrigues[1], J. Silva Cardoso[2], C. Abreu-Lima[1]. [1]*Hospital de S. João, HF & transplant clinic, Dpt Cardiology, Porto, Portugal;* [2]*Porto, Portugal*

Background: Nurses can play a very important role in heart failure (HF) clinics by helping in the implementation of current guidelines for the treatment of heart failure and by enhancing patient compliance regarding medication, diet and exercise programs. These programs of HF team management showed to be effective in improving quality of life and functional status and reducing hospital readmissions. However the costs associated with such programs are unknown in Portugal.

Aim: We evaluated the costs involved in the work developed during one year by a HF specialist nurse in an outpatient HF clinic of the cardiology department of an university hospital.

Methods: We evaluated the costs involved in the regular patient care during the weekly 4 hours-period of the clinic activity. We also evaluated the costs involved in the nurse participation in the clinical research activity developed at the clinic during a weekly 2 hours-period: during 2001, 22 patients (pts) participated in a randomised multicentric international trial involving 5 visits/pt during the first month of follow-up and a visit every 3 months thereafter.

Results: A) costs associated with clinical investigation: 1. time spent per visit and per pt: a) management of visits' agenda: 5 min; b) blood samples processing: 10 min; c) Haematology and blood chemistry results processing: 5 min; d) patient evaluation (evaluation of symptoms and vital signs, and of therapy, diet and exercise program compliance; urine dipstick; education): 10 min; total time per visit/pt: 30 min. 2. Total of visits per year = 119. Total hours/year = 59h 30 min. 3. Cost/hour = 15 Euro. Cost/year = 892 Euro. B) costs associated with regular patient care: 1. time spent per visit and per pt: a) patient evaluation: 10 min; 2. Total of visits per year = 787. Total hours/year = 131h 10 min. 3. Cost/hour = 15 Euro. Cost/year = 1963 Euro. C) Total of costs: 892 + 1963 Euro = 2855 Euro.

Conclusion: Nurse involvement in a HF clinic activities, including the participation in a tipical randomised multicentric international HF trial, is associated with moderate costs. They seem fairly acceptable since these kinds of programs showed to reduce hospital readmissions which are the main economic burden associated with heart failure.

P2401 Multidisciplinary team in heart failure outpatients at high risk of hospital readmission: benefit of combined hospital and home-based care

M. Piepoli[1], A. Gioia[2], D. Pozzetti[2], M. Gasparini[2], M. Arvedi[2], A. Capucci[2]. [1]Piacenza, Italy; [2]General Hospital, Cardiology, Piacenza, Italy

Background: Hospital admission for chronic heart failure (CHF) is a major health emergency. We sought to determine whether a multidisciplinary outpatient management program decreases hospital readmissions and mortality over a six-month period.
Methods: 81 patients hospitalised with CHF at increased risk of hospital readmission were randomised to a multidisciplinary program or usual care. An hospital cardiologist and a CHF nurse evaluated each patient and made recommendations to the patient before randomisation. The intervention team included 4 cardiologists and 4 medical doctors from Internal Medicine Dept, 9 CHF nurses, and the patient's general practitioners. Contact with the patient was on a pre-specified schedule, and included a programme of hospital visits, regular phone call at home; in case of NYHA functional class III and IV patients also home visits by specialised nurses were planned. At each telephone calls or home visit, the CHF nurse performed a questionnaire to the patients to monitor the adherence to the therapy and for the early detection of symptoms and signs of clinical deterioration. The general practitioner of each patient was fully involved in the planning of patient care and kept informed of any change in clinical conditions. Patients in the non-intervention group were followed as usual. The primary outcome was the composite of the number of CHF hospital admissions and deaths over six months, compared by using a log transformation t test by intention-to-treat analysis.
Results: The median age of the study patients was 73.7 years, and 44.5% were women: the 41 patients randomised to the multidisciplinary care did not differentiate in terms of age, sex, medication, NYHA functional class, peak O2 consumption vs. those patients under control therapy. However there were fewer CHF hospital admissions (13 vs. 20) and deaths (2 vs. 4) in the intervention group vs. the control group ($p = 0.05$). The quality-of-life score, percentage of patients on target vasodilator beta-blockade agent therapy and percentage of patients compliant with diet recommendations were significantly better in the intervention group.
Conclusions: This study demonstrates that a six-month, multidisciplinary approach to CHF management can improve important clinical outcomes in recently hospitalised high-risk patients with CHF.

P2402 Reduction of readmission rate by a novel outpatient program in heart failure patients: combination of outpatient clinic and home nurse

R. Pacher[1], K. Schenk[2], D. Sponer[1], P. Moser[2], R. Berger[1], J. Bergler[1], M. Huelsmann[1]. [1]University of Vienna, General Hospital, Dpt of Cardiology, Vienna, Austria; [2]Ludwig Boltzmann Institute, Cardiovascular Research, Vienna, Austria

Background: We compared the influence of a heart failure (HF) outpatient clinic associated with a HF nurse specialist (special outpatient care,"SOPC") with conventional outpatient care ("COPC") on readmssion rate and length of stay (LOS) due to HF in a randomized study. Methods: 112 HF patients (mean age: 68±12 years, 63% males) who were hospitalized 3 months prior to study entrance were randomized to SOPC (n=48) or COPC (n=64). In all 112 patients an individual prescription of RAAS antagonists and additional betablockade including an uptitration schedule according to the ESC guidelines was performed by a cardiologist at the first visit in the HF outpatient clinic. Diuretic regimens and additional therapies (digitalis, anticoagulants, antiarrhythmics) were prescribed as clinical appropriate. In the SOPC group regular home visits by a nurse specialist were arranged after 3,6 and 12 months as well as in case of worsening HF to controll the precribed therapeutic regimen, body weight, heart rate, blood pressure and signs and symptoms of HF.
Results: At time of randomization, neurohumoral status (BNP, N-BNP, N-ANP) and concomitant therapy with RAAS antagonists, additional betablockade, diuretics and digitalis were comparable in both goups. Systolic (146±26 mmHg vs. 127±24 mmHg; $p<0.001$) and diastolic (78±13 mmHg vs. 70±12 mmHg; $p<0.01$) blood pressure was higher in SOPC patients, wheras no difference in heart rate (78±13 beats/minute vs. 70±12 beats/minute) was found. After 1 year follow-up a significant reduction in readmission rate due to worsening HF (13% vs. 33%; $p=0.01$) and a significant reduction in LOS (2,4±9,4 vs. 10,9±22,6; $p<0.01$) was observed in the SOPC group. Additionally, the combined endpoint of readmission due to worsening CHF and/or all cause mortality was significantly lower (17% vs. 33%) in the SOPC group. Conclusion: The use of a HF outpatient clinic in combination with a home nurse specialist is helpful in reducing readmision rate, duration of rehospitalisation and decreasing costs.

MISCELLANEOUS MYOCARDIAL DISEASES

P2403 Alpha-tocopherol attenuates cardiac hypertrophy due to energy metabolic disorder via a non-antioxidant mechanism

R. Takahashi, K. Matsubara, Y. Saburi, H. Kamiya, H. Matsui, K. Okumura. Nagoya University School of Medicine, Internal Medicine 2, Nagoya, Japan

Background: The juvenile visceral steatosis (JVS) mouse is a murine model of systemic carnitine deficiency, which shows disorder of fatty acid oxidation and develops cardiac hypertrophy associated with lipid accumulation. Therefore, the assessment of lipid second messengers including 1,2-diacylglycerol (DAG), an activator of protein kinase C (PKC), may be important to elucidate the pathogenesis of cardiac hypertrophy in this model. Recently, molecular functions of alpha-tocopherol have been reported. Alpha-tocopherol activates DAG kinase and inhibits PKC activity independent of its antioxidant ability. In this study, we investigated the mechanism of cardiac hypertrophy in JVS mice by evaluating the effect of alpha-tocopherol administration.
Methods: Both JVS and control mice were fed a high alpha-tocopherol diet (containing 1000 IU as vitamin E/kg chow) or a standard diet from 4 to 8 weeks of age. Myocardial DAG content was measured by FID-TLC method at 8 weeks of age. Furthermore, its fatty acid composition was analyzed by capillary gas chromatography.
Results: The ventricular to body weight ratio in JVS mice was significantly higher than that in control mice (11.2 vs 3.7 mg/g, $P<0.01$). Cardiac hypertrophy in JVS mice was attenuated by alpha-tocopherol treatment (10.2 mg/g, $P<0.05$). Morphological analysis showed a significantly increased LV wall thickness ($P<0.01$) and myocyte width ($P<0.01$) in JVS mice compared with those in control mice. Alpha-tocopherol treatment also significantly attenuated them. In contrast, alpha-tocopherol treatment had no beneficial effect on cardiac function although echocardiographic analysis revealed lower ventricular fractional shortening in JVS mice than those in control mice ($P<0.01$). The myocardial thiobarbituric acid reactive substance level, an index of oxidative stress, was not affected by alpha-tocopherol treatment. The myocardial DAG level was 2.5-fold higher in JVS mice (2004 ng/ventricular weight vs 806 ng/ventricular weight, $P<0.01$) with a significant increase in fatty acids of 18:1 and 18:2 compared with that in control mice. Alpha-tocopherol treatment reduced the myocardial DAG level in JVS mice (1443 ng/ventricular weight, $P<0.01$ vs JVS mice) without any alteration of fatty acid composition.
Conclusions: These results suggest that alpha-tocopherol partially attenuates cardiac hypertrophy in JVS mice via a non-antioxidant mechanism. An increase in DAG might be involved in the mechanism of cardiac hypertrophy due to energy metabolic disorder.

P2404 Noncompacted ventricular myocardium. Preliminary report of nine cases

G. Sinagra[1], G. Sabbadini[2], A. Di Lenarda[1], B. Pinamonti[1], E. Carniel[1], M. Driussi[1] on behalf of The Heart Muscle Disease Registry. [1]*Ospedale Maggiore, Cardiology Department, Trieste, Italy;* [2]*Institute of Geriatrics, Department of Internal Medicine, Trieste, Italy*

Background: The isolated persistence (i.e., not associated to other congenital abnormalities) of "spongy" ventricular myocardium is a rarely reported and poorly characterized cardiac disorder, due to an incomplete transformation of embryonic trabecular network into adult compact musculature.
Methods: From 1978 to 2001, among 760 consecutive patients (pts) with any heart muscle disease referred to our Institution, 9 (6 males and 3 females, ranging in age from 7 to 48 years) were diagnosed as having isolated noncompaction of the ventricular myocardium (NCVM); 4 cases were familial (2 families). At baseline, pts underwent careful clinical and complete non-invasive and invasive assessment (3 pts refused cardiac catheterisation and myocardial biopsy procedures). All the pts were included in a long-term follow-up program.
Results: Pts had been identified because of the presence of symptoms (dyspnoea n=2, pre-cordial palpitations n=2, complete loss of consciousness n=1), on the basis of EKG abnormalities (n=2), or during family screening for the disease (n=2). At diagnosis (mean time from identification: 63 months, range 1-252) 6, 2 and 1 pts were respectively in NYHA class I/II and III heart failure symptoms. In all the pts, echocardiography demonstrated excessively and grossly prominent trabeculation involving the apical portion of the left (n=3) or both ventricles (n=6), with associated LV dysfunction (mean LVEF 35%, range 17-44). Holter monitoring documented episodes of supraventricular paroxysmal tachycardia in 2 pts and frequent premature ventricular beats in other 2 pts. Long-term medical treatment included ACE-inhibitors (n=6), beta-blockers (n=4), diuretics (n=3), digoxin (n=3), vasodilators (n=1), anticoagulants (n=1), and anti-arrhythmic drugs (n=3). At a mean follow-up of 88.5 months (range 48-144), 7 patients were alive while 1 died for unknown cause 12 years after diagnosis. Among survivors, clinical status was unchanged in 4 cases, worsened in 2 and improved in 1; LV function was unchanged in 3 pts and significantly improved (increase in LVEF>10%) in 2 pts. None of the 7 surviving pts had symptomatic arrhythmias.
Conclusions: Differently from previously published reports, our data on 9 consecutive NCVM pts suggest a favourable long-term outcome, sometimes associated with significant improvement of symptoms and LV function. However, it has to be clarified how the prognosis of the disease depends on the degree of cardiac structural abnormalities, and/or efficacy of heart failure therapies.

P2405 Activities of a national registry of heart tumours

F. García-Gallego[1], C. Gamallo[2] on behalf of RNTC participants. [1]*Hospital La Paz, Servicio de Cardiología, Madrid, Spain;* [2]*Hospital de La Princesa, Servicio de Anatomía Patológica, Madrid, Spain*

From 1996 till 2000 we collected 295 heart tumors. The cases were requested annually by a form aproved by the Spanish Society of Cardiology and distributed between the members all around the country (Registro Nacional de Tumores Cardiacos, RNTC). This form contained a questionaire made according to the guidelines of general tumours' registries of Madrid Regional Health Authorities adapted to the heart. It includes case identification, dates of diagnosis and treatment, method of diagnosis, surgical procedures, pathologic examinations and follow up.
Results: 279 pts (126 M/153F. mean age 44.5±25 (range 0-89), 53 were 18 years old or less and 18 were 30 days old or younger) had 295 tumors. Main clinical manifestation were: heart failure (31,1%), arterial embolism (12,9%), arrithmias (9,1%), angina (4%), syncope (3,4%), pericardial tamponade (2,3%), heart block (2%), sudden death (1,8%), asymptomatics (26,1%). Two hundred and sixty were primary heart tumors distributed as follows: myxomas (60,7%), rhabdomyomas (14,2%), angiosarcomas (4,2%), pericardial cysts (3,8%), fibroelastomas (3,4%), linfomas (2,3%), rhabdomyosarcomas (1,9%), leiomyosarcomas (1,5%), hemangiomas (1,5%), mesoteliomas of the AV node (1,1%), malignant histiocytomas (0,7%), teratomas (0,7%), fibromas (0,7%), condrosarcomas (0,7%), lipomas (0,7%), fibrosarcomas (0,3%), myxosarcomas (0,3%), hemagioendoteliomas (0,3%), Purkinje's cells tumours (0,3%). In young cases rhabdomyomas were more frequent in adult cases myxomas. Seven pts had relapsing myxomas, in 4 one time and in 3 two times. Thirty three pts had malignant primitive tumors, (mean age 46,8±22. 16 M/17 F). Left and right atrium were the heart chambers more frequently involved. In malignant cases 20 pts were surgically treated, 2 of them with heart transplantation, 10 received chemotherapy and 6 radiotherapy. Death ocurred in 48 cases. 27 due to tumoral progression, 9 to clinical complications, 9 to other causes not related with the tumour and 3 were undetermined.
Conclusion: The information obtained with the RNTC is useful to put together the experience on these rare heart diseases for epidemiological, clinical and research proposals.

P2406 Herpes simplex virus type 1 infection associated with atrial myxoma

L. Archard[1], Z. Pan[2], Y. Ji[3], M. Sheppard[4], D. Jeffries[5], H. Zhang[1], Y. Li[1]. [1]*Imperial College Faculty of Medicine, Division of Biomedical Sciences, London, United Kingdom;* [2]*Zhongshan Hospital, Fudan University, Department of General Practice, Shanghai, China;* [3]*Zhonshan Hospital, Fudan University, Department of Pathology, Shanghai, China;* [4]*Royal Brompton Hospital, Department of Histopathology, London, United Kingdom;* [5]*St Bartholomews & London Hospital, Department of Virology, London, United Kingdom*

Background: The etiology of atrial myxoma is unknown, although the constitutional symptoms and laboratory findings suggest an infectious disease. As some histopathological features are similar to Herpes simplex virus type 1 (HSV-1) infections, we hypothesized that HSV-1 may be involved in the pathogenesis of cardiac myxoma.
Methods: Paraffin-embedded tissue samples resected from 17 patients with atrial myxoma were investigated for HSV-1 antigen by immunohistochemistry and virus genomic DNA by nested polymerase chain reaction (nPCR). The histogenesis and oncogenesis of atrial myxoma were assessed by the expression of calretinin, Ki67 and p53 protein respectively and inflammatory infiltrates were characterised by a panel of antibodies against lymphocyte markers. Autopsy samples of cerebrum or myocardium from 5 patients who died of amniotic embolism or enteroviral myocarditis were used for comparison.
Results: HSV-1 antigen was detected in resected atrial myxoma from 12 of 17 patients. Of these 12, eight samples were positive also for HSV-1 genomic DNA: the identity of representative PCR amplicons was confirmed by direct nucleotide sequencing. No HSV-1 antigen or DNA was found in tissue from the comparison group. Most infiltrating lymphoid cells in atrial myxomas were cytotoxic T lymphocytes, although a few T helper cells, natural killer cells and B lymphocytes were present also. Calretinin was found in myxoma cells from all 17 cases but Ki67 was present only in smooth muscle cells or infiltrating cells in some cases. p53 was not detectable in any of the myxomas.
Conclusions: These data suggest that HSV-1 is involved in the pathogenesis of myxoma of neural origin and that atrial myxoma may be a chronic inflammatory lesion of endocardium.

P2407 Cardiac manifestations in patients with primary Sjogren's syndrome

I. Moyssakis[1], V. Vassiliou[2], K.A. Boki[2], N.J. Pantazopoulos[1], M. Kyriakidis[1], H.M. Moutsopoulos[2]. [1]*"Laiko" Hospital, Department of Cardiology, Athens, Greece;* [2]*University of Athens Medical School, Department of Pathophysiology, Athens, Greece*

Objectives: The echocardiographic evaluation of the anatomic and functional heart lesions in patients with primary Sjogren's syndrome (pSS) (without overt heart disease), the comparison of these findings with those of the control group, and the correlation with clinical and laboratory data.
Methods: Seventy eight patients (pts) with pSS (75 women and 3 men, mean age 51 ± 11.6 years and mean disease duration 7.7 ± 4.26 years) and 80 healthy controls (78 women and 2 men, aged 51 ± 9.5 years) were evaluated echocardiographically. Parameters measured included: Left ventricular (LV) dimensions, interventricular septum and posterior wall thickness at end-diastole were measured for the calculation of fractional shortening (FS) and left ventricular mass index with the Penn convention formula. We also evaluated parameters of right ventricular (RV) and LV diastolic function, including early and late atrioventricular (AV) flow velocities (E and A wave respectively), E/A ratio, deceleration time (DT) and isovolumic relaxation time (IVRT). Pulmonary artery systolic pressure (PASP) was estimated by the peak transtricuspid regurgitant velocity jet plus the estimated right atrial pressure, whereas organic valvular involvement was defined as valve thickening and/or regurgitation.
Results: Twenty three (29.5%) pts had mitral valve regurgitation versus 7 controls ($p<0.01$), 6 pts had mild tricuspid regurgitation ($p<0.05$) and 14 (18%) pts had mild aortic valve regurgitation. Pericardial effusion was found in 3 pts whereas fourteen (18%) pts had pulmonary hypertension (PASP > 35 mmHg) ($p<0.001$). Mitral valve regurgitation was significantly associated with the presence of the anti-La antibodies ($p<0.05$) and pulmonary hypertension with lung disease($p<0.05$). The LV mass index of the pts differed significantly from the controls (105.4 ± 14.27 g.m-2 vs 84.71 ± 15.36 g.m-2, $p<0.001$) and was correlated with the presence of purpura ($p=0.02$), lung disease ($p<0.001$), and a positive rheumatoid factor ($p=0.02$). From the indices of LV or RV diastolic function, only the LV IVRT showed significant difference between pts and controls (77.2 ± 4.6 vs 68 ± 5.3 respectively, $p<0.01$).
Conclusion: Patients with pSS and no clinically apparent heart disease had, more often than healthy controls, mild mitral and tricuspid valve regurgitation, and pulmonary hypertension, and had increased left ventricular mass index. The LV mass index is correlated with purpura, lung disease and the presence of rheumatoid factor.

P2408 Left and right atrial remodelling in 153 patients with biopsy-proven cardiac amyloidosis

A. Rossi[1], M.E. Sarano[2], J.B. Seward[2], J.A. Tajik[2], M. Grogan[2]. [1]*Ospedale Maggiore, Divisione Clinicizzata di Cardiologia, Verona, Italy;* [2]*Mayo Clinic, Division of Cardiovascular Disease, Rochester, United States of America*

Purpose: Cardiac amyloidosis is characterized by extracellular infiltration of myocardial tissue which leads to increased ventricular stiffness. Atrial dilation is expected because of increased filling pressure and amyloid infiltration of atrial wall. However information regarding the frequency and the degree of left and right atrial remodeling in this disease are lacking. Aims of this study were to describe left and right atrial volume and to analyze the variables associatiated with atrial volume increase in a large population of patients with biopsy-proven cardiac amyloidosis. Methods: 153 pts with primary amyloidosis and biopsy-proved cardiac involvement and 26 age and gender matched normal subjects underwent echocardiographic assessment. Left ventricular (LV) septum (ST) and posterior wall (PWT) thickness, diastolic (LVD), systolic (LVS) diameters and ejection fraction (EF) were measured by m-mode echocardiography. E (E) and A (A) waves velocities, E/A ratio and E deceleration time (DTe) were measured. Left atrial volume (LAmax) was measured from biplane apical view (4 and 2 chambers) and the area-length method. Right atrial volume (RAV) was measure from monoplane apical view. Mitral (MR) and tricuspid (TR) regurgitation were semiquantitatively assessed in 4-grades scale. Results: Amyloidosis pts compared with normals have thicker ST (16±3 vs 10±1, p<0.0001), lower EF (47±14 vs 65±7, p<0.0001), shorter DTe (164±44 vs 215±47, p<0.0001) and larger both left (103±3 vs 59±19, p<0.0001) and right atrial volume (96±35 vs 26±6, p<0.0001). In the subgroup of pts with no ST thickness (defined as ST < 13 mm), the difference in term of left atrial volume compare with normals remained highly significant (92±32 vs 59±19 p<0.0001). Determinants of LAmax was ST thickness (r=0.26; p=0.008), LVS (r=0.26; p=0.005), degree of MR (r=0.19; p<0.05), presence of atrial fibrillation (r=0.23; p=0.01) and E/A (r=0.21; p=0.055). Conclusions: Left and right atrial remodeling is a frequent phenomenon in patients with cardiac amyloidosis, even in early phase of the disease. Left atrial volume is mainly related to ventricular remodeling and it might reflect the chronicity and degree of diastolic burden in this unique subset of patients.

P2409 Segmental myocardial wall function by pulsed-wave Doppler tissue imaging in people with human imunodeficiency virus infection

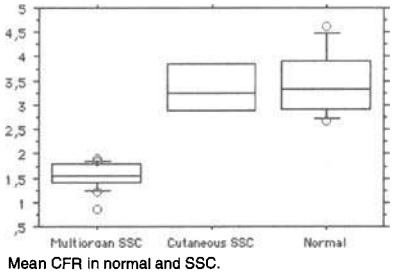
H. Custódio, A. Galiano, I. Arroja, V. Azevedo, J. Galvão, L. Bronze, J. Azevedo, A. Aleixo. *Hospital São Francisco Xavier, Echocardiographic Laboratory, Lisbon, Portugal*

HIV infected patients (pts) have a longer survival, that may lead to the involvement of organs that are not present in intial phases of this disease, other than the preferential target of this virus, justifying the investigation of its early cardiac manifestations. Pulsed Doppler tissue imaging (DTI) analysis of the left ventricular (LV) myocardial wall velocities during systole and diastole, allows the quantitative evaluation of the segmental (seg) myocardial wall function, preceding its functional LV global dysfunction. The purpose of our study was to investigate early signals of myocardial involvement in HIV infected pts, stage 1 assymptomatic bearers, with no cardiac symptoms and no objective signals of LV global dysfunction (LV fractional shortenning >30% and LV% ejection fraction >50%). With pulsed DTI, we studied a population of 44 HIV 1 and 2 infected young people (Group HIV), mean age 34±11 yrs, 54.6% male gender. Pulsed DTI sample was placed on each one of the 16 LV seg (ASE classification). During 3 consecutive cardiac cycles, we calculated the maximal velocities (Vmax-cm/sec) of the seg pulsed DTI waves, the systolic wave s, early e and late a diastolic waves, and its e/a Vmax diastolic ratio. The pulsed DTI profile was analysed with a Sequoia C256 Acuson equipment, with electronic probes, after B-mode colour Doppler study, sample Doppler 2 mm, and appropriate imaging filters. The results were compared with those of an age matched control group (Group NL) with 15 young healthy volunteers. Both groups were submitted to the same pulsed DTI study protocol. In HIV group, we achieved a greater rate of bifasic s (32% vs 2%; p=0.01) DTI wave profile, a significantly decrease in Vmax s <10 cm/sec (20% vs 3%; p=0.02) seg DTI wave, a significantly decrease in the Vmax e <10 cm/sec (27% vs 3.5%; p=0.01) and a <10 cm/sec (30% vs 4.2%; p=0.01) seg diastolic DTI waves, a greater rate of trifasic (17% vs 1.5%, p=0.03) and quadrifasic (10% vs 0%, p=0.02) seg DTI diastolic waves and a greater rate of Vmax e/a<1 (21% vs 2.5%; p=0.02) seg DTI diastolic wave velocity ratio. Conclusion: In HIV infected patients with no cardiac symptoms and no objective signals of left ventricle global dysfunction, the pulsed DTI was an useful method for segmental quantitative functional analysis. In these HIV pts, we found a remarkable rate of LV seg myocardial dysfunction signals, that suggest the early presence of a certain degree of segmental LV myocardial involvement, despite the initial stage of this viral infection.

P2410 Coronary flow reserve in systemic sclerosis as early marker of cardiac impairment

G.P. Bezante[1], M. Ghio[2], V. Sebastiani[2], L. Deferrari[2], G. Molinari[2], R. Villa[2], F. Indiveri[2], A. Barsotti[2]. [1]*Cardiologia, DIMI - Dipartimento Medicina Interna, Genova, Italy;* [2]*Dipartimento di Medicina Interna, Genova, Italy*

In the last years the advances in medical therapy improved the life expectancy of patients affected by systemic sclerosis (SSC). To the best of our present knowledge, SSC related mortality is frequently associated with cardiovascular impairment and in particular with heart failure. Therefore, we investigated whether the non-invasive determination of coronary flow reserve (CFR) by transthoracic Doppler could be a potential method to detect early dysfunction of cardiovascular system in patients with no apparent cardiac impairment symptoms. 21 patients (19 female, age 49,7± 13,9 years) with an onset of SSC > 2 years, were evaluated. The cardiac evaluation (LVEF, presence of pericardial effusion, EKG rhythm or conduction abnormalities) was normal in all patients whereas cutaneous and visceral involvements was detected in 17 patients and 4 patients showed only cutaneous involvement. The CFR by contrast (Levovist® -300 mg/ml at 1mg/min infusion) enhanced transthoracic second harmonic Doppler was sampled in the left anterior descending coronary artery in SSC patients and in 7 control subjects (normal). CFR was determinated at rest and during hyperemia induced by administration of adenosine at 0,14 mg/kg/min over 5 minutes The CFR was calculated as the ratio of hyperemic to basal peak (VCFR) and mean (MCFR) diastolic flow velocity. We found a reduced CFR (< 2) in the same group of patients with multiorgan involvement and normal CFR (> 2) in the remaining SSC 4 patients and in the normal group. CFR impairment could relate to an earlier coronary microvascular dysfunction and seems to be an effective, noninvasive tool to assess cardiac involvement in SSC. Further evaluation could be performed to assess the prognostic value of these findings.



Mean CFR in normal and SSC.

P2411 Cardiac involvement in systemic lupus erythematodes – visualization with contrast enhanced cardiac magnetic resonance imaging

J. Schulz-Menger[1], N. Siegle[1], A. Natusch[2], E. Gromnica-Ihle[2], M. Friedrich[1]. [1]*Franz-Volhard-Klinik; Charité, Cardiology, Berlin, Germany;* [2]*Rheumatology, Klinikum Buch, Berlin, Germany*

Background: Systemic lupus erythematodes (sLE) is a systemic rheumatic disease involving different organs. Cardiac manifestation is more commonly found at autopsy than clinically. Myocarditis is clinically found in up to 10% of patients, whereas the incidence in autopsy studies is about 40%. On the other hand for the guiding of new therapeutic strategies the diagnosis is essential. Contrast enhanced Magnetic resonance imaging was shown to be sufficient in detecting myocardial injury due to different causes.

Patients and Method: We applied contrast-enhanced MRI in 18 patients with proven sLE. 10 patients suffered from stable disease (sLE), whereas 8 patients suffered from acute disease as defined by the ECLAM-activity-score and ANA-values (sLE acute). We performed standard T1-weighted multislice spin-echo sequences (TE 30ms; TR 480-725 ms; slice thickness 6 mm) in an axial and short-axis orientation (before and after application of 0.1 mmol/kg Gd-DTPA (Magnevist®, Schering AG; Berlin, Germany) on conventional MRI systems (1.0 T; Siemens-Expert; Siemens AG, Erlangen, Germany and 1.5 TSigna CV/i; GE; Milwaukee, USA, respectively) using a body coil. The relative global signal enhancement (RE) of the myocardium as related to the skeletal muscle was calculated. Furthermore, we compared the left ventricular ejection fraction (LVEF) as determined by gradient echo sequences. Results ot both patient groups were compared with 10 healthy volunteers (vol).

Results: The RE of patients with acute sLE (5.5±0.9) was significantly higher than that of the other patients with sLE (3.0±0.4; p<0,004). The RE of the volunteers (2.0±0.3) was significant lower as compared to that of acute sLE (p<0,0001), and there was also no significant difference to the group with the stable sLE-patients. There was no significant difference of the LVEF between any of the groups (vol: 70±2%; sLE:69±4%; sLE acute 68±3%; p=n.s.). Furthermore, in all patients with acute sLE, a subendocardial pronouncement of the enhancement was evident, whereas this pattern was present in only 50% of the other sLE patients and never detectable in vol.

Discussion: In patients with normal LVEF, the acute myocardial injury in patients with SLE is detectable by ceMRI. The impact of the subendocardially pronounced signal enhancement for the degree of the disease is not yet clarified.

Conclusion: Contrast enhanced MRI is helpful in detection of myocardial involment in patients with systemic lupus erythematodes.

P2412 Cardiac dimensions in junior elite athletes

S. Firoozi, S. Sharma, G. Whyte, M.S. Hamid, R. Thaman, P.M. Elliott, W.J. McKenna. *St George's Hospital Medical School, Cardiological Sciences, London, United Kingdom*

Background: Regular intense physical exercise can cause cardiac adaptations reflected by increased left ventricular cavity size raising the differentiation from cardiomyopathy. Unlike senior athletes, there is a paucity of data regarding cardiac dimensions in junior elite athletes. This is particular relevance as death due to cardiomyopathy is most prevalent in this age group.
Methods: Between 1996 and 2000, 1610 asymptomatic junior elite athletes (74% male) in the United Kingdom were evaluated using 2-D echocardiography. The athletes (age 15.6 ± 1.4 years; range 14-18 years inclusive; body surface area (BSA) 1.74 ± 0.16 m^2; range 1.09-2.23 m^2) were from a variety of sporting disciplines including endurance, team and technical sports (tennis 26%, football 24%, swimming 12%, rugby 9%, rowing 8%, cycling 8%, triathlon 5%, other 8%). In addition, 368 healthy non-athletic controls matched for age, gender and BSA were evaluated.
Results: Both groups were matched for age (15.5 ± 1.6 v 15.2 ± 1.2 years; p = 0.1) and BSA (1.74 ± 0.2 v 1.73 ± 0.4; p = 0.2). Athletes had a greater left ventricular end-diastolic diameter (LVEDD) than the control group (50.8 ± 3.2 v 47.9 ± 3.5 mm; p < 0.0001). The LVEDD correlated with BSA (r = 0.6, p > 0.0001) and was greater in males despite correction for BSA (51.6 ± 3.3 v 47.7 ± 3.3; p > 0.001). The left atrial size was also greater in athletes (33 ± 3.5 v 31 ± 5 mm; p = 0.0002). Systolic function (fractional shortening 33.1 ± 3.5 v 31.9 ± 3.9; p = 0.4) and E/A ratio (2.25 ± 0.7 v 2.14 ± 0.2; p = 0.3) was similar in the two groups.
33% of athletes had a LVEDD exceeding predicted upper limits of normal. The LVEDD in this group was 54.4 ± 2.1 mm (range 52-60mm). The fractional shortening in this group was normal (38 ± 3%; range 32-43%). No female athlete had a LVEDD > 55mm and no male athlete had a LVEDD > 60mm.
Conclusion: (1) The increase in cavity dimension seen in junior athletes is modest (2.9mm; 6%) and less than that reported in studies of senior athletes. This may reflect shorter cumulative duration of training. (2) Left ventricular dilatation in athletes occurs in the context of normal systolic function differentiating it from dilated cardiomyopathy. A LVEDD > 60mm suggests pathological dilatation rather than physiological adaptation. (3) The LA is dilated in athletes but in proportion to LVEDD reflecting a generalised increase in preload with exercise rather than elevated end-diastolic pressures and diastolic abnormalities.

P2413 QTc-interval dispersion is not associated with mortality in patients with heart failure due to Chagas' cardiomyopathy

R. Bestetti[1], D. Haber[2]. [1]*Centro Universitário Barão de Mauá, Internal Medicine, Ribeirão Preto, Brazil;* [2]*FAMERP, Cardiology, São José do Rio Preto, Brazil*

QTc-interval dispersion (QTc-d) has been considered a marker of mortality for patients with nonchagasic heart failure. QTc-d is increased in patients with heart failure due to Chagas' cardiomyopathy as compared with controls. Nevertheless, the value of QTc-d to predict mortality in patients with heart failure due to Chagas' cardiomyopathy is unknown. Accordingly, this study aimed at assessing the association of QTc-d with mortality in patients with heart failure due to Chagas' cardiomyopathy.
From january, 2000 to june, 2001, 63 consecutive patients followed at the Heart Failure Outpatient Service with a positive serologic test for Chagas' disease were considered for the study. All chagasic patients underwent history-taking, physical examination on admission, 12-lead resting ECG, X-Ray chest, serological tests and dopplerechocardiography. Patients were diagnosed as having heart failure due to Chagas' cardiomyopathy on the basis of cardiomegaly on X-Ray chest or decreased left ventricular ejection fraction on dopplerechocardiography. Twenty-two patients wearing artificial pacemakers and 11 patients with atrial fibrillation were ruled out, whereas the remaining 30 patients were entered the study. The QTc interval was measured in at least 5 leads. QTc-d was defined as the difference between maximum and minimum QTc. Fifteen patients with no previous cardiac history served as controls.
Eleven (37%) of 30 patients with heart failure due to Chagas' cardiomyopathy died during the study period. Mean left ventricular ejection fraction was 32±13% in survivors and 30±13% in nonsurvivors chagasic patients (p>0.05). QTc-d was 40.6±10.94 msec in controls, 98.75±37.13 msec in survivors and 117.59±37.91 msec in nonsurvivors chagasic patients (p<0.0001 by Kruskal-Wallis test). No difference was observed between survivors and nonsurvivors chagasic patients with regard to mean QTc-d values.
Thus, QTc-d seems not to be associated with total mortality in patients with moderate to severe heart failure due to Chagas' cardiomyopathy.®

P2414 Microangiopathy as diagnostic and prognostic marker in cardiac sarcoidosis

Y. Yazaki[1], Y. Kamiyoshi[1], K. Kogashi[1], H. Imamura[1], M. Owa[1], K. Kubo[1], M. Sekiguchi[2]. [1]*Shinshu University School of Medicine, First department of Internal Medicine, Matsumoto, Japan;* [2]*Akasaka Sekiguchi Clinic, Tokyo, Japan*

Background: Microangiopathy presenting as basal lamina layering (BLL) around the microvasculature detected by electron microscopy is often observed in various tissues affected by sarcoidosis, including the heart. The clinical significance of microangiopathy is unknown, however in relation to cardiac sarcoidosis. Methods: To clarify the diagnostic and prognostic significance of microangiopathy, we analyzed the clinicopathological findings and outcomes in 15 cases of CS in which sarcoidosis in the lung, skin, lymphnode, or heart was confirmed histologically, and in which ultrastructural observations of heart biopsy specimens were made. Electron microscopy findings in 25 cases of idiopathic dilated cardiomyopathy (IDC) were used for comparison. Results: Granulomas were confirmed in only 3 patients (20%) by heart biopsy. The incidence of BLL was significantly greater in cases of CS than in cases of IDC (12/15:73% vs. 7/25:28%, p<0.05). The presence of BLL >4 layers showed a sensitivity of 60%, a specificity of 92%, and a predictive accuracy of 78% for differential diagnosis of CS and IDC. Left ventricular (LV) ejection fraction (39±13% vs. 59±23%, p<0.05) and % area of interstitial fibrosis (16±8 vs. 8±4, p<0.05) in 9 patients with BLL >4 layers (group A) was significantly lower than that in the other 6 patients (group B). A cardiac event (worsening heart failure requiring hospitalization, sustained ventricular tachycardia, or cardiac death) occurred in 6 group A patients (67%) and 1 group B patient (17%) during the mean follow-up period of 54 months (p<0.05), and 5 group A patients (56%) died. Despite corticosteroid treatment, group A patients showed a significant increase in LV volume index (78±21ml/m^2 to 103±23ml/m^2, p<0.01) and thinning of the interventricular septum (12±4mm to 9±3mm, p<0.01). No group B patient died, and echocardiographic parameters were unchanged in this group. Conclusions: BLL is a useful diagnostic marker of CS. Microangiopathy may be related to ventricular remodeling, disease progression, and poor clinical outcome in cases of CS.

VALVE DISEASE – MISCELLANEOUS

P2415 Alterations in myocardial creatine kinase may be used to detect myocardial maladaptation in chronic valvar heart disease

C. Piper[1], A.K. Bock[2], D. Horstkotte[1], A. Doerner[2]. [1]*Heart Center North Rhine-Westphalia, Department of Cardiology, Bad Oeynhausen, Germany;* [2]*University Hospital Benjamin Franklin, Department of Cardiology and Pulmology, Berlin, Germany*

Background: The creatine kinase (CK) system (creatine-phospat + ADP = creatine + ATP) is the primary energy providing system of the heart. To maintain increased myocardial workload an upregulation of the CK activity, which results in fastened ATP resyntheses, is necessary to meet the elevated energy demand. It is still controversial whether CK activity is decreased in patients with cardiac failure. The isoenzyme CK-MB has a higher affinity to ADP and in case of a reduced amount of phosphocreatine ATP produces more efficiently than CK-MM. A shift of the isoenzyme pattern from CK-MM to CK-MB is regarded as a mechanism of myocardial adaptation. We analyzed whether changes of the CK system can be used as a biochemical marker to determine myocardial maladaptation to volume and/or pressure overload in valvar heart disease (VHD).
Methods: In right ventricular biopsies from 12 patients (P) with aortic stenosis (pressure loss (PL) 0.2-2.9 mmHg/ml stroke volume, cardiac index (CI) 2.0-4.4 ml/min/m^2, wall stress (WS) 85-174 g/cm^2) and from 12 P with valvar regurgitation (aortic[AR] n=6, mitral[MR], n=6) (regurgitation fraction (RF) 22-55%, CI 1.8-4.5 ml/min/m^2, WS 75-164 g/cm^2), total CK activity was measured by disappearance of NADP at 450 nm and CK isoenzyme pattern by gel electrophoresis. As controls, endomyocardium from explanted organs with terminal heart failure (EXPL,n=7), from P with dilated cardiomyopathy (DCM,n=12) and from 6 healthy hearts (C) were examined.
Results: In comparison to C (47.2±5.2 U/mg protein) mean CK activity was reduced in P with pressure overload (AS: 41.9+13.6 U/mg), volume overload (AR/MR: 38.4±17), in EXPL (43.3+16.2) and significantly in P with DCM (20.1±9.9)(p<0.05). In VHD, CK activity increased parallel to the severity of diastolic (LVEDP, r=0.42) and decreased parallel to systolic dysfunction (CI, r=-0.22). In DCM, CK activity decreased parallel to systolic (CI, r=0.40)and diastolic (LVEDP, r=0.24) dysfunction. There was no correlation between CK activity and DV or RF. An CK isoenzyme shift was found in P with VDH parallel to an elevation of WS (CK-MB/CK-MM vs WS, r=0.41).
Conclusion: A decrease of myocardial CK activity and an isoenzyme shift from CK-MM to CK-MB indicates myocardial maladaptation in VHD.

P2416 Coagulations, fibrinolytic system activation and endothelial dysfunction in patients with mitral stenosis in sinus rhythm

S. Topaloglu[1], A. boyaci[1], S. Ayaz[2], S. Yilmaz[2], O. Yanik[3], O. Ozdemir[1], A. Duran demir[1], S. Korkmaz[1]. [1]*Turkiye Yuksek Ihtisas Hospital, Cardiology, Ankara, Turkey;* [2]*Turkiye Yuksek Ihtisas Hospital, Haematology, Ankara, Turkey;* [3]*S.B Ankara hospital, Internal medicine, Ankara, Turkey*

SUMMARY Background. Systemic embolism is an important complication in patients with mitral stenosis. Anticoagulation treatment can prevent this serious complication in patients with mitral stenosis in atrial fibrillation, but in sinus rhythm the place of this treatment is in argument. In this study, our aim is to determine the hemostatic parameters of mitral stenotic patients in sinus rhythm and also to compare the systemic hemostatic parameters of patients both in atrial fibrillation with LASEC (left atrium spontaneous echo contrast) and without LASEC and normal population.

Methods: 46 patients with mitral stenosis contributed to this study. 28 patients were in sinus rhythm and 18 patients were in atrial fibrillation. None of the patients had left atrial trombus in transesophageal echocardiography. We studied systemic venous fibrinogen, D-dimer, antitrombin-III, tissue plasminogen activator, plasminogen activator inhibitor-I, von Willebrand factor, platelet factor 4 in these patients. The patients were divided into subgroups, first according to their rhythm as sinus and atrial fibrillation than those with LASEC and sinus rhythm, those with LASEC and atrial fibrillation, those without LASEC and sinus rhythm, those without LASEC and atrial fibrillation. All of these groups were compared with control group.

Results: Our results suggest that fibrinogen, D-dimer, antitrombin-III, von Willebrand factor, platelet factor 4 levels were greater in sinus rhythm and atrial fibrillation groups than the control group. This was significant statistically ($p<0.05$). Also in presence of LASEC both in sinus rhythm and atrial fibrillation fibrinogen, D-dimer, antitrombin-III, von willebrand factor and platelet factor 4 levels were significantly higher compare to control group ($p< 0.05$). Without LASEC fibrinogen, antitrombin-III, von Willebrand levels were high only in atrial fibrillation group ($p<0.05$). D- dimer, platelet factor 4 were greater in atrial fibrillation and sinus rhythm than controls ($p<0.01$). These parameters were also high in atrial fibrillation than sinus rhythm ($p<0.05$). We studied also tissue plasminogen activator and plasminogen activator inhibitor-I levels. Only tissue plasminogen activator levels were higher in atrial fibrillation group than sinus rhythm and control group ($p<0.05$).

Conclusions: In patients with mitral stenosis but in sinus rhythm, especially the patients with LASEC, coagulation activation, platelet activation and endothelial dysfunction are similar in patients with atrial fibrillation.

P2417 Should we still anticoagulate patients with atrial fibrillation and/or mitral stenosis in presence of severe mitral regurgitation?

N. Ozdemir[1], C. Kaymaz[2], C. Çevik[2], C. Ýzgi[2], O. Özveren[2], M. Akçay[2], O. Karakaya[2], M. Özkan[2]. [1]*Kosuyolu Heart & Research Hospital, Cardiology Clinic, Istanbul, Turkey;* [2]*Kosuyolu Heart & Research Hospital, Cardiology Clinic, Ýstanbul, Turkey*

The risk of left atrial thrombus (LAT) formation and/or systemic embolism (SE) have been documented to be high in pts with atrial fibrillation (AF) and/or mitral stenosis (MS),and to be low in pts with severe mitral regurgitation (MR). However, indications of anticoagulation in pts with severe MR concommitant with AF and/or MS does not consider any beneficial impact of MR on thromboembolic risk. We aimed to investigate the incidence of LAT and history of SE in patients who underwent mitral valve surgery,and to assess whether severe MR prevents LAT and SE in pts with chronic AF.The study population comprised 979 pts(F 636,M 343,age 40±14.5) in whom valve surgery was performed because of pure or predominant MS(n=517),severe MR(n=388),and MS concomitant with severe MR (n= 74).Preoperative rhythm was AF in 530 pts, and sinus rhythm (SR) in the remainder. History of SE before surgery was documented in 146 pts with MS, but in none of them with severe MR with or without MS. Anticoagulation was noted in 166 pts with history of SE and/or LAT diagnosed by echo. Age, sex, and left atrial diameter were not different between three groups ($p>0.05$). Intraoperative assessment disclosed LAT in 108 pts. In MS group, pts with AF had a higher incidence of LAT as compared to pts with SR (31.3% vs 4.8%,$p<0.001$). However, none of pts with severe MR had LAT,and LAT within the appendage was detected in one pt with MS+MR with AF. Incidence of LAT was lower in MR group regardless of rhythm as compared to pts either with MS concommitant with AF ($p<0.001$) or SR ($p<0.05$). Similarly, pts with MS+MR had a lower incidence of LAT than pts with MS and AF ($p<0.001$), and pts with MS and SR ($p<0.05$).

We conclude that incidence of LAT and/or SE are the highest in MS with AF, and even high in MS with SR whereas pts with severe MR carry the lowest risk regardless of rhythm and MS. Severe MR seems to prevent LAT and SE in chronic AF even in the absence of anticoagulation. In patients with severe MR indications of anticoagulation for AF and MS may need to be reevaluated.

P2418 The relationship between tumor markers and echocardiographic findings in carcinoid heart disease

J. Ravnik[1], M. Podlesnik[2], M. Kozelj[2], S. Markovic[3], J. Osredkar[4]. [1]*University Medical Centre Ljubljana, Department of Cardiovascular Diseases, Ljubljana, Slovenia;* [2]*University Medical Centre Ljubljana, Department of Cardiovascular Diseases, Ljubljana, Slovenia;* [3]*University Medical Centre Ljubljana, Department of Gastroenterology, Ljubljana, Slovenia;* [4]*University Medical Centre Ljubljana, Institute of Clinical Biochemistry, Ljubljana, Slovenia*

Background: Carcinoids are neuroendocrine tumours that secrete active substances which could cause carcinoid syndrome (CS) and carcinoid heart disease (CHD). Pathogenesis of CHD is not completely understood. AIM: To explore differences in biochemical markers (urine levels of 5-HIAA and serum levels of chromogranin A and TGF-beta1) between two groups of patients with CS (group A with CHD and group B without CHD) through which we wanted to gain more insight in the pathogenesis of CHD and confirm the diagnostic value of biochemical markers for CHD. METHODS: The prospective study included 12 pts who were at the time of study diagnosed and treated for CS. Group A included 5 pts and group B 7 pts. All pts but 1 had already started with octreotid treatment before our echocardiographic analysis were made. 5-HIAA (mg/24h urine), chromogranin A (μg/l) and TGF-beta1 (μg/l) were measured for each patient at the time of echocardiographic analysis (control measures); pre-treatment measures of 5-HIAA before treatment with octreotide were also obtained. RESULTS: The two groups did not differ in duration of symptoms of CS (53 vs. 50 months). The most common echocardiographic findings in group A were morphologic changes of the tricuspid valve with tricuspid regurgitation. Group A had significantly higher concentrations of chromogranin A (median 216 vs. 36; $p<0.05$). The correlations between levels of chromogranin A and 5-HIAA were statistically significant both for the time before (Kendall Tau= 0.49; $p<0.05$) treatment with octreotide and for the time when echocardiographic analysis were made (Kendall Tau= 0.69; $p<0.01$). Only control (median 600 vs. 70) but not the pre-treatment measures (median 219 vs. 33) of 5-HIAA between two groups were statistically significant ($p<0.01$). Decrease of 5-HIAA levels after treatment with octreotide was insignificant. The two groups did not differ in serum levels of TGF-beta1 (median 23.5 vs. 39.4). CONCLUSIONS: Appearance of CHD is not dependent on the duration of symptoms of CS. Chromogranin A and 5-HIAA are useful in diagnostics and follow-up for patients with carcinoid syndrome and carcinoid heart disease. The levels of 5-HIAA in our study confirm the important role of serotonin in pathogenesis of CHD. Treatment with octreotide does not cause a significant fall in the 5-HIAA concentrations and apparently has no impact on development of CHD. Serum concentrations of TGF-beta1 were not found to be helpful in diagnostics of CS or CHD.

P2419 Outcome of percutaneous mitral baloon valvuloplasty: comparison of the inoue and retrograde non-transseptal techniques, from a single center

I. Iakovou, G. Pavlides, V. Voudris, G. Athanasopoulos, G. Karatasakis, A. Manginas, D.V. Cokkinos. *Onassis Cardiac Surgery Center, 1st Cardiology Department, Athens, Greece*

Introduction: The transseptal Inoue (IN) and to a lesser extend retrograde non-transseptal (RNT) techniques are established procedures for percutaneous mitral balloon valvuloplasty (PBMV) in patients with mitral stenosis. However, a head to head comparison of these two techniques, especially from a single center, has not been reported yet.

Methods: 72 consecutive patients (IN:35 and RNT: 37) underwent PMBV in our clinic from October 1993 to December 1999. All baseline and procedural characteristics were compared, as well as the immediate and long-term (42 ± 12 months) outcome of the pts.

Results: Baseline characteristics were similar in the two groups. Immediately after the PMBV, mitral valve area (MVA) increased from 1.04 ± 0.16 to 1.6 ± 0.3 in group A and from 1.06 ± 0.23 to 1.55 ± 0.3 in group B. There was a higher percentage of mild mitral regurgitation (MR) after the RNT technique, compared with the IN ($p=0.034$). A successful immediate result was achieved in 91% of patients in IN and 89% of patients in RNT group. Mean fluoroscopy time was 31 ± 16.1 in IN and 39 ± 11 min in RNT ($p=0.024$). There were no procedural deaths in either group. After discharge, major adverse cardiac events (MACE: mitral valve replacement, repeat BMV) occurred in 3 (8%) pts in IN and 5 (13.5%) patients in RNT group (NS). There were no deaths at follow-up. Follow-up echocardiographic assessment of MVA revealed no significant change.

Conclusions: The IN and RNT techniques are comparable regarding the achieved MVA with slightly more frequent MR post-RNT PBMV. The IN requires significantly less fluoroscopy time. MACE and event free survival rates at follow-up were similar in the two groups.

P2420 Prevalence of rheumatic heart disease among schoolchildren in urban areas of Hamedan province, situated in the west of Iran

M.J. Mahmoudi[1], N. Rezaei[2], M. Mahmoudi[1]. [1]*Tehran University of Medical Sciences, Tehran, Iran (Islamic Republic of);* [2]*Tehran University of Medical Sciences, Tehran, Iran (Islamic Republic of)*

Background and Objectives: Rheumatic heart disease(RHD), the most important cardiovascular disease, continues to be a common health problem in the developing world, causing morbidity and mortality among both children and adults. There are only a few population surveys available in Iran to determine the prevalence of RHD. This survey was undertaken to estimate its prevalence among schoolchildren in urban areas of Hamedan province, situated in the west of Iran.
Material and Methods: The study was a cross sectional survey, carried out by a specially trained medical team headed by a cardiologist. The study involved all of the schoolchildren (7-18 years of age) from 7 city of Hamedan province in 1992. Diagnosis of rheumatic heart disease was confirmed only after Doppler echocardiography in suspected cases.
Results: A total of 167,786 children on the school register (104,242 boys and 63,544 girls) were examined generally and specifically for evidence of RHD. Out of the 167,786 children screened, 714 were suspected cases and 23 were confirmed cases of RHD (14 boys and 9 girls), giving an overall prevalence rate of 1.37 per 10000 children with no significant difference among the age groups of 7-11, 12-14 and 15-18 years. Only sixteen of the 23 patients were aware of their disease (69.6%). The mitral valve was affected in all of the cases. Out of 23 cases of RHD, isolated mitral regurgitation(MR) was present in six (26%), combined MR and mitral stenosis (MS) in nine (39.1%), combined MS and aortic insufficiency(AI) in one, and combined MR and MS and AI in four patients (17.3%). Also one patient had acute rheumatic carditis. The tricuspid valve and pulmonary valve involvement were not seen in any cases.
Conclusion: This study revealed a lower prevelance of RHD than that, reported in most earlier studies from developing countries. The lack of patient's awareness about their disease, noted among the patients revealed that public health education is necessary. Also, regular surveys are needed to identify new cases and to ensure secondary prophylaxis; thereby preventing the progression and the severity of the valvular lesion.

P2421 Herpes simplex virus type 1 infection in rheumatic heart disease

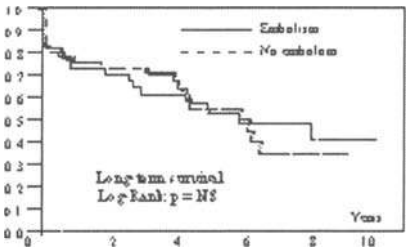
L. Archard[1], Z. Pan[2], Y. Ji[3], H. Zhang[1], Y. Li[1]. [1]*Imperial College Faculty of Medicine, Division of Biomedical Sciences, London, United Kingdom;* [2]*Zhongshan Hospital, Fudan University, Department of General Practice, Shanghai, China;* [3]*Zhongshan Hospital, Fudan University, Department of Pathology, Shanghai, China*

Background: Rheumatic heart disease (RHD) is the most important sequela of rheumatic fever: evidence that streptococcal infection is the etiological agent is strong, but indirect. Herpes simplex virus type 1 (HSV-1) can establish latent infection in autonomic ganglia innervating cardiac valves and virus reactivation produces mucocutaneous lesions within the distribution of the affected nerve. We hypothesized that reactivation of HSV-1 in autonomic nerves, by infection, stress or trauma, may involve cardiac valves and contribute to the onset and development of rheumatic valvular disease.
Materials and Methods: Formalin-fixed, paraffin-embedded valvular samples from 17 patients diagnosed clinically and histologically with RHD were investigated for HSV-1 infection. HSV-1 antigen in tissue was detected by immunohistochemistry with an HSV-1-specific monoclonal antibody and the EnVision detection system (DAKO). Part of the glycoprotein D gene sequence of HSV-1 was amplified by nested PCR using HSV-1 specific primers. PCR products were characterized by agarose gel electrophoresis and direct nucleotide sequencing. b-globin gene sequences were amplified from each sample at the same time, as reagent control. Valvular tissues collected at autopsy from 5 cases of sudden death without myocardial or valvular lesions served as a comparison group. HSV-1-infected lung tissue was used as positive control.
Results: HSV-1 antigen was detected in valvular tissues from 14 of 17 patients. Five of these 14, but no antigen-negative sample, were positive also for HSV genomic DNA. Nucleotide sequence of nPCR-amplified HSV DNA, determined by automated cycle sequencing in both orientations, was homologous with the HSV-1 glycoprotein D gene. HSV-1 antigen was present also in one case of sudden death but HSV-1 DNA was not found in tissue from any case in the comparison group. Results from reagent and positive controls were as anticipated.
Conclusions: This is the first study to show the presence of HSV-1 antigen and genomic DNA in valvular tissues, supporting the concept of HSV-1 involvement in rheumatic valvular disease. HSV-1 infection may damage valves directly or act with additional etiological factors such as prior streptococcal pharyngitis, leading to initial and recurrent episodes of rheumatic heart disease.

P2422 Long-term prognosis of infective endocarditis. Are embolic phenomena associated with a higher mortality?

L. Moura, J.L. Zamorano, R. Moreno, C. Almería, J.L. Rodrigo, A. Aubele, D. Herrera, L. Sánchez-Harguindey. *Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain*

Infective endocarditis (IE) may be complicated with embolic phenomena (EP). However, it is not clear if EP imply itlself higher mortality in these patients. Aim of the study was to elucidate whether EP in IE are associated with higher long-term mortality.
We studied and followed-up for a mean of 3.1 years (range 0.5-15) 150 patients with IE. Of them, 65 (43%) had any EP at clinical presentation or during hospitalization.
Patients with EP were younger (46±18 vs. 55±18 yr, $p<0.01$) and more often drug abusers (38% vs. 19%, p=0.02), and had less frequency of heart failure (29% vs. 50%, $p<0.01$), S. aureus as etiological agent (44% vs. 23%, p=0.02), and mitral involvement (35% vs. 21%, $p<0.05$).



Long-term outcome.

Prognosis of patients with vs without EP

		Embolisms	No embolism	p
During hospitalization	Mortality	19%	15%	NS
	Surgery	36%	53%	0.03
1-year	Mortality	21%	26%	NS
	Surgery	39%	58%	0.01
5-year	Mortality	43%	45%	NS
	Surgery	49%	62%	0.01

Thus, EP are not associated with higher mortality neither during hospitalization nor at long-term.

Day 4

Tuesday 3 September 2002

FAMILIAL ARRHYTHMIAS: THE DOOR TO THE GENETIC BASIS OF SUDDEN DEATH

2515 Genotype/phenotype correlation in catecholaminergic ventricular tachycardia: evidence for heterogeneous clinical presentation

C. Napolitano[1], R. Bloise[1], M. Memmi[1], F. Drago[2], G. Vignati[3], B. Colombi[1], S.G. Priori[1], L. De Simone[4]. [1]*Salvatore Maugeri Fondation, Molecular Cardiology Dept., Pavia, Italy;* [2]*Ospedale Bambin Gesù, Pediatric Cardiology Dept., Rome, Italy;* [3]*Niguarda Hospital, Cardiology, Milan, Italy;* [4]*Meyer Hospital, Pediatric Cardiology, Firenze, Italy*

We recently demonstrated that mutations in the cardiac ryanodine receptor gene (RyR2) cause an inherited form of cardiac arrhythmia and sudden death, called catecholaminergic polymorphic ventricular tachycardia (CPVT). CPVT is inherited as an autosomal dominant trait and its phenotype is characterized by polymorphic ventricular tachycardia triggered by physical activity or emotional stress. RyR2-mutations most likely cause a "gain of function" leading to intracellular calcium overload predisposing to the development of delayed afterdepolarization-mediated triggered arrhythmias. Here, we report the first assessment of genotype-phenotype correlations in patients with (RyR2-CPVT) and without (nonRyR2-CPVT) mutations on the RyR2 gene. Thirty probands (PB) and of 118 family members (FM) were evaluated and molecular screening of the RyR2 gene was performed. The clinical evaluation of PB showed a heterogeneous morphology of the ventricular tachycardia (VT): 14/30 bidirectional VT(bVT), 12/30 polymorphic VT (pVT) and 4/30 catecholaminergic idiopathic ventricular fibrillation (cIVF). RyR2 mutations were identified in 14/30 PB and in 9 FM (4 silent mutation carriers). All the mutations identified involved highly conserved and functionally relevant regions of the RyR2 channel. When CPVT patients with and without mutations in the RyR2 gene are compared it is shown that no difference is present in the distribution of the VT morphologies and in the history of sudden cardiac death among family members (37% and 31% in RyR2-CPVT and in non RyR2-CPVT families respectively). Interestingly however RyR2-CPVT patients develop events at younger age than non RyR2-CPVT (8±2 vs. 20±12 years; $p < 0.004$). Among RyR2-CPVT patients, male gender is a strong risk factor for syncope (Relative Risk 4.2). Based on these data, that represent the first genotype-phenotype correlation study in CPVT on the largest reported series of patients it may be concluded that: 1) The morphology of ventricular tachycardia in CPVT may be either bi-directional or polymorphic. 2) A defect in the RyR2 gene is the underlying substrate of adrenergically-mediated idiopathic ventricular fibrillation. 3) RyR2 mutations account for approximately 45% of all cases of CPVT. 4) RyR2 mutation carriers present cardiac events at younger age and male gender is a risk factor for the development of cardiac arrhythmias.

2516 Codon 218 within the KCNJ2 gene is a hot-spot for mutation in Andersen Syndrome

C.R. Bezzina[1], L. Bok[2], I.M. van Langen[3], L. Beekman[1], P. Helderman[4], M.M. Mannens[3], N.A. Blom[5], A.A.M Wilde[1]. [1]*AMC, Experimental Cardiology, Amsterdam, Netherlands;* [2]*St Joseph Hospital, Pediatrics, Veldhoven, Netherlands;* [3]*AMC, Clinical Genetics, Amsterdam, Netherlands;* [4]*LUMC, Clinical Genetics, Leiden, Netherlands;* [5]*LUMC, Pediatric Cardiology, Leiden, Netherlands*

Introduction: Andersen syndrome (AS) is characterised by the triad: cardiac arrhythmias, periodic paralysis (PP) and dysmorphic features. It has recently been associated with mutations in the KCNJ2 gene that encodes the inward rectifying potassium channel Kir2.1. In this study: 1) we carried out mutational analysis in KCNJ2 in 2 families with features of AS. The families had predominantly the cardiac phenotype and mild dysmorphic features. Neither family had PP. 2) We tested the possibility that mutation in KCNJ2 could form the basis of prolonged QT in patients (n = 18) presenting solely with prolonged QT-interval (in the absence of PP and dysmorphic features; i.e. congenital Long QT syndrome patients; cLQTS), in whom mutation in the known cLQTS genes (KCNQ1, KCNH2, KCNE1, KCNE2, SCN5A) has been excluded.
Methods: Mutational analysis was carried out on the entire coding region of the gene by sequencing of PCR-amplified fragments.
Results: 1) Two different mutations, both within codon 218 were identified in the two families with features of AS: a CGG->TGG and a CGG->CCG, leading to the substitution of Arg 218 into Trp and Pro respectively. The mutations segregated with features of the disorder in the two families. 2) No mutations were identified within the cohort of cLQTS patients.
Conclusions: 1) Besides the two families presented herein, mutation at codon 218 within KCNJ2 has been reported in two other families with AS. One of these reported mutations results in the same nucleotide substitution (CGG->TGG; resulting in R218W) as in one of our families. Taken together, it appears that this codon represents a hot-spot for mutation. This could relate, at least in part, to the fact that this codon contains a CpG motif, a known hot-spot for mutation. Furthermore, the fact that the two families presented here displayed predominantly the cardiac phenotype together with mild dysmorphic features and no PP, underscores the variable expressivity of the disorder. 2) However, the fact that no mutations were identified in the cLQTS cohort implies that mutation in KCNJ2 does not form the basis for QT-prolongation in patients presenting solely with prolonged QT-interval, i.e. in the absence of PP and dysmorphic features.

2517 Female predominance and increased maternal transmission in genotyped families affected by long-QT Syndrome

M. Imboden[1], I. Denjoy[2], M. Berthet[1], V. Fressart[3], D. Klug[4], B. Hainque[3], J. Feingold[5], P. Guicheney[1]. [1]*Hopital Pitié-Salpêtrière, INSERM U523, Paris, France;* [2]*Hopital Lariboisière, Service Cardiologie, Paris, France;* [3]*Hopital Pitié-Salpetrière, Service de Biochimie, Paris, France;* [4]*Hopital Cardiologique, Lille, France;* [5]*Pitié-Salpetrière, Institut de Myologie, Paris, France*

Introduction: Female predominance has repeatedly been observed in long-QT syndrome (LQTS) which is apparently not in accordance with Mendelian transmission of an autosomal dominant character. We thus analyzed the segregation of paternally versus maternally inherited LQTS mutations in order to state whether a disequilibrium could explain the female predominance.
Methods: 97 French LQTS families recruited by a single index case were found to carry mutations in KCNQ1 or KCNH2 (LQT1: n=64; LQT2: n=33). Analysis was performed only on genotypically ascertained individuals with genotyped ascendants and/or descendants, as well as completely genotyped sibships (n=488 for LQT1 and n=186 for LQT2). Single ascertainment correction of the proband family nucleus was done according to Li (1961).
Results: Sex ratio analysis: The female predominance among the probands was marked (67%, for LQT1, n=43 and 66% for LQT2, n=22), while it was less evident, after single ascertainement correction, among the genotyped subpopulations presenting 58% of female mutation carriers for LQT1 and 56% for LQT2.
Transmission analysis: Analysis of the maternal versus paternal inheritance of the mutation revealed a higher incidence of maternal transmission (61% for LQT1, n=64, 59% for LQT2, n=37) than paternal one. We examined in more detail the segregation and sex ratio of the offspring of LQT1 and LQT2 carriers and noted a pronounced segregation disequilibrium in the offspring (n=115) of female LQT1 carriers. Indeed, the distribution of the offspring was the following: 41 affected females, 23 unaffected females, 27 affected males and 24 unaffected males, showing a significant excess of affected female offspring (60,3% affected females vs 39.7% affected males, $p < 0, 05$). In constrast, the offspring (n=88) of male LQT1 carriers showed a cassical Mendelian distribution. Due to the small number of LQT2 carriers(n=23), more data need to be collected to conclude for this subgroup.
Conclusions: We confirmed a female predominance not only among probands, but also among proband-independent LQT1 and LQT2 carriers. A segregation disequilibrium in the transmission pattern of LQT1 mutations was found and clearly revealed a tendency for female LQT1 carriers to transmit the deficient trait more often to the female than male offspring. The physiological mechanism underlying such a selection of female versus male is yet unknown.

2518 Complete sequencing of Ryanodine Receptor 2 gene in isolated cases affected with effort-induced polymorphic arrhythmias

A. Bagattin[1], A. Nava[2], B. Bauce[2], K. King[1], C. Basso[3], G. Thiene[3], G. A. Danieli[1], A. Rampazzo[1]. [1]*Laboratory of Human Genetics, Dep. of Biology, Padova, Italy;* [2]*University of Padova, Department of Cardiology, Padova, Italy;* [3]*University of Padova, Department of Cardiovascular Pathology, Padova, Italy*

Effort-induced polymorphic ventricular arrhythmias (PVA) consist of left and right bundle branch block morphology and different axis deviation, which appear in response to vigorous exercise. Coupling interval of first premature beats is never short.
Ryanodine receptor gene type 2 (RYR2) mutations have been associated to this arrhythmias, which occur either in subjects with apparently normal heart or in patients affected with arrhythmogenic right ventricular cardiomyopathy type 2 (ARVD2).
We detected 7 different RYR2 mutations in 10 apparently unrelated subjects affected with PVA (in three instances, the same mutation was found in two patients). In 9 cases, the mutation was detected in additional family members, thereby confirming familial inheritance; in one case, familiarity could not be assessed due to the small size of the family.
In additional 3 subjects affected with PVA, considered to be isolated cases due to the lack of affected relatives, the complete sequencing of the RYR2 gene was performed. All the 105 exons were PCR amplified from genomic DNA and directly sequenced in both strands. Although several single-nucleotide polymorphisms (SNPs) were observed, no mutations were identified. The negative results obtained in these 3 isolated cases support the hypothesis of heterogeneity of PVAs.

2519 Overexpression of A1 and A3 adenosine receptors causes bradycardia and atrioventricular nodal conduction delay-a molecular model for sinus node dysfunction?

P. Kirchhof[1], L. Fabritz[2], L. Fortmueller[2], G. P. Matherne[3], J. A. Auchampach[4], W. Haverkamp[2], J. Neumann[5], P. Boknik[5]. *[1]University Hospital Münster, Cardiology and Angiology Dpt., Münster, Germany; [2]Cardiology and Angiology and IfA, Münster, Germany; [3]University of Virginia, Pediatrics and Cardiovasc. Res. Center, Charlottesville, USA, United States of America; [4]University of Louisville, Department of Medicine (Cardiology), Louisville, United States of America; [5]University Hospital Münster, Pharmacology and Toxicology, Münster, Germany*

The molecular causes of sinus node dysfunction and the often associated AV nodal conduction disturbances are not well understood. Acute administration of adenosine suppresses AV nodal conduction and affects sinus node function. We studied whether a chronically enhanced response to adenosine changes sinus nodal and AV nodal function.

Three months old mice with cardiac-specific overexpression of A1 adenosine receptor (A1AR+) and mice with high-level cardiac-specific overexpression of A3 adenosine receptor (A3AR+) and their wild-type littermates (WT) were instrumented with a telemetric Holter ECG system. The ECG was continuously analyzed during defined periods of normal activity, during a standardized exercise protocol (4 minutes swimming), and 1 hour after exercise. Pertussis toxin (PTx, 150microg/kg body weight, n=4 A1AR+, 3 WT) was injected intraperitonally to block the Gi-adenosine signaling pathway. Atrial size was measured by biplane echocardiography.

A1AR+ mice (n=7) had lower mean heart rates during exercise (580±47 vs 698±84*, all values given in beats/min as mean±SD, * indicates $p<0.05$), and 1h after exercise (495±38 vs 592±61*). During normal activity, mean heart rate was not significantly different (414±47 vs 455±60), but the difference between the lowest and highest heart rate was smaller in A1AR+ mice (38±9 vs 123±64*). Maximal heart rate was lower in A1AR+ mice during all protocol parts (normal activity: 496±40 vs 522±55*, exercise: 640±37 vs 768±73*, 1hr after exercise: 638±45 vs 798±57*). Minimal heart rate was not different during normal activity (361±64 vs 405±75), 1hr after exercise (422±37 vs 455±63), or during exercise (515±43 vs 540±115). PTx reversed bradycardia in AR1+ mice after 36-48 hrs. Atrial size was not different between A1AR+ and WT hearts.

A3AR+ mice (n=3) also had lower mean heart rates during normal activity (393±100 vs 517±55*), exercise (539 ±50 vs 756±28*), and 1h after exercise (470±75 vs 671±61*). Maximal and minimal heart rates were lower in A3AR+ mice during all protocol parts (normal activity: Max 438±35 vs 558±41*, min 360±135 vs 449 ±49*, exercise: Max 654±39 vs 853±114*, min 231±34 vs 459±57*, 1hr after exercise: Max 667±15 vs 834±31*, min 381±68 vs 623±80*). In A3AR+ mice, PQ interval was dramatically increased at rest (66±2 vs. 32±5ms*), and also during exercise (36±4 vs. 23±5ms*). Left atrial size was enlarged in A3AR+ mice (2.0±0.2 vs 1.6±0.1mm*).

Conclusions: Increased function of adenosine receptors in mice may be a molecular model for sinus node dysfunction in man (Supported by SFB 556, project Z2).

CATHETER ABLATION OF ISCHAEMIC VENTRICULAR TACHYCARDIA

2521 Ventricular tachycardia ablation during sinus rhythm: importance of an isthmus and relation to the presence of exact pace-mapping

S. del Castillo, A. Arenal, E.G. Torrecilla, J. Almendral, M. Ortiz, H. Sousa, D. Pascual, R. Yotti. *Hospital Gregorio Marañón, Servicio de Cardiología, Madrid, Spain*

Background: Substrate ablation of ventricular tachycardia (VT) can be a useful tool to treat unmappable VT.

Methods AND RESULTS: 22 Patients with cardiomyopathy referred for recurrent ventricular tachycardia ablation were evaluated. 19 Patients had ischemic cardiomyopathy and 3 patients had nonischemic cardiomyopathy. An electroanatomic system (CARTO, Biosense) was used to map the left or right ventricle during stimulation from a catheter situated in the right ventricular apex. We investigated the feasibility of identifying a conduction isthmus between 2 scar zones, its relationship with the tachycardia circuit and whether this could be used to locate successful ablation points. On voltage amplitude maps an amplitude <0.10 mV was defined as scar. A conduction isthmus was defined by the presence of several consecutive electrograms with an amplitude >=10 mV surrounded by 2 scar areas. In 9 patients (0.39) an isthmus could be recognised. Isthmus sites were characteristically zones in which multiple components ventriculograms were recorded. Pace-mapping from these sites exactly reproduced the documented clinical VT (12-lead ECG) in 7 of the 9 patients (0.77) in which an isthmus had been identified. Stimulus-QRS interval was longer than 80 ms in all the cases. Ablation was performed during sinus rhythm. Radiofrecuency was applied at points located inside isthmus zones and around them, sites where exact pace-mapping and late potentials were recorded. In the 2 patients in which mapping couldn't reproduce the clinical tachycardia, substrate ablation was attempt. Successful ablation of the clinical ventricular tachycardia was achieved in 6 of the 9 patients in which an isthmus was present.

Cases with an isthmus between scars

	VTabl successful	VT abl not successful	TOTAL
EPM	5	2	7
NEPM	1	1	2
TOTAL	6	3	9

EPM:exact pace-mapping (12 ECG-lead). NEPM: absence of an exact pace-mapping. VT abl: Ventricular tachycardia ablation.

Conclusions: An isthmus is detected in 39% of cardiomyopathy patients referred for VT ablation. Multiple component electrograms are recorded in these areas. Mapping from points inside the isthmus reproduces VT in 77% of them. Detection of conduction isthmus can be useful for VT ablation during sinus rhythm.

2522 Do all ventricular tachycardia patients need an ICD? Results from the Leiden VT ablation trial

A.E. Borger van der Burg, N.M.S de Groot, L. van Erven, M. Bootsma, E.E. van der Wall, M.J. Schalij. *Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Introduction: ICD guidelines recommend implantation of an ICD in the majority of VT pts. Radiofrequency catheter ablation may be an alternative treatment option for selected pts. We studied long term outcome of catheter ablation procedures in pts with VT. Results: One hundred and fifty-one consecutive pts (122 male, age 57±16 years) with drug refractory VT were referred for RFCA. Underlying heart disease: ischemic heart disease (IHD, 89, 59%); arrhythmogenic right ventricular cardiomyopathy (ARVC, 32, 21%); idiopathic VT (IDIO, 30, 19%; LV: 9, 30%; RV: 21, 70%). Ablation was performed using standard mapping and ablation techniques. Results: Three hundred and six different VT's were treated (cycle length 334±87 ms, 2.0±1.4 VT/pt). Procedural success (non-inducibility of VT after RFCA) was achieved in 126 (83%) pts (70 (79%) IHD pts; 28 (88%) ARVC pts; 27 (93%) IDIO pts). Procedure-related complications (<48 hrs after RFCA) occurred in 11 (7%) pts: death 3 (2.0%); cerebrovascular accident 2 (1.3%); complete heart block 4 (2.6%); and pericardial effusion 3 (2.0%). Before discharge, 25 (17%) pts received an Implantable Cardioverter Defibrillator device (ICD). During follow-up (34±11 mos), recurrence of VT occurred in 38 (26%) pts. VT recurrences occurred in 19% of the successfully ablated pts and in 64% of the non-successfully ablated pts ($p < 0.001$). During follow-up, 12 (8%) pts died (all IHD, 8 pts due to heart failure, 1 pt died due to an unknown cause, 3 pts due to a noncardiac cause). Conclusion: RFCA of VT can be performed with a high degree of procedural success (83%). The long-term outcome of successfully ablated pts is promising with a 75% relative risk reduction compared to non-successfully ablated pts. During follow-up only 1 pt died suddenly supporting a selective ICD implantation approach in pts with hemodynamically stable VT.

2523 Linear ablation of ventricular tachycardia during sinus rhythm after identification of the infarcted area by electroanatomical voltage mapping

L. Rodriguez[1], C. Timmermans[1], S. Willems[2], C. Weiss[2], J. Kautzer[3], C. Pandozzi[4], P. Adragao[5], S. Schepel[6]. [1]*Academic Hospital Maastricht, Department of Cardiology, Maastricht, Netherlands;* [2]*University Hospital Eppendorf, Hamburg, Germany;* [3]*IKEM, Prague, Czech Republic;* [4]*Ospedale San Filippo Neri, Rome, Italy;* [5]*Hospital Santa Cruz, Carnaxide, Portugal;* [6]*Biosense Webster (Europe), Waterloo, Belgium*

Background: RF ablation of ischemic ventricular tachycardia (VT) guided by conventional activation mapping is difficult in pts having poorly tolerated VT and multiple morphologies.
Methods: We evaluated 21 pts (66±10 years, 20 men) with ischemic VT, LVEF: 33±9.6%. One pt was excluded from the study. Thirteen pts had an ICD and drug refractory VT with frequent ICD shocks (1 to 62) before procedure. The remaining 6 pts had frequent episodes of VTs (1.45/pt). All pts underwent detailed catheter mapping during sinus rhythm. Normal endocardium was defined by amplitude>1.5mV. Dense scar was defined by amplitude<0.05mV. Deliniation and size of the densely scarred myocardium was assessed using the 3-D color voltage map display (CARTO, Biosense Webster). Point-by-point RF lesions (max. 45°C [ThermoCool cath.)], 70°C [standard cath.], during max 90") to create linear lesions (LL) (around the scar, lines connecting scars, lines started from the exit point (determined by pacemapping) to normal myocardium) were performed. Site of LL was delinated by 12-lead pacemap matching VT. No drug therapy was added after ablation. ICD interrogation or visits to the First Heart Aid documented VT recurrence.
Results: Fifty-two VTs were induced in 20 pts (2.6/pt). The clinical VT was induced prior ablation in 18 pts (0.9/pt); cycle length:391±82 ms. Point-by-point RF LL applied in the left ventricle ranged from 1 to 3, average lenght = 33mm (range 9-55 mm). No adverse events were observed. In four additional patients an ICD was implanted after the procedure. Acute success was obtained in 19/20 pts (95%). In-hospital recurrence occurred in 2 pts (10%). Seventeen pts completed the 6-month follow-up. Ten pts (59%) have been free of VT. Seven pts had VT reccurrences, but these are less frequent than before ablation.
Conclusions: Linear ablation around the scar, lines connecting scars or started from the exit point of the VT to normal myocardium appears to be an effective approach to control frequent, drug refractory ischemic VT.

2524 The use of a percutaneous non-contact mapping system in targeting human ventricular tachycardia ablation: results from the first 50 patients

O.R. Segal, A.W. Chow, R.J. Schilling, V. Markides, N.S. Peters, D.W. Davies. *Imperial College, St. Mary's Hospital, National Heart & Lung Institute, London, United Kingdom*

The predominant treatment for human ventricular tachycardia (VT) remains palliative, utilising internal cardioverter-defibrillators (ICDs) and/or drugs. RF catheter ablation offers a potential cure but mapping the diastolic pathway (DP) of VT circuits in patients with structural heart disease has proved difficult with conventional techniques. A percutaeous, non-contact endocardial mapping system was used to guide ablation in 50 consecutive patients (age 61.7±11.8 years (mean±SD), 9 female) with VT. All patients presented with VT refractory to antiarrhythmic therapy and 78% had ischaemic heart disease. Results: 153 of 176 morphologies of VT (87%) were mapped (3.5 VTs per patient) of which 45 were clinical VT morphologies (29%). Successful ablation, defined as termination of VT or morphological change, followed by failure of inducibilty was completed in 44 patients (88%). 78/153 VT were ablated, the position of successful ablation always located within the DP. An exit site was identified in 49 out of 50 of patients (98%). DP activity was seen in 85/153 VT morphologies (56%), complete reentrant circuits were identified in 24 VT (16%), and partial DP activity mapped in a further 61 VT, traced over 27±22% of the diastolic interval (range 5-95%). 6.6±6.8 RF applications (range 1 to 34/patient) were used to ablate a total of 78 VT (4.2 applications per VT ablated) of which 22 VT were ablated by 18 RF applications on common shared diastolic pathways. No patient suffered a cardiac complication as a result of deployment of the non-contact mapping system. Follow up: 30 patients (60%) have had no recurrence of VT over follow up of 12.9±9.3 months (range 0.2 to 3.6 years). There has been a recurrence of 6/78 targeted VT (7.7%). 13 patients had ICD therapy histories available before and after ablation. ICD shock frequency was reduced from 9.1±6.3 per month (range 2-21) to 0.2±0.5 per month ($p<0.05$) over mean 14.2±15.5 months. Devices were implanted post ablation in 8 patients for fast VT/VF, with no arrhythmia detected or therapy delivered to date (mean follow-up approx 18 months). Conclusions: These data show that identification of DP activity as a target for RF catheter ablation using this system can be achieved safely and with a high degree of success. In addition, VT recurrence necessitating ICD therapy delivery, is significantly reduced.

2525 Catheter ablation of ventricular tachycardia using electroanatomical mapping and irrigated ablation technology: first results of the EuroVT study

G. Hindricks[1], M. Volkmer[2], S. Furniss[3], V. Kühlkamp[4], C.H. De Chillou[5], D. Lacroix[6], J. Almendral[7], D. Caponi[8] on behalf of Euro-VT investigators. [1]*University Leipzig Heart Center, Electrophysiology, Leipzig, Germany;* [2]*St. Georg hospital, Cardiology, Hamburg, Germany;* [3]*Freeman hospital, cardiology, Newcastle-upon-Tyne, United Kingdom;* [4]*University hospital, cardiology, Tübingen, Germany;* [5]*hopital Central, cardiology, Nancy, France;* [6]*hopital cardiologique, cardiology, Lille, France;* [7]*university hospital Gregorio Maranon, cardiology, Madrid, Spain;* [8]*Ospedale Civile, cardiology, Asti, Italy*

The Euro-VT-Study is a prospective multicenter study assessing the efficiency and safety of electroanatomical mapping (Carto, Biosense Webster) and saline irrigated ablation technology (Thermocool, Biosense Webster) for ablation of chronic recurrent ventricular tachycardia (VT). In 8 institutions, a total of 58 pts. (84% male, 64 ± 8.6 yrs.) were prospectively enrolled in the study. All pts. had coronary artery disease and remote myocardial infarction, left ventricular ejection fraction measured 29 ± 12%. The pts. had a mean of 50 ± 94 episodes of VT prior to the ablation session (range: 1 - 380, median 12 episodes), 12/58 pts. (20%) were in incessant VT. The treatment strategy for ablation was based on the induction of multiple linear lesions through target sites defined by activation mapping or complete isolation of scar areas defined by voltage mapping in the majority of pts.. A mean of 18 radiofrequency applications (range 4 - 33, duration 76 ± 31 sec.) terminated 84% of target VT's or rendered these VT's non-inducible. Major adverse events occurred in 3/58 pts. (5,2%). Two months follow-up data are complete for 27 pts.. During this early follow-up period, 10 of 27 pts. (37%) developed a recurrence of target VT or new VT's not targeted during the ablation session.
In this prospective multicenter study using electroanatomical mapping and saline irrigated ablation to treat ventricular tachycardia, an acute success rate of 84% could be achieved. However, early recurrence rate of any ventricular tachycardia during the first two months after the procedure was 37%. Detailed analysis and comparison of the different ablation strategies applied in this prospective study may provide further information to define the role of catheter ablation for the treatment of chronic recurrent ventricular tachycardia.

2526 Is the implantable cardiac defibrillator associated with a higher ventricular tachycardia recurrence after radiofrequency catheter ablation?

M. Ortiz, J. Almendral, A. Arenal, E. Gonzalez-Torrecilla, S. del Castillo, D. Pascual. *Hospital Gregorio Maranón, Department of Cardiology, Madrid, Spain*

Background: Some studies suggest a higher incidence of ventricular tachycardia (VT) recurrence in patients (P) with an implantable defibrillator (ICD) comparing with similar P without an ICD.
Objective: To study the influence of the ICD in the assessment of ischemic VT recurrence in our population of P who were acutely successful treated with radiofrequency catheter ablation (RFA).
Methods: Thirty-seven consecutive P (32 male, aged 63±10 years, left ventricular ejection fraction (LVEF) 33±11%) with ischemic VT in whom all mappable VTs were acutely successful ablated were included in the study. Ten P (27%) were discharged with an ICD (Group I) and the remaining P did not (Group II). No statistically significant differences were found comparing clinical and electrophysiologic characteristics (age, LVEF, spontaneous VT cycle length and inducibility of non-clinical VT at discharge) between both groups. ICD was implanted according to the physician criterion.
Results: After a long-term follow-up period (37±26 months) 12 P (32%) had VT recurrence. The presence of an ICD was significantly associated with a higher VT recurrence rate (20%/year in group I vs 7%/year in group II, $p<0.05$). Sudden death was 1%/year in group II (1 P). No statistical differences were found comparing LVEF (33% vs 34%), inducibility of non clinical VT at discharge (36% vs 30%), spontaneous VT cycle length (360±70 vs 370±79 ms and number of VT episodes previous to radiofrequency ablation (6±6 vs 6±9) between P who recurred and those who did not, respectively. A multivariate analysis, including LVEF, presence of an ICD, inducibility of nonclinical VT at discharge and number of VT episodes previous to radiofrequency ablation identified only the presence of an ICD as significant and independent predictor of VT recurrence ($p=0.04$, OR=6.7)
Conclusions: An ICD seems to be a predictor for VT recurrence. Given the absence of significant differences in clinical and electrophysiological variables, these results raise the question whether the ICD could overestimate the VT recurrence rate by treating VTs that could be non sustained.

DRUG TREATMENT OF ATRIAL FIBRILLATION

2527 Proarrhythmic events and mortality in the "Prevention of Atrial Fibrillation after Cardioversion" (PAFAC) trial

E.G. Vester[1], T. Fetsch[2], L. Seipel[3], G. Breithardt[2] on behalf of PAFAC study group. [1]*Evangelic Hospital Duesseldorf, Cardiology, Duesseldorf, Germany;* [2]*University of Muenster, Cardiology and Inst. Arterioscl. Res., Muenster, Germany;* [3]*University of Tuebingen, Cardiology, Tuebingen, Germany*

Purpose of the study: The PAFAC trial addressed in patients with chronic atrial fibrillation (CAF) after successful direct current (DC) cardioversion (CV) the efficacy and safety of two commonly used antiarrhythmic drugs.
Methods used: 848 pts were randomised after DC-CV to either sotalol (S)(383 pts), quinidine plus verapamil (QV)(377 pts) or placebo (P)(88 pts). Study endpoint was the recurrence of CAF. All pts transmitted daily ECGs by event recorder (Tele-ECG) and performed Holter-ECGs. An independent critical event committee (CEC) reviewed all serious adverse events (SAE).
Summary of results: 20 pts (23%) in the placebo (P) group, 94 pts (25%) under S and 92 pts (24%) under QV presented SAE. The total number of SAE of 'special interest' except of death amounted to 31(3,6%) and were distributed to the P-, S- and QV-group as follows: Syncope: 1(1,1%); 3(0,8%) and 7(1,9%), TdP-tachycardia: 0; 9(2,3) and 0, ventricular fibrillation (VF):0; 2(0,5%) and 1(0,3%) and ventricular tachycardia (VT): 2(2,9%); 2(0,5%) and 4(1,1%) – in total: 3(3,4%) in the P-; 16(4,1%) in the S- and 12(3,2%) in the QV-group. 65% of life threatening arrhythmic events happened during the first 4 days. 12 death occurred during the active phase, 9 of them (75%) due to arrhythmic cause: VF (3), sudden cardiac death (5) and bradycardia (1). No death occurred in the placebo group. There were another 12 deaths after the end of the study participation only 2 being primary arrhythmic (17%).
Conclusion: Risk profiles between Sotalol and Quinidine-Verapamil were comparable with the exception of TdP occurring only under Sotalol. Total mortality during and after the active study period was comparable, however arrhythmic death occurred more frequently under study medication.

2528 Exercise performance and variability of ventricular rate in chronic atrial fibrillation patients: effects of digoxin, amiodarone and diltiazem

H.E. Mavrakis[1], E.M. Kanoupakis[1], E.M. Kallergis[1], D.C. Kambouraki[1], E.G. Manios[1], P.E. Vardas[2]. [1]*Heraklion University Hospital, Cardiology Dept., Heraklion, Crete, Greece;* [2]*Heraklion University Hospital, Cardiology, Heraklion, Greece*

Aim: We compared the effects of digoxin, amiodarone and diltiazem on heart rate control and rhythm irregularity during isotonic exercise and daily activities, in patients with chronic atrial fibrillation (AF).
Methods: 59 chronic AF pts were randomly assigned to three treatment groups for 3 months: group A (19 pts, 270 mg oral diltiazem per day), group B (20 pts, 200 mg oral amiodarone per day) and group C (20 pts, 0,25 mg oral digoxin). No differences in clinical and echocardiographic characteristics were observed among the three groups. At baseline and at 3 months follow up, Holter monitor recording and cardiopulmonary exercise test were performed to assess variability of ventricular rate and exercise capacity.
Results: Digoxin, diltiazem and amiodarone significantly decreased the mean ventricular rate during daily activities and peak exercise compared with baseline ($P < 0.05$). There were no significant differences among digoxin, diltiazem and amiodarone in the percentage reduction in ventricular rate during daily activities and peak exercise.
The exercise capacity, as measured by exercise maximal oxygen consumption, minute ventilation, ventilatory equivalent and oxygen pulse, was not significantly changed after treatment with digoxin, diltiazem or amiodarone.
The variability of ventricular rate during daily activities, as measured by standard deviation (SD) of RR intervals and the root mean square of the SD of RR intervals, was significantly reduced only after treatment with diltiazem ($P < 0.05$).AF related patients symptomatology, was also significantly improved after treatment with diltiazem.
Conclusion: Diltiazem, digoxin and amiodarone had similar effects in the control of ventricular rate and in exercise capacity. However, digoxin and amiodarone did not significantly affect rhythm irregularity and AF symptomatology in patients with chronic AF. These variables were significantly improved only after treatment with diltiazem.

2529 Rate control versus rhythm control in patients with nonvalvular chronic atrial fibrillation: the results of HOT CAFE Polish study

G. Opolski[1], A. Torbicki[2], D. Kosior[1], M. Szulc[3], D. Wretowski[1], M. Zawadzka[1], P. Stolarz[1], D. Rabczenko[4]. [1]*Warsaw University of Medicine, Dept. of Cardiology, Warsaw, Poland;* [2]*Institute of Pulmonary Disease, Internal Medicine Dept., Warsaw, Poland;* [3]*Warsaw University of Medicine, Hypertension Dept., Warsaw, Poland;* [4]*Institute of Higiene, Dept. of Biostatistic, Warsaw, Poland*

HOT CAFE Polish Study (How To Treat Patients With Chronic Atrial Fibrillation) was designed to evaluate in randomized, multicenter and prospective manner risks and advantages of two therapeutical strategies in patients (pts) with chronic atrial fibrillation (CAF): rate control vs rhythm control. Inclusion criteria were: pts age 50-75 years, CAF lasting from 7 days up to 2 years with acceptable etiology of arrhythmia related to hypertension, ischemic heart disease and hemodynamic insignificant valvular heart disease or lack of assessable etiology (idiopathic AF). Our study population comprised 205 pts (F/M 71/134; mean age 61±17 year) with mean time of AF duration 273.7±112.4 days. Observation period was 12 months. 101 pts were randomly assigned to rate control (Group I). The treatment goal in this group was optimizing the heart rate (HR) frequency by 24-hours Holter monitoring using calcium antagonists (7.9%), beta-blockers (49.5%), beta-blockers+digoxin (39.6%) or digoxin by itself (3.0%). As thromboembolic prophylaxis were used oral anticoagulants (acenocumarol 74.3%) or antiplatelet drugs (aspirin 19.8%, ticlopidine 1.0%). 104 pts (F/M 33/71) were randomized to sinus rhythm (SR) restoration by DC cardioversion (CV) and its subsequent maintenance with serial antiarrhythmic drug usage (disopiramide, propafenon, sotalol and amiodarone) – rhythm control (Group II). After 12 months SR was presented in 75% pts.
Results: The incidence of hospital admission was higher in group II in comparison to group I (12% vs 74%; $p<0.001$). In both groups significant improvement of heart failure symptoms estimated by NYHA scale was observed during first 2 months ($p<0.02$ and $p<0.001$). In group II exercise tolerability measured by maximal workload during treadmill test significantly improved (5.2±5.1 vs 7.6±3.3 MET; $p<0.0001$). SR restoration influenced improving LV function and increasing value of shortening fraction (29±7% vs 31±7%; $p<0.01$). No thromboembolic complications were observed in pts left with AF. 3 pts suffered ischemic stroke in group II: 2 cases were associated with CV, the third one with late AF recurrence.
Conclusion: HOT CAFE Polish Study did not reveal the significant differences in two treatment strategies in CAF in 12 months follow-up.

2530 Class IC or amiodarone induced atrial flutter during chronic treatment of AF: long-term follow-up of hybrid pharmacological and ablative therapy

A. Bonso[1], A. Rossillo[1], M. Bertaglia[2], A. Proclemer[3], R. Verlato[4], L. Corò[5], S. Themistoclakis[1], A. Raviele[1]. [1]*Umberto I, Department of Cardiology, Mestre (Venice), Italy;* [2]*Civil Hospital, Department of Cardiology, Mirano, Venice, Italy;* [3]*Civil Hospital, Department of Cardiology, Udine, Italy;* [4]*Civil Hospital, Department of Cardiology, Camposampiero, Padua, Italy;* [5]*Civil Hospital, Departmet of Cardiology, Conegliano (TV), Italy*

Patients (pts) chronically treated with amiodarone or class IC antiarrhythmic drugs (AAD) for recurrent atrial fibrillation (AF), can experience conversion of AF to atrial flutter (AFL) in about 5-22%. In these pts, hybrid ablative and pharmacological treatment can be effective in maintaining sinus rhythm (SR). The aim of this study was to evaluate the long-term results of this therapeutic strategy. Methods: From October 1996 to May 2001, 101 pts (75 male, mean age 62±10 years) chronically treated with class IC AAD (57 pts, 56%), amiodarone (37 pts, 36%) or amiodarone plus IC AAD (7 pts, 8%) had conversion of AF into typical AFL. Mean AF duration was 5.4±9 years (median 2 years). A mean of 2±0.9 drugs had been ineffective in maintaining SR. History of more than 10 episodes of AFL was present in 24.7% of pts. Seventy-eight pts (78%) had structural heart disease (14 ischemic, 28 hypertensive, 13 valvular, 23 other). Mean LVEF was 59±10% and mean left atrial diameter was 4.4±0.5 cm. All pts underwent radiofrequency ablation of cavo-tricuspidal isthmus maintaining previous AAD at discharge. All pts underwent baseline evaluation, ECG and Holter monitoring at 1, 3 and every six months. These evaluations were also performed if symptoms were referred. Results: AFL ablation was effective in 97 pts (97%) achieving bidirectional isthmus conduction block. In 3 pts bidirectional isthmus block was reached after a second procedure performed for AFL recurrence. Complications were observed in 2 pts (2%): 1 pts had complete AV block and 1 deep vein thrombosis. After a mean follow-up of 20±11 months 51 pts (50.5%) maintained SR continuing the same drugs as before ablation. AFL recurred in 7 pts (7%). The actuarial recurrence rate of AFL/AF was 31% at 1 month, 46% at 6 month, 49.5% at 1, 2, 3 and 4 years. Conclusions: Hybrid pharmacological and ablative therapy of class IC or amiodarone AFL is effective in preventing recurrence of AFL and AF. During long-term follow-up a low risk of AF recurrences was observed in pts treated with hybrid therapy, that were event-free for more than 6 months after AFL ablation.

2531 Comparison of acute and long-term effects of Ibutilide and verapamil for the management of immediate recurrence of atrial fibrillation

C. Sticherling[1], H. Tada[2], M. Ozaydin[2], H. Oral[2], B.P. Knight[2], S.A. Strickberger[2], F. Morady[2]. [1]*Free University of Berlin-UKBF, Dept. of Cardiology, Berlin, Germany;* [2]*University of Michigan Medical Center, Dept. of Internal Medicine, Cardiology, Ann Arbor, Michigan 48109-0022, United States of America*

Immediate recurrence of atrial fibrillation (IRAF) after successful transthoracic cardioversion (TCV) is a common clinical finding. There is evidence that atrial remodeling is due to intracellular calcium (iCA) overload and that calcium channel blocking (CCB) agents attenuate these electrophysiological changes. Ibutilide (Ibu) is a class III drug that has recently been shown to markedly facilitate TCV. The aim of this prospective study was to determine the incidence of IRAF, to compare the efficacy of i.v. verapamil (Ver) and i.v. Ibu for the prevention of IRAF, and to compare the long-term AF-recurrence rate of pts with and without IRAF.

Methods: TCV was performed in 223 pts using a step-up protocol (100J-200J-300J-360J). After successful TCV, pts were monitored for 30 minutes. If two IRAFs occurred, pts were randomized to i.v. Ver (0.15 mg/kg) or i.v. Ibu (1 mg) 10 minutes prior to another TCV attempt. In the event of another IRAF, pts crossed over to the other treatment arm and TCV was repeated.

Results: A total of 21 pts (9.4%, 17 males, age 59±12 yrs, LVEF 0.52±0.08) had IRAF 86±51 sec. after TCV. The mean duration of AF was 28±37 weeks. Six pts (29%) were on amiodarone, 10 pts on b-blockers, and four pts on a CCB. One pt was not randomized because the LVEF was <0.3. Eleven pts were randomized to Ver. 8/11 pts (73%) experienced another IRAF after 18±10 sec and 7/8 pts crossed over to the Ibu arm. One (14%) of these patients had another IRAF. Nine pts were randomized to Ibu and 2 (22%) of these had another IRAF, which was significantly less often than in the Ver group (P=0.02). One of the latter pts received Ver and had no further IRAF. Including the pts who crossed over, IRAF occurred in 3/16 pts (19%) after administration of Ibu, compared to 8/12 pts (67%) in the Ver arm (p=0.01). 18/223 (8%) in the non-IRAF and 2/20 pts (10%) in the IRAF group were lost to follow-up. After a mean follow-up of 27±30 weeks, 5/18 pts (28%) in the IRAF and 73/185 (39%) in the non-IRAF group remained in sinus rhythm (p=0.3).

Conclusions: The incidence of IRAF is 9.4%. Ibutilide is significantly more effective than verapamil in treating IRAF. Since the long-term AF recurrence rate does not differ significantly in pts with and without IRAF, it is worthwhile to treat IRAF.

2532 Atrial fibrillation in hypertrophic obstructive cardiomyopathy: prevalence, symptoms and quality of live

L. Obergassel, T. Lawrenz, F.H. Gietzen, C. Strunk - Mueller, H. Kuhn. *The Bielefeld Hospital, Cardiology and Angiology, Bielefeld, Germany*

Background: At present influence of atrial fibrillation (AF) on symptoms and quality of live (QoL) in hypertrophic obstructive cardiomyopathy (HOCM) is not clearly defined. Corresponding to prevalence of AF in HOCM only few reports are available.

Patients and Methods: The study population consisted of 80 consecutive patients (pts, 38 f, mean age 56 ± 17 y) with severe symptoms due to HOCM, who were treated by transcoronary ablation of septal hypertrophy (TASH). Prevalence of AF was detected by three holter ECG registrations before and 2 weeks respectively 7 months after TASH. Symptoms and QoL were evaluated by a standardised and validated questionnaire before and in long term follow up after TASH. Pts in AF and sinus rhythm (SR) were compared with regard to symptoms and QoL.

Results: The overall prevalence of AF was 29%. Paroxysmal AF in 17 pts (21.3%) and persistent AF in 5 pts (6.3%) were detected. Only 1 pt (1.3%) suffered from permanent AF. Symptoms due to AF were present in 12 pts (52.6%). Mean follow up after TASH was 32 ± 13 months. Both groups (AF and SR) showed significant improvement of symptoms, exercise tolerance and QoL, but there was no difference between the groups with AF and SR. Although those 6 pts with permanent or persistent AF at baseline showed superior improvement by TASH than the other 74 pts (QoL-score 4.0 ± 0 vs. 3.3 ± 0.7, p = 0.017).

Conclusions: Prevalence of AF is high (29%) in HOCM associated with severe symptoms. Nevertheless in the vast majority paroxysmal AF is present (21%). Half of patients suffered from symptoms due to AF. TASH improves QoL in both AF and SR patients. In particular HOCM pts with persistent and permanent AF profit by TASH

YOUNG INVESTIGATORS' AWARD SESSION (CLINICAL SCIENCE)

2533 Prognostic impact of matrix metalloproteinase (MMP)-9 plasma concentration and genetic variation of the MMP-9 gene

S. Blankenberg[1], H.J. Rupprecht[2], O. Poirier[3], C. Bickel[2], J. Meyer[2], F. Cambien[3], L. Tiret[3] on behalf of AtheroGene Group. [1]*Johannes Gutenberg-University Mainz, Department of Medicine II, Mainz, Germany;* [2]*Johannes Gutenberg-University, Department of Medicine II, Mainz, Germany;* [3]*Faculte de Medecine Pitie-Salpetriere, INSERM U525, Paris, France*

Introduction: As part of an ongoing inflammatory process within the atherosclerotic plaque Metalloproteinases (MMP) probably play a central role in atherosclerotic plaque destabilization. MMP-9 underlies in part genetic regulation. A functional G/A mutation within the MMP-9 binding domaine leads to aminoacid exchange (MMP-9/R279Q) and probably influences the MMP-9 enzyme activity. We evaluated first the relationship between MMP-9 plasma levels and future cardiovascular mortality and second the influence of the newly detected MMP-9/R279Q mutation on this relationship.

Methods: In 1176 patients with documented CAD MMP-9 plasma levels [ng/ml] were measured and the MMP-9/R279Q genotype determined. 1169 pts (99.4%) had a follow up (f/u) after a median of 4.1 (maximum 5.2) years.

Results: During f/u 127 pts died, 100 due to cardiovascular causes. Increasing quartiles of MMP-9 were associated with an 1.4 (95% CI 1.2 to 1.7, P<0.0001) increase in risk. The highest quartile compared to the lowest revealed a 2.7 (95% CI 1.5 to 5.1, P=0.002) increase in risk to suffer from future cardiovascular mortality. These associations were hardly weakened by controlling of most potential confounders. Most importantly, the association was strongly restricted to A allele carriers of the MMP-9/R279Q genotype(58.2% of the study population, P for interaction = 0.03, see Table).

MMP-9	Q1	Q2	Q3	Q4	P-univ.	P-multiv.
range [ng/ml]	<33.4	33.4 - 49.5	>49.5 - 73.8	>73.8		
all pts	4.4	6.2	9.6	14.1	<0.0001	0.002
MMP-9/GG	3.0	7.8	5.3	6.0	0.4	0.7
MMP-9/GA + AA	2.6	4.3	8.8	13.1	<0.0001	0.002

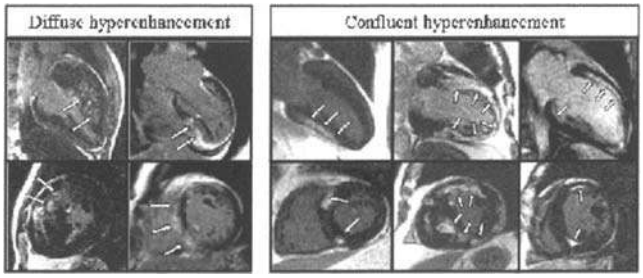
P values are given as P for trend; P multiv. controlled for age, sex, classical risk factors, clinical and therapeutic features including unstable angina, extent of vessel disease, history of MI, betablocker and statin therapy, interventional therapy, and ejection fraction.

Conclusion: In this large prospective cohort of pts we could demonstrate for the first time that plasma MMP-9 concentration is a strong and independent predictor of future cardiovascular mortality. This association was strongly restricted to A allele carriers of the newly detected, functional MMP-9/R279Q genotype. These findings should further be evaluated with special regard to newly developed MMP-9 inhibitors.

2534 Gadolinium enhanced MRI detects abnormal myocardium in HCM which correlates with clinical risk

J.C.C. Moon[1], W.J. McKenna[2], J.M. McCrohon[1], G.C. Smith[1], D.J. Pennell[1]. [1]*Royal Brompton Hospital, Department of MRI, London, United Kingdom;* [2]*St George's medical school, Cardiological Sciences, London, United Kingdom*

Background: Hypertrophic Cardiomyopathy (HCM) may be complicated by sudden death in the young and heart failure in the old. It is thought that myocardial fibrosis is a key underlying pathological process. Gadolinium enhanced Cardiovascular Magnetic Resonance (CMR) can demonstrate fibrosis in myocardial infarction. We hypothesised that it could demonstrate abnormal myocardial hyperenhancement in HCM and that it would be linked to clinical events.
Methods: A blinded prospective study. 40 HCM patients were selected for the number of clinical risk factors for sudden death and for the presence or absence of adverse remodelling on serial echocardiography (progressive disease). Gadolinium enhanced CMR was performed.
Results: 31(77%) patients had abnormal hyperenhancement. The mean percentage of LV hyperenhancement was 10.7%(0-40%). There was more hyperenhancement in patients with progressive disease (26% vs 8.4%, p=0.0004), and a trend in patients at higher risk of sudden death (13.6% vs 9.2%, p=0.12). Subgroup analysis demonstrated that in young patients (<40), there was more hyperenhancement in patients at higher risk of sudden death (16.3% vs 2.53%, p=0.03) whilst in older patients more hyperenhancement in patients with progressive disease risk (26.5% vs 5.4%, p=0.0005). Different patterns of hyperenhancement (myocardial phenotypes) were seen which associated with different clinical parameters (clinical phenotypes).



Types of hyperenhancement in HCM.

Conclusion: Gadolinium enhanced CMR can demonstrate abnormal myocardium in HCM. This has the potential to classify and follow HCM disease progression in-vivo and serve as a clinical risk factor for sudden death and heart failure.

2535 Relationship between pressure derived collateral flow and angiographic TMP grading during rescue angioplasty

K P. Balachandran[1], C. Berry[1], T.J. Gilbert[2], A.C.H. Pell[2], M. Malekian[3], B.D. Vallance[1], K.G. Oldroyd[1]. [1]*Hairmyres Hospital, Cardiology Dept., East Kilbride, United Kingdom;* [2]*Monklands Hospital, cardiology, Airdrie, United Kingdom;* [3]*Wishaw General Hospital, Cardiology, Wishaw, United Kingdom*

Introduction: In patients with chronic stable angina, pressure wire derived fractional collateral flow (Qc/Qn) of >0.28 has been associated with improved outcomes following percutaneous coronary intervention (PCI). The utility of the pressure wire derived parameters in patients with acute myocardial infarction (AMI) may be compromised by microvascular dysfunction.
Objective: To assess the relationship between maximum recruitable Qc/Qn and TIMI myocardial perfusion (TMP) grading in the setting of rescue PCI.
Methods: 28 consecutive patients underwent rescue PCI for failed thrombolysis based on standard ECG criteria. A pressure wire (RADI, Sweden) was used as the primary guide wire. Fractional flow reserve (FFR), coronary wedge pressure (Pw) and Qc/Qn pre PCI, during balloon inflation and post PCI were estimated under conditions of maximal hyperaemia induced with intracoronary adenosine. Pre and post PCI TIMI flow and post PCI TMP grading were assessed by a physician blinded to the study protocol.
Statistics: Maximum recruitable Qc/Qn (during balloon inflation) were compared for the different TMP grades. Qc/Qn during balloon inflation and post PCI Qc/Qn were compared with pre PCI values. The students t test was used to assess significance.
Results: The pressure wire was successfully manipulated in all patients. Pre PCI TIMI flows were as follows: 14 TIMI 0-1, 11 TIMI 2 and 3 TIMI 3. Post PCI, TIMI 3 flow was established in 24 patients with 4 only achieving TIMI 2 flow. Post PCI TMP grades were as follows: 21 patients (75%) TMP 0 grade and 7 TMP 1-2 grade. The pressure wire derived parameters are detailed in the table. There was an inverse relationship between maximum recruitable Qc/Qn and TMP grading [p=0.003;mean(SD)Qc/Qn of 0.28(0.1) with TMP 0 grade versus 0.16(0.08) with TMP 1-2 grades]
Conclusion: The pressure wire can be used as the standard guide wire during rescue PCI. Higher pressure derived fractional collateral flow (Qc/Qn) is associated with angiographic evidence of microvascular dysfunction.

	FFR - mean (SD)	Qc/Qn - mean (SD)
Pre PCI	0.52 (0.2)	0.15 (0.1)
Occlusion		0.24 (0.1) p<0.001 vs pre PCI
Post PCI	0.94 (0.04)	0.03 (0.03) p<0.001 vs pre PCI

2536 Endothelin-1 is involved in coronary no-reflow

C. Adlbrecht, D. Bonderman, J. Jakowitsch, M. Gyöngyösi, W. Sperker, P. Probst, H.D. Glogar, I.M. Lang. *General Hospital, Cardiology, Vienna, Austria*

Background: No-reflow (NR) is a multifactorial condition comprising an acute reduction in coronary flow in the absence of epicardial vessel obstruction. Current concepts invoke vasoconstriction as a key factor in NR. Therefore, we investigated the role of endothelin-1 (ET-1), a potent vasoconstrictor peptide that is abundant in atherosclerotic lesions. Methods and Results: Initial experiments utilized homogenates from atherosclerotic arteries and confirmed the presence of ET-1 antigen. In the next step, right coronary arteries (RCAs) from 6 domestic pigs were selectively injected with 2ml each of homogenized atherosclerotic human plaque material containing 6.9±4fmol/ml ET-1. Angiographically, flow was compromised in 5 of 6 animals. Fractional flow reserve (FFR) dropped from 2.0±1.0 to 0.8±0.2 (p=0.0045) with a marked decrease of baseline flow immediately after the injection. The same effect was achieved with direct injection of 0.15μg/kg purified human ET-1 in two pigs. To examine the role of ET-1 in human acute coronary NR, coronary blood was drawn from patients undergoing percutaneous interventions using the distal protection devices PercuSurge GuardWire (n=10), the X-Sizer Catheter System Thrombus Removal Device (n=9) and Angioguard (n=2). Fine particulate plaque material that was recovered from each of those devices contained on an average 0.13±0.18fmol ET antigen/40ml whole blood.
Conclusions: The data suggest that ET-1 is released into the coronary circulation from ruptured atherosclerotic plaque and contributes to the NR phenomenon, possibly by inducing spasm in the depending coronary microvasculature. The data suggest that ET-receptor antagonists could become powerful tools in the prevention and treatment of NR or slow flow.

2537 Histologic findings in patients with clinical and instrumental diagnosis of arrhythmogenic right ventricular dysplasia

C. Chimenti[1], M. Pieroni[1], R. Verardo[1], A. Maseri[2], A. Frustaci[1]. [1]*Catholic University, Department of Cardiology, Rome, Italy;* [2]*Istituto San Raffaele, Department of cardiology, Milan, Italy*

Objectives: The value of endomyocardial biopsy compared with other non-invasive and invasive cardiac exams in the diagnosis of arrhythmogenic right ventricular dysplasia (ARVD) is still controversial. We report the biventricular histologic findings of 30 patients (pts) with a diagnosis of ARVD established by applying the conventional clinical and instrumental criteria.
Methods and Results: Among 78 consecutive pts with ventricular arrhythmias, normal left ventricular (LV) global function and coronary arteries, 30 (38%) had arrhythmias with left bundle branch block morphology and right ventricle (RV) abnormalities. All pts underwent non invasive (2D-echo, magnetic resonance) and invasive cardiac studies (including LV, RV angiography with biventricular endomyocardial biopsy and electrophysiologic study). Endomyocardial biopsies were performed in the septal-apical region of the LV and in specific sites of the RV (i.e. apex, anterior free wall, inferior wall). On the basis of electrocardiographic, arrhythmic and morpho-functional criteria all pts would have received the diagnosis of ARVD. At histology, the diagnosis of ARVD was confirmed only in 9 pts, while in 21 pts a focal inflammatory infiltrate with necrosis of the adjacent myocytes diagnostic for myocarditis was present in all RV specimens and even in the LV biopsies from 10 pts. No fatty tissue infiltration was observed in myocarditic pts, while foci of inflammatory cells were present both in the RV and LV of 4 pts with ARVD. No statistically significant difference was found between pts with ARVD and with myocarditis regarding the severity of ventricular arrhythmias (p=0.9359), ECG depolarization and repolarization abnormalities (p=0.92), structural RV abnormalities, including global or regional RV dilatation (p=0.8731) and dysfunction (p=0.8731). Finally, magnetic resonance imaging showed the typical signal of high intensity in T1 weighted images in 66% of ARVD pts and in 62% of myocarditic pts (p=0.8687).
Conclusions: An elective RV myocarditis can mimic an ARVD. Histology seems the most correct diagnostic tool with significant impact on prognosis and treatment.

PULMONARY HYPERTENSION

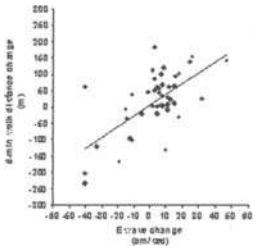
2559 Relationship of exercise capacity to echocardiographic parameters in patients with pulmonary arterial hypertension: the BREATHE-1 echo substudy

N. Galie', A. Hinderliter, A. Torbicki, G. Simonneau, N. Espinola-Zabaleta, A. Manes, I. Leconte, S. Roux on behalf of BREATHE-1 Echo Substudy Group. *University of Bologna, Institute of Cardiology, Bologna, Italy*

Background: Pulmonary arterial hypertension (PAH) is associated with abnormalities in cardiac structure and function which contribute to impaired functional capacity. We evaluated the relations of echocardiographic and Doppler measures to exercise performance in a subgroup of 85 patients with WHO class III and IV PAH enrolled in the prospective, multicenter, double blind, placebo-controlled BREATHE-1 study.

Methods: Patients had primary pulmonary hypertension or PAH associated to scleroderma. 29 patients received placebo and 56 the orally active dual endothelin receptor antagonist bosentan in a 1:2 randomization procedure. 6-minute walk tests and echocardiograms were performed at baseline and after 16 weeks of treatment.

Results: Compared to placebo, bosentan resulted in an increase of 37 m in 6-minute walk distance (p=0.036) and an increase of 0.4 l/min/m^2 in Doppler-derived cardiac index (p=0.007). On the baseline evaluation, multiple stepwise regression analysis showed that the distance walked in 6 min was correlated with right ventricular (RV) end-diastolic area (r=-0.39, p=0.009), Doppler RV index (r=0.35, p=0.022) and left ventricular (LV) end-diastolic area (r=0.35, p=0.022). Serial changes of distance walked in 6 min from baseline to week-12 were correlated on multivariate analysis with changes of LV early diastolic filling (E wave) velocity (r=0.65, p<0.001)(Fig 1) and with changes of pericardial effusion score (r=-0.43, p=0.004).



Conclusions: In patients with PAH, poor exercise tolerance is correlated with echocardiographic evidence of RV dilatation and failure and of LV reduction. Serial improvements in exercise capacity are related to improved early LV filling, and pericardial effusion score.

2560 Pharmacokinetics and safety of bosentan, an oral dual endothelin receptor antagonist in children with pulmonary arterial hypertension: BREATHE-3

R. Barst[1], D. Ivy[2], A.C. Widlitz[1], K. Moore[1], A. Doran[2], N. Nguyen[3], M.D. Gaitonde[3]. *[1]Columbia University, Pediatric Cardiology, New York, United States of America; [2]University of Colorado, Pediatric Cardiology, Denver, United States of America; [3]Actelion Pharmaceuticals Ltd., Allschwill, Switzerland*

Background: Bosentan, an orally active dual endothelin receptor antagonist, significantly improved exercise capacity and hemodynamics in two double-blind, placebo-controlled studies in adults with pulmonary arterial hypertension (PAH). Therefore, BREATHE-3 was designed to evaluate tolerability and safety of bosentan in children with PAH.

Methods: This open-label, uncontrolled single and multiple-dose study assessed pharmacokinetics, tolerability and safety of bosentan in children 4-17 years of age with PAH. Children with and without epoprostenol were stratified according to weight to 3 different doses; n=6 per group. Children with PPH or PAH associated with congenital heart defects (functional class II or III) who were clinically stable for at least 3 months prior to enrollment with a systemic arterial oxygen saturation > 88% were studied. Patients with ALT/AST levels of > 2xULN were excluded. At baseline and after 12 weeks of treatment,hemodynamic measurements and pharmacokinetic parameters (e.g. Cmax, tmax, t1/2, AUC0-μ, AUCt, CL/F) were recorded for each child. Safety was evaluated by laboratory tests and adverse event recording. Cardiopulmonary exercise testing was performed on children > 8 years old at baseline and after 12 weeks.

Results: Eighteen children were enrolled (10 with and 8 without epoprostenol), 10 female, 8 male with a mean age of 12 ± 4 years. The hemodynamic and exercise results (mean ± SD) are shown below. Following the week 12 assessment, patients continued open label treatment with bosentan and the dose of epoprostenol was decreased in all four children in whom this was attempted without any apparent change in overall clinical status.

	Peak VO2 (ml/min) N=12	Six Minute Walk Distance (m) N=12	PAPm* (mmHg) N=18	CI (L/m/M2) N=17	PVRI (units · M2) N=18
Baseline	798 ± 401	492 ± 68	58 ± 16	4.1 ± 1.6	14 ± 7
Week 12	841 ± 495	492 ± 92	51 ± 20	4.6 ± 1.3	11 ± 9

*p=0.004 vs. baseline

Conclusion: BREATHE-3 provides valuable data regarding the tolerability and safety for bosentan, an orally active, dual endothelin receptor antagonist, in pediatric patients with PAH. This study suggests that the addition of bosentan to epoprostenol may allow a subsequent decrease in dose of intravenous epoprostenol, potentially decreasing the prostanoid-related side effects and thereby improving the risk-benefit profile for patients with PAH.

2561 Improved oxygenation relieves baroreflex dysfunction in Andean altitude natives with chronic mountain sickness

L. Bernardi[1], C. Passino[1], J. Gamboa[2], A. Gamboa[2], M. Bonfichi[3], M. Vargas[2], L. Malcovati[3], R. Roach[4]. *[1]IRCCS S.Matteo University of Pavia, Clinica Medica 1, Pavia, Italy; [2]Universita Peruana Cayetano Heredia, laboratorio de transporte de oxygeno, Lima, Peru; [3]IRCCS S.Matteo UNiversity of Pavia, hematology, Pavia, Italy; [4]New Mexico Resonance, Montezuma, United States of America*

Andean altitude natives with chronic mountain sickness (CMS) have neurologic and autonomic symptoms at altitude, which disappear at sea-level. To test whether baroreflex abnormalities contribute to CMS, we measured RR interval (RR), systolic blood pressure (SBP), and respiratory variabilities, by spectral analysis, in 31 natives of Cerro de Pasco (CP), (4338m, Peru), with variable degrees of CMS (CMS score 4-26) at baseline and during carotid baroreflex modulation by neck suction (NS) at 0.1Hz (LF, sympathetic modulation on SBP, vagal and symapthetic on RR), and at 0.2Hz (HF, vagal modulation on RR), in CP, before and during normoxia (CP+ox), and in Lima, sea-level, after one night sleeping in normoxia (SL) and during hypoxia. Subjects were divided according to CMS score (CMS+: =/> 12, N=15, CMS-: <12, N=16).

In CP, compared to CMS-, CMS+ showed reduced resting HF (p<0.05), reduced HF-NS modulation on RR (p<0.02), and reduced LF-NS on RR (p>0.02) but not on SBP, indicating preserved sympathetic modulation but reduced cardiac baroreflex vagal modulation. CP+OX increased RR modulation in CMS-, so all differences became more significant. At SL, CMS score dropped to 2.9 ±0.5 (p<0.0001); RR resting and NS-induced HF increased (p<0.01) in CMS+, attenuating the differences with respect to CMS- (p<0.05 during both LF-NS and HF-NS). Hypoxic gas mixture administrated at SL restored the differences seen at CP in the RR response to either LF-NS or HF NS (both p<0.01). Resting HF (p<0.01) and HF-NS in RR correlated inversely with CMS score (p<0.0002) in CP.

Vagal and baroreflex dysfunction may be implicated in the origin of CMS symptoms; this can partially reverse with improved oxygenation.

Abstract 2562 – Table

Parameter	APE whole group n=64	Survivors n= 56	Nonsurvivors n=8	Odds ratio (95% CI)
Repetitive cTnT > 0.1ng/ml [%]	50.0	42.8	100	21 (1,2-389) #

2562 Cardiac troponin T (cTnT) monitoring identifies high risk group among patients with acute pulmonary embolism (APE)

A. Bochowicz[1], M. Szulc[1], M. Kurzyna[2], A. Fijalkowska[2], K. Kuczynska[1], H. Berent[1], A. Torbicki[2], P. Pruszczyk[1]. *[1]Medical University of Warsaw, Internal Medicine and Hypertension, Warsaw, Poland; [2]Institute of Lung Diseases, Dept. of Chest Medicine, Warsaw, Poland*

Identification for thrombolysis in normotensive pts with APE based on the presence of right ventricular (RV) strain at echocardiography is controversial. We checked whether monitoring of cTnT might help in risk stratification detecting patients with ongoing RV myocardial injury.

Material and methods: We studied 64 normotensive pts (30F, 34 M) aged 61.3+17.0 yrs with APE. All pts underwent TTE for of RV strain. Plasma cTnT (ELISA, Roche, detection limit >0.1ng/ml) were measured at the admission, and subsequently 3 times in 6 hours intervals. Managing physicians were unaware of cTnT results, therefore troponins levels did not influence the therapy. Anticoagulation only was used in 87.5% pts, while 12.5% pts received thrombolysis.

Results: During hospital observation 8/64 pts died. (in hospital mortality 12,5%) due to irreversible RV failure in 6 pts, in 2 others recurrent fatal APE was diagnosed. CTnT was elevated at the admission in 45.3% pts. Repetitive assays showed elevated cTnT in additional 3 pts. All death occurred in cTnT positive group, however in 1 case first three assays were negative. Odds ratio analysis revealed that elevated plasma cTnT mostly affected short term prognosis. Older age, decreased blood pressure and tachycardia only moderately influenced the outcome. There were no differences in RV/LV ratio between survivors and nonsurvivors. However, elevated tricuspid valve peak systolic gradient moderately indicated worse prognosis.

Conclusion: Patients with APE and elevated cTnT plasma levels at repetitive assays are at significant risk of fatal outcome and should be regarded for high risk group. Clinical and echocardiographic parameters are of limited value in the risk stratification among normotensive patients with APE.

2563 Prevalence and outcome in systemic sclerosis associated pulmonary hypertension: a four-year follow-up study

D. mukerjee[1], D. St George[2], J.G. Coghlan[3], C.M. Black[1]. *[1]royal free hospital, rheumatology, london, United Kingdom; [2]Royal Free Hospital, clinical epidemiology, London, United Kingdom; [3]Royal Free Hospital, Cardiology, London, United Kingdom*

Objective: Determine the prevalence of Systemic Sclerosis-related Pulmonary Hypertension (SSc PHT) and identify predictors of mortality in a large patient cohort.

Design: Prospective 4-year follow-up study between March 1997-September 2001.

Setting: A large teaching hospital providing a national referral service for the management of Systemic Sclerosis.

Patients: 950 patients with Systemic Sclerosis under regular follow up at the Royal Free Hospital, London. All patients were screened for pulmonary hypertension using a combination of echocardiography, lung function testing and clinical assessment. Patients with suspected elevated pulmonary artery systolic pressures (PASP) of>35 mmHg on echocardiography and/or diffusing capacity (DLCO)<40% expected on lung function tests or dyspnoea of unexplained cause underwent right-heart catheterisation.

Intervention: Right-heart cardiac catheterisation with haemodynamic measurements at baseline and after acute vasodilator challenge. All patients were actively treated with warfarin, calcium channel blockers, and prostacyclin therapy in accordance with current best practice.

Results: The prevalence of pulmonary hypertension was 12% (118/950) by right-heart catheter. Survival was 78% at 1-year, 52% at 2-years and 40% at 3 years from the diagnosis, with no significant difference between those with and without pulmonary fibrosis. Our survival data, derived from a patient cohort treated with best-available therapy significantly differed from previous studies that had suggested 1,2 and 3-year survivals of 45%, 36% and 28%. The main cause of death was right ventricular failure. Elevated right atrial pressure (P=<0.01), low cardiac index (P=<0.001), reduced mixed venous oxygen saturations (P=0.05) and higher levels of pulmonary pressure (P=0.05) each independently predicted an increased mortality. Absence of vasodilator response on acute challenge did not predict outcome.

Conclusions: The prevalence of SSc-related pulmonary hypertension was lower than expected from previous studies that have relied on echocardiographic data. Measures of right ventricular function (RAP,CI, mPAP)predicted an adverse prognosis. The future outlook is encouraging with improvement in survival compared to historical controls

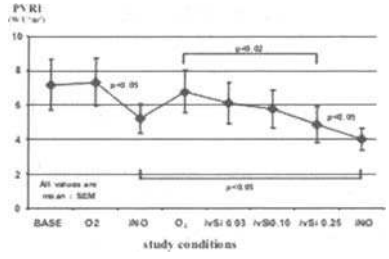
2564 Sildenafil lowers pulmonary vascular resistance in children after heart surgery

I. Schulze-Neick[1], P. Dietz[1], B. Stiller[1], N. Nagdyman[1], G. Butrous[2], K. Falke[3], A.N. Redington[4], P.E. Lange[1]. *[1]Deutsches Herzzentrum Berlin, Angeborene Herzfehler, Berlin, Germany; [2]Pfizer Medical, Cardiovascular Division, Sandwich, United Kingdom; [3]CVK, Charité, Humboldt-Universität, Anästhesie und Intensivmedizin, Berlin, Germany; [4]Hospital for Sick Children, Cardiology, Toronto, Canada*

Background: Children with elevated pulmonary vascular resistance (PVR) after congenital heart surgery show increased postoperative morbidity and mortality. Inhaled nitric oxide (iNO) selectively lowers pulmonary vascular resistance (PVR)in patients, but it has important side effects which limit its use. Sildenafil (Si) enhances the NO-cGMP pathway by blocking phosphodiesterase typ 5 (PDE-5), thus augmenting the bioavailability of cGMP, the second messenger of NO. We studied the effects of intravenous Si (ivSi) on PVR in children after heart surgery with cardiopulmonary bypass.

Method: 8 infants (age 3.8±1.2 months, weight 4.6±0.6 kg) with preoperative pulmonary hypertension due to intracardiac shunting defects and an elevated risk of postoperative increased PVR were included. All were examined in the early postoperative period while they were still sedated and paralysed. PVR was measured using the direct Fick principle with measurement of oxygen consumption by respiratory mass spectrometry. Measurements were performed at baseline, with FiO2 =0.65, and then with the addition of iNO (20ppm) before and after ivSi (cumulative doses of 0.03, 0.10 and 0.25 mg/kg).

Results: No clinically relevant systemic hypotension or other side effects occurred during ivSi. PVR fell with iNO both before and after PDE-5 blockade. However, ivSi alone lowered PVR to a similar level as iNO. The combination of iNO and ivSi produced the lowest PVR (see Figure 1).



Conclusion: Pulmonary endothelial dysfunction in postoperative children with a decreased endogenous NO-production may be ameliorated by increasing cGMP-availability by PDE-5 blockade. Sildenafil may be useful as an additional treatment option for patients with increased pulmonary vascular resistance.

CLINICAL RELEVANCE OF CIRCADIAN VARIATIONS OF BLOOD PRESSURE AND HEART RATE

2565 Heart rate and heart rate variability in white-coat hypertension

K. Stolarz[1], T. Grodzicki[2], A. Olszancka[1], W. Lubaszewski[1], B. Wizner[2], K. Kawecka-Jaszcz[1]. [1]*Collegium Medicum, I Cardiac Department, Krakow, Poland;* [2]*Collegium Medicum UJ, Chair of Internal Medicine, Krakow, Poland*

The aim of the study was to assess heart rate and heart rate variability among patients with white coat hypertension.

Methods: 168 persons over 30 years old, entered the study. In each subject, conventional blood pressure was measured during three separate visits, 5 times on each visit. Arterial hypertension was diagnosed if the patient was receiving antihypertensive treatment or average blood pressure (BP) measured on three separate occasions exceeded 140/90 mmHg. White coat hypertension was defined as BP>140/90 mmHg only at the first visit, in untreated subjects. The group was subdivided into three subgroups: Hypertensives (group 1): n=88, age=45.6±12.6 years, BMI=28.7±4.6 kg/m^2, BP at the first home visit=157.5±19.3/96.9±10.6 mmHg; subjects with white-coat hypertension (group 2): n=37, age=43.5±4.5 years, BMI=27.4±4.5 kg/m^2, BP at the first home visit=144.0±7.9/89.7±6.9 mmHg; and normotensives (group 3): n=43, age=43.3±11.7 years, BMI=28.6±4.1 kg/m^2, BP at the first home visit=120.0±19.3/75.4±8.4 mmHg.

In each subject, in standardised laboratory conditions, 30 min ECG was recorded: 15 min supine, 15 min standing, using a validated device - CardioPSA System, Medatec. Fast Fourier transform was used to obtain power spectrum analysis (PSA) of heart rate variability components: total variance, low frequency (LF: 0.04-0.15 Hz) and high frequency (HF: 0.15-0.40 Hz) values.

Results from supine recordings are summarised in the table. Similar findings were observed in the standing position.

	Hypertensives (n=88)	White-coat hypertensives (n=37)	Normotensives (n=43)
RR interval (ms)	941.0±147.7*	938.5±123.6*	915.3±127.7
Total variance (ms2)	2531.9±4956.9†	2871.8±3656.2†	4271.3±4597.9
HF component (%)	38.2±13.3†	38.3±14.7†	35.4±13.7
LF component (%)	45.7±17.7*	47.7±16.6	53.2±17.5

* $p<0.05$ vs normotensives;† $p<0.01$ vs normotensives

Conclusion: Patterns of heart rate and heart rate variability in subjects with white coat hypertension are similar to these observed among hypertensives, with increased heart rate, decreased total variance and decreased parasympathetic activity (HF component). These data suggest impaired sympatho-vagal balance in white-coat hypertension.

2566 A new index for the quantitative evaluation of the cardiovascular effects of obstructive sleep apnea syndrome

P. Castiglioni[1], G. Parati[2], M. Di Rienzo[1], M.R. Bonsignore[3], G. Insalaco[3], G. Mancia[4]. [1]*Fondaz. Don Gnocchi, LaRC, Centro di Bioingengeria, Milano, Italy;* [2]*Osp. S. Luca, Ist. Auxologico Italiano, Cardiology Dept., Milan, Italy;* [3]*CNR, Inst. Respiratory Physiology, Palermo, Italy;* [4]*Università Milano-Bicocca, Clinica Medica, Ospedale S. Gearado, Monza, Italy*

Obstructive Sleep Apnea Syndrome (OSAS) is associated with increased cardiovascular (CV) morbidity and mortality, due to frequent nocturnal blood pressure (BP) peaks that follow apneic episodes. OSAS severity is usually assessed by the apnea-hypopnea index (AHI, n of episodes/h) which quantifies the degree of respiratory impairment but not the negative effects of OSAS on the CV system, largely due to hypertensive peaks. Aim of this study is: 1)to propose a new index to quantify the severity of OSAS CV effects, 2)to compare the values of this index in OSAS and healthy volunteers and 3)to evaluate its changes under acute and chronic nasal continuous positive airway pressure (CPAP)tretment. The new index, Cross-Power Index (CPI), quantifies the beat by beat effects of changes in oxygen saturation on changes in systolic(S)BP, and is defined as the integral of the cross-spectrum modulus between SBP and oxygen saturation (SaO2) over a broad range of frequencies where SaO2 and SBP spectral powers are linearly correlated. In 15 severe OSAS patients (AHI>50, age range 38-65 years) and in 7 normal volunteers of comparable age, a complete multichannel polysomnography (PSMG) was performed overnight. PSMG was repeated in 6 severe OSAS patients under acute CPAP treatment, and in 10 OSAS patients when discontinuing CPAP after 6 months of regular treatment. To compute CPI only SBP and SaO2 were considered, by computing their broad band spectral powers. The cross-spectrum between SBP and SaO2 was computed by the Welch method. CPI was calculated by the averaged cross-spectrum modulus.

In the control group CPI was invariably lower than 5 mmHg (90% tolerance limits:2.6-4.8 mmHg). In OSAS CPI was markedly and significantly greater (tolerance limits 32-97 mmHg). In the 6 OSAS patients evaluated after acute CPAP, CPI decreased on average from about 60 to values <20 mmHg (normal levels reached in 4 out of 6 cases. In the 10 OSAS patients evaluated after chronic CPAP was discontinued, AHI returned to pre-treatment high values, while CPI remained significantly reduced by more than 50% as compared to before treatment.

Thus, high CPI values may detect severe OSAS patients with no need of complete PSMG, but only of continuous SBP and SaO2 monitoring. CPI may complement AHI in OSAS diagnosis by quantifying its cardiovascular effects, and may assess the efficacy of treatment over and above the information provided by AHI. Given the simpler setup required,CPI might more easily allow to screen the hypertensive population, in which OSAS is highly prevalent and represents an additional risk factor.

2567 Strong genetic effect on ambulatory pulse pressure in a sample of Polish twins

P. Jedrusik[1], A. Januszewicz[2], A. Busjahn[3], B. Wocial[1], H. Ignatowska-Switalska[1], J. Strelau[4], F C. Luft[3], W. Januszewicz[1]. [1]*Medical University of Warsaw, Internal Medicine and Hypertension, Warsaw, Poland;* [2]*Institute of Cardiology, Department of Hypertension, Warsaw, Poland;* [3]*Humboldt University of Berlin, FranzVolhard Clinic MaxDelbrück Centr, Berlin, Germany;* [4]*University of Warsaw, Interdiscipl Center Behavior Genetics, Warsaw, Poland*

Background and Objective: Emerging data show pulse pressure is an important prognostic marker of cardiovascular risk. We determined genetic and environmental contributions to pulse pressure in a group of Polish twins aged 18-45 years.

Design and methods: 39 monozygotic (MZ, age 33±7 years, BMI 23±3 kg/m^2) and 37 same-sex dizygotic (DZ, age 36±7 years, BMI 24±4 kg/m^2) twin pairs recruited by inviting letters were studied, including 30/152 (19.7%) subjects with hypertension (defined as high blood pressure or antihypertensive treatment). Zygosity was determined with microsatellite markers and a questionnaire. Systolic (SBP) and diastolic blood pressure (DBP) were measured clinically and by ambulatory blood pressure monitoring (ABPM, SpaceLabs 90271). Pulse pressure (PP) was calculated as the difference between SBP and DBP. Statistical analysis was performed using the SPSS program and parameters of the genetic models were estimated by model fitting and path analysis technique using the LISREL 8 program.

Results: Mean 24-hour blood pressure was 116/74±10/8 mmHg in MZ twins and 121/76±10/7 mmHg in DZ twins. We found strong genetic effect on pulse pressure derived from ABPM (60%-80% of PP variability) that was larger than genetic effect on pulse pressure measured clinically (PP clinic, 35% of PP variability). Effect of genetic factors on daytime values (PP day) was similar to the effect on 24-hour mean values (PP 24-hour) and larger than the effect on nighttime values (PP night). SBP and DBP (clinic and ABPM) were also significantly influenced by genetic factors. Estimates of genetic (h2), shared environmental (c2) and unshared environmental (e2) effects, goodness of fit statistics, and correlation coefficients for MZ (rMZ) and DZ (rDZ) twin pairs are shown below (*ADE model).

	h2	c2	e2	chi2(df)	p	rMZ	rDZ
PP clinic	0.35	0.65	0.00 (4)	1.00	0.35	0.18	
SBP clinic	0.53	0.47	7.12 (4)	0.13	0.53	-0.12	
DBP clinic	0.62	0.38	2.65 (4)	0.62	0.67	0.18	
PP 24-hour	0.77	0.23	0.00 (3*)	1.00	0.77	0.26	
SBP 24-hour	0.73	0.27	2.37 (4)	0.67	0.71	0.34	
DBP 24-hour	0.47	0.19	0.34	1.73 (3)	0.63	0.66	0.37
PP day	0.80	0.20	0.00 (3*)	1.00	0.80	0.24	
PP night	0.60	0.40	0.00 (3*)	1.00	0.60	0.28	

Conclusions: We found strong genetic effect on pulse pressure derived from ambulatory blood pressure monitoring.

2568 Behaviour of sympathetic nerve traffic and baroreflex function in dipper and non-dipper essential hypertensives

G. Grassi[1], G. Seravalle[2], G. Bertinieri[3], F. Quarti Trevano[1], G. Foglia[1], G. Mancia[1]. [1]*Hpt. S. Gerardo, Medicina Interna, Monza, Italy;* [2]*Istituto Auxologico Italiano, Cardiology, Milan, Italy;* [3]*Centro Interuniv. Fisiol./Ipertens., Clinica Medica, Milan, Italy*

Objective: Recent studies have prompted the hypothesis that neuroadrenergic and reflex mechanisms contribute to the occurrence of the "non-dipping" phoenomenon. These results, however, 1) were collected by employing indirect approaches to assess adrenergic function and 2) were based on a single (and thus poorly reproducible) assessment of the nocturnal blood pressure (BP) fall. Design and Methods: In 39 untreated lean essential hypertensives (age 51.9±1.1 yrs, mean±SEM) undergoing repeated 24 h BP monitorings in 2 non consecutive days (Spacelab 90207), we measured beat-to-beat systolic (S) and diastolic (D) BP (Finapres), heart rate (HR, EKG), plasma norepinephrine (NE, HPLC) and efferent postganglionic muscle sympathetic nerve traffic (MSNA, microneurography) at rest and during arterial baroreceptor manipulation via the vasoactive drugs infusion technique. 26 of the original 39 patients displayed reproducible nocturnal BP profile in the 2 monitoring periods and were classified as dippers (D, n=18, 50.8±1.6 yrs) or non-dippers (ND, n=8, 53.1±2.3 yrs) according to the magnitude of nocturnal BP fall > or < 10% of diurnal values.
Results: D and ND had similar 24h SBP (143.5±2.3 vs 145.7±2.8 mmHg), 24h DBP (87.9±1.9 vs 89.6±2.9 mmHg) and 24h HR (74.5±1.8 vs 71.9±2.6 b/min), while nocturnal DBP was less in D than in ND (77.8±2.0 vs 85.5±3 mmHg, $p<0.03$). NE levels were similar in the two groups (308±23 vs 321±35 pg/ml). This was also the case for MSNA values (63.0±3.8 vs 67.9±4.9 bs/100hb). Furthermore, HR and MSNA baroreflex responses were superimposable in D and ND. In the group as a whole, MSNA was significantly and directly related to both HR ($r=0.40, p<0.05$) and NE values ($r=0.44, p<0.03$).
Conclusions: Thus, the magnitude of sympathetic activation and the sensitivity of baroreflex control of both vagal and sympathetic outflows are similar in D and in ND. These data are therefore against the hypothesis that the "non dipping" phoenomenon depends on neuroadrenergic or baroreflex alterations.

2569 The real blood pressure load in smokers is not reflected by office blood pressure

K.S. Kristensen[1], L.E. Bang[2], T.L. Svendsen[3], N. Wiinberg[4], L. Buttenschoen[3], H. Diemer[5]. [1]*Holbaek, B1, Holbaek;* [2]*Glostrup County Hospital, Internal medicine, Glostrup;* [3]*Holbaek Hospital, Cardiology B1, Holbaek;* [4]*Frederiksberg Hospital, Clinical Physiology, Frederiksberg;* [5]*Holbaek Hospital, Clinical Physiology, Holbaek, Denmark*

Although the acute effect of smoking is a rise in blood pressure(BP)and heart rate, several epidemiologic studies show that smokers tend to have a slightly lower BP than non-smokers. To test the hypothesis that smoking is associated with a rise in ambulatory BP, we examined the 24 h ambulatory BP in hypertensive smokers and hypertensive non-smokers. From February 2000 to October 2001 we performed 24 h ambulatory BP consecutively in treated or non treated hypertensive smokers (n=122) and hypertensive non-smokers (n=315) referred to our out-patient clinic. There were no differences in age, gender and Body Mass Index between the smoking group and the non-smoking group. The smokers were divided into heavy smokers (> 10 cigarettes per day) and light smokers. No differences were seen in office BP between heavy smokers and non-smokers (148.7 +19.6/92.4+12.7 mmHg vs. 149.7+20.7/91.2+11.6 mmHg). However, we found a significantly higher day-time systolic and diastolic BP in heavy smokers compared to non-smokers (147.5+15.6/90.8+10.1 mmHg vs. 142.5+14.6/87.5+11.0 mmHg). The well known tendency of day-time BP being lower than office BP was seen in all groups, but it was significantly less pronounced in heavy smokers, meaning that the day-time BP tends to be higher. Differences between office BP and day-time BP for heavy smokers were 1.0+12.1/1.6+8.0 mmHg and for non-smokers 7.3+13.9/3.8+9.3 mmHg ($p<0.05$). No significant difference were found for light smokers. We did not observe differences between the groups concerning office BP and night-time BP. In heavy smokers the office BP did not reflect the real BP load, meaning that the patients tended to be undertreated looking only at the office BP. As a consequence we routinely recommend 24 h ambulatory BP measurement in heavy smokers, at least before accepting the patient as well-treated on the basis of office BP alone.

2570 Lowering of ambulatory and daytime (but not clinic and nighttime) blood pressure by statin treatment

L. Terzoli[1], R. Raco[1], L. Mircoli[2], A.U. Ferrari[3]. [1]*Div Cardioriabilitazione, Az Osp Vimercate, Seregno, Seregno, Italy;* [2]*IRCCS Ospedale Maggiore, Divisione di Cardiologia, Milano, Italy;* [3]*Centro Fisiologia Clinica Ipertensione, Dipt Med., Prev. e Biotecnol. Sanit., Milano, Italy*

A BP lowering effect of statins has been described by several authors but denied by others. Since only clinic BP was measured in most studies on this topic, we examined the BP effects of statins by 24-hour ambulatory BP monitoring (ABPM) which, compared to the clinic BP approach, i) provides a more reliable overall BP assessment and ii) allows the circadian BP profile to be tracked. We also addressed a further controversial issue, i.e. whether or not the putative BP lowering parallels the statin-induced lipid-lowering.
Outpatients referred to for hypertension or coronary artery disease, previously never treated with statins and having total serum cholesterol (TC) >5.17 mmol l^{-1} (200 mg dl^{-1}), were consecutively enrolled and randomized to a 2 month-treatment course of a statin (n=44, drug selection by clinic doctor: simvastatin or pravastatin, 10-40 mg daily; atorvastatin, 5-20 mg daily; cerivastatin, 0.2-0.4 mg daily) or of a control agent (Ctrl, n=18, soja lecitine 20 g daily). Any ongoing drug regimens were kept unchanged throughout. Pre- and post-treatment measurements included blood chemistry as well as clinic, 24-h, daytime (8am-22pm) and nighttime (24pm-6am) BP. Patients assigned to statin treatment were analyzed both as an overall group and as two subgroups identified as "stronger" or "weaker" responders according to the magnitude of the reduction in TC, the pre-defined, arbitrary cutoff being 1.3 mmol l^{-1} (50 mg dl^{-1}).
In the whole statin group, post- vs pre-treatment changes were -1.53±0.1 (mean±SEM) from 6.8±0.1 mmol l^{-1} for TC ($p<0.01$), -3.7±2.6 from 144±3 mmHg for clinic BP (p=ns, data refer to systolic), -3.7±1.0 from 130±2 mmHg for 24-h BP ($p<0.01$), -4.3±1.1 from 133±2 mmHg for daytime BP ($p<0.01$) and -1.4±1.2 from 120±2 mmHg for nighttime BP (p=ns). No significant lipid or BP changes were observed in the Ctrl group. In the "stronger" statin subgroup, the drop in TC was 1.87±0.1 mmol l^{-1} (n=27, $p<0.01$) and the BP changes were -8.5±2.6, -4.5±1.4 and -5.0±1.3, (all $p<0.01$) for the clinic, 24-hour and daytime values but -2.0±1.3 (p=ns) for the nighttime values, whereas in the "weaker" statin subgroup the drop in TC was 0.98±0.1 mmol l^{-1} (n=17, $p<0.01$) but no consistent change in any of the measured BPs was observed.
Our study indicates that statins do exert a mild-to-moderate BP lowering effect that: i) is consistently observed using an ABPM but not a clinic BP assessment, ii) is clearcut during the daytime but not the nightime, and iii) is more pronounced when there is a concomitant pronounced lowering of TC.

ENDOTHELIAL DYSFUNCTION: NEW TARGETS?

2571 The PPAR-gamma agonist rosiglitazone reduces endothelial activation in non-diabetic coronary artery disease patients

J S. Sidhu, D. Cowan, J C. Kaski on behalf of Cardiological Sciences, St. George's Hospital Medical School.. *London, United Kingdom*

Background: Endothelial cell activation is a key event in atherogenesis and atherosclerotic disease progression. Rosiglitazone, a Peroxisome Proliferator-Activated Receptor-gamma (PPAR-gamma) agonist, is an insulin-sensitising agent and is used in the treatment of type 2 diabetes mellitus. Recent experiments suggest that PPAR-gamma agonists directly modulate inflammatory processes within the vessel wall and may therefore inhibit endothelial activation. The aim of this study was to assess the effect of rosiglitazone on markers of endothelial activation in non-diabetic coronary artery disease patients.
Methods: We studied ninety-two patients (mean age 62 years, 78 males & 14 females) with stable angina and angiographically documented coronary artery disease. None of the patients had diabetes mellitus. Maintaining their current therapies, patients were randomised in a double-blind manner to placebo (n=46) or rosiglitazone (n=46, 4 mg/day for 8 weeks followed by 8mg/day for 4 weeks) for 12 weeks. Plasma levels of E-selectin and von Willebrand factor (vWF), markers of endothelial cell activation, were measured by enzyme-linked immunosorbent assay at baseline and at study end. Fasting insulin, glucose and lipid profile were also measured. The homeostasis model of insulin resistance index (HOMA-R) was calculated as a measure of insulin resistance. Results are shown as mean ± SD. One way ANOVA for repeated measurement was used to assess the effect of treatment on measured parameters.
Results: Eighty-four subjects completed the study. The levels of E-selectin and vWF were significantly reduced by rosiglitazone treatment compared with placebo. In the rosiglitazone group E-selectin decreased from 49 ± 16 to 43 ± 16 ng/mL (P=0.03) while vWF decreased from 139 ± 47 to 131 ± 44 IU/dl (P=0.01). Rosiglitazone treatment also significantly reduced insulin resistance (HOMA-R) compared to placebo (P = 0.02). However, significant increases in both LDL (2.63 ± 0.71 to 2.93 ± 0.71 mmol/L, P=0.01) and triglyceride levels (1.22 ± 0.62 to 1.47 ± 0.71 mmol/L, P=0.005) were observed in the rosiglitazone group compared to placebo. There was no treatment effect on HDL or fasting glucose levels. No significant correlation was noted between change in endothelial markers and change in HOMA-R.
Conclusions: We have shown for the first time that rosiglitazone significantly reduces endothelial cell activation in coronary artery disease patients without diabetes mellitus. This effect appears to be independent of other effects on lipid and glucose metabolism, suggesting a direct action on the vessel wall.

2572 Raloxifene reduces oxidative stress and improves endothelial dysfunction in spontaneously hypertensive rats

S. Wassmann[1], U. Laufs[1], D. Stamenkovic[1], W. Linz[2], K. Ahlbory[1], M. Boehm[1], G. Nickenig[1]. [1]Universitaetskliniken des Saarlandes, Medizinische Klinik-Innere Medizin III, Homburg/Saar, Germany; [2]Aventis Pharma, Frankfurt/Main, Germany

Selective estrogen receptor modulators (SERM) such as raloxifene have beneficial estrogenic effects on lipids and bones without increasing the risk of breast or endometrial cancer. To investigate whether SERM exert vasoprotective effects similar to estrogens, male spontaneously hypertensive rats (SHR) were treated for 10 weeks with raloxifene (ralox) (10 mg/kg/d) or vehicle.

Methods and Results: Ralox improved endothelium-dependent vasodilatation of isolated aortic segments but did not affect endothelium-independent vasorelaxation or phenyleprine-induced vasoconstriction. Ralox treatment increased the release of NO from the vessel wall (NO electrode measurements) by enhanced expression and activity of endothelial NO synthase (eNOS) (arginine-citrulline conversion assays, RT-PCR). The vascular production of reactive oxygen species (ROS) was decreased by ralox (lucigenin chemiluminescence assays). Ralox did not alter the vascular expression of the NAD(P)H oxidase subunits p22phox and nox1 (RT-PCR), but reduced the activity and expression of vascular membrane-bound rac1, a GTPase required for the activation of the NAD(P)H oxidase (Western Blot, GTP-binding assays). Blood pressure reduction after bradykinin infusion was increased in ralox-treated SHR. Finally, systolic blood pressure was significantly decreased in SHR treated with ralox (tail-cuff method). All SERM effects were also detected in healthy, age-matched Wistar rats. In cultured rat aortic vascular smooth muscle cells, ralox inhibited angiotensin II-induced ROS production dependent on estrogen receptor activation (DCF fluorescence lasermicroscopy).

Conclusions: Raloxifene improves hypertension-induced endothelial dysfunction by increased bioavailability of NO. This is mediated by enhanced eNOS activity and reduced release of ROS from vascular cells. These vascular effects lead to blood pressure reduction and decreased vascular damage in male SHR.

2573 Impaired NOS pathway in diabetes mellitus: role of ADMA and DDAH

K. Lin, P. Tsao, J. Cooke. *Stanford University, Cardiovascular Medicine, Stanford, United States of America*

Background: An endogenous inhibitor of nitric oxide synthase, asymmetric dimethylarginine (ADMA) is elevated in patients with type 2 diabetic mellitus (DM). The mechanism by which ADMA becomes elevated is unclear. We determined if elevated glucose increases ADMA by impairing the activity of dimethylarginine dimethylaminohydrolase (DDAH), which metabolizes ADMA to citrulline. We further investigated the role of oxidative stress in glucose-induced ADMA elevation.

Methods and Results: Male Sprague-Dawley rats were fed normal chow or high-fat diet (n=5 each) with moderate streptozotocin injection to induce type 2 DM. The diabetic rats showed substantially elevated plasma ADMA compared to normal rats (1.33±0.31 vs. 0.48±0.08mM; $p<0.05$). Aortic DDAH activity, but not expression, was significantly reduced in diabetic rats and negatively correlated with their plasma ADMA levels ($p<0.05$). In vitro studies of vascular smooth muscle cells and endothelial cells revealed that DDAH activity was significantly reduced in both cell types exposed to high glucose (25.5mM). Glucose dose-dependently elevated endothelial elaboration of ADMA, which could be reduced to baseline by the addition of the antioxidant PEG-SOD (22U/mL). To determine if elevated glucose impairs the nitric oxide pathway, cGMP production by endothelial cells was measured and found to be significantly less in cells exposed to high glucose than cells grown in normal level of glucose (5.5mM). Addition of PEG-SOD restored both cGMP production and DDAH activity.

Conclusions: Mediated by oxidative stress, DDAH impairment accounts for ADMA elevation in high glucose condition and leads to reduced nitric oxide synthesis. This observation represents a new insight into diabetes-induced endothelial dysfunction.

2574 The functional integrity of the endothelium modulates dendritic cell adhesion and transmigration

M. Weis[1], C.L. Schlichting[2], E.G. Engleman[2], J.P. Cooke[3]. [1]University Hospital Grosshadern, Medizinische Klinik I, Munich, Germany; [2]Stnaford University, Dep. of Pathology and Medicine, Stanford, United States of America; [3]Stanford University, Cardiovascular Medicine Div., Stanford CA, United States of America

Atherosclerosis is a chronic disease triggered by endothelial injury and sustained by inflammation. The role of dendritic cells (DCs) in this inflammatory response has not been addressed. DCs are critical for the cell-mediated arm of an immune response, and are known to initiate inflammatory immunity. A fundamental aspect of DCs function is their capacity to adhere and migrate through vascular endothelial cells (EC). The aim of the study was to investigate DC/EC interaction under pro-atherosclerotic conditions. Human DC precursors were negatively separated from PBMC by magnetic beads and cultured in GM-CSF and IL-4. Typical phenotype of immature and mature DC was assessed by FACS. Confluent primary human microvascular ECs were incubated with isolated immature and mature DCs. Functional adhesion and transmigration assays were performed and analyzed using confocal laser microscopy and a fluorescent plate reader. We discovered that DC adhesion and migration are modulated by changes in endothelial function. Specifically, the endogenous NOS inhibitor ADMA (1 and 10 uM) (but not the prostacyclin inhibitor indomethacin) significantly increased DC binding and transmigration (+73 and +109%; $p<0.001$). DC adhesion and transmigration was markedly increased after exposing endothelial cells to hypoxia, oxLDL and/or TNFa (73-600%; $p<0.01$). Strikingly, HMG-CoA reductase inhibition (0.5 uM atorvastatin) and L-Arginine significantly decreased DC/EC interaction. The results of this study suggest that adhesion and migration of DCs is increased by stimuli known to accelerate atherogenesis. Vice versa, improvement of NOS activity inhibits DC adhesion. These findings may provide insight into the inflammatory processes occurring in atherosclerosis. As DCs control immunity, regulating DC/EC interaction may have relevance to inflammation and atherogenesis.

2575 Combined B-vitamin complexes and folate improve endothelial function in insulin-resistant hypertensive patients with microvascular disease

A. Palloshi[1], E. Setola[2], G. Fragasso[1], L.D. Monti[2], E.P. Sandoli[2], E. Galluccio[2], P.M. Piattti[2], A. Margonato[1]. [1]Istituto Scientifico San Raffaele, Cardiologia Clinica, Milano, Italy; [2]Istituto Scientifico San Raffaele, Metabolic Unit, Milano, Italy

Background: Microvascular involvement observed in patients with arterial hypertension could be related to endothelial dysfunction. High homocysteine levels are associated with impaired peripheral endothelium-dependent vasodilation. Several studies suggest that folic acid or B vitamins supplementations decrease homocysteine levels and possibly reduce cardiovascular risk. A link between endothelial dysfunction and the metabolic alterations typical of the Insulin Resistance Syndrome (IRS) has been previously demonstrated. However, little is known about the impact of homocysteine decrease, regardless of its basal levels, on endothelial function and metabolic features of IRS.

Methods: Sixteen patients (age 67±2 yrs; BMI 27.6±0.7 kg/m^2) with essential hypertension, chest pain, positive exercise testing and normal coronary arteries, impaired fasting glucose according to American Diabetes Association classification, hyperinsulinaemia and hypertriglyceridaemia were studied. A double blind randomised one month cross-over study with folic acid (5mg/day) plus vitamin B1-B6-B12 (250 mg-250 mg-500μg/day) or placebo was performed. After the end of each period, basal, post-ischaemic and post-nitrate forearm blood flow was evaluated by venous occlusion plethysmography. Blood pressure measurements and blood sampling were also performed.

Results; Compared to placebo, folic acid plus vitamin B treatment significantly decreased homocysteine levels (10.9±0.8 vs 17.2±2.0 μmol/l: $p<0.01$), mean blood pressure (104±2 vs 111±3 mmHG; $p<0.05$) and forearm basal (37.9±2.4 vs 49.2±4.9U; $p<0.05$) and post-ischaemic vascular resistance (28.8±2.8 vs 37.1±2.7U; <0.05) while a significant increment in post-ischaemic forearm blood flow (4.00±0.28 vs 3.16±0.17 ml/100ml/min; $p<0.02$) was observed. On the other hand, no differences were found on endothelium-independent nitrate-mediated vasodilation. Interestingly, no changes in blood glucose, insulin, HOMA index and triglyceride levels were observed. No evaluation of tetrahydrobiopterin levels was carried out.

Conclusions: In hypertensive patients with microvascular involvement, folic acid plus vitamin B supplementations improve endothelium-dependent vasodilation independently from modification of the main features of IRS. Homocysteine reduction may account for this improvement.

2576 Structural markers of atherosclerosis and functional markers of endothelial dysfunction in patients with unstable coronary artery disease

A. Lupi, C. Rassat, S.A. Rizzo, P. Cristallini, M. De Marchi. *Ospedale Generale Valle d'Aosta, Cardiologia, AOSTA, Italy*

Intima-media thickness of the common carotid artery (IMT) and an impaired arterial dilation in response to reactive hyperemia ("flow-mediated" dilation, FMD) are considered markers of atherosclerosis and endothelial dysfunction, which are thought to play a major role in the pathogenesis of coronary artery disease (CAD). A significant correlation between IMT and FMD has been described in patients (pts) with stable CAD. To investigate if a similar relationship occurs in pts with unstable CAD, we compared 30 consecutive pts referred to our CCU for acute coronary syndrome (Group A: 20 males, 59.2±9.8 years, 20 with acute myocardial infarction and 10 with unstable angina Braunwald Class IIIB) and 72 outpatients with stable CAD and/or multiple cardiovascular risk factors (CRF) (Group B: 43 males, 55.9±13.1 years, 22 with stable CAD and 50 with 2 or more CRF). For each patient we collected: 1) a cardiovascular risk score based upon several CFRs, previously validated in the SMART study (SMART#) 2) an high resolution US scan evaluation (linear array probe, 12-5MHz) of the common carotid artery IMT and of the percentage change of radial artery diameter in response to reactive hyperemia (FMD) induced by 5 min forearm stop-flow (brachial pneumatic tourniquet). At the moment of the US evaluation pts were fasting (12h) and in wash out from nitrates and calcium-antagonists (48h). Pts with acute CAD were evaluated from 4 to 6 days after the last spontaneous episode of transient myocardial ischemia. Sex prevalence and mean age of the 2 groups were not significantly different. Group A SMART# were slightly higher than Group B (7.70±1.39 vs 6.08±2.50, p=0.001). IMT (0.82±0.25 vs 0.76±0.19 mm, p NS) and FMD (9.01±5.57% vs 9.95±5.85%, p NS) were similar in the 2 groups. FMD was significantly correlated to IMT in Group B (R= -0.32, p=0.006) but not in Group A (R= -0.09, p NS). Finally, in Group B SMART# was strongly correlated to IMT (R= 0.79, p<0.0001) and FMD (R= -0.44, p<0.0001), whereas in Group A these correlations were weaker (SMART# vs IMT: R= 0.61, p=0.004, SMART# vs FMD: R= -0.29, p NS). In conclusion, this study confirms that IMT and FMD are correlated in pts with stable CAD. Similar findings were not observed in the population with unstable CAD studied. Moreover structural and functional markers of vascular disease correlated closely to SMART# in pts with stable CAD, but this was not the case for pts with unstable CAD. These intriguing finding, probably due to the multifactorial pathogenesis of the acute coronary syndromes and the eterogeneity of the pts studied, deserves further study.

THE "ACTIVE" PLATELET

2577 The RNA-binding protein TIA-R is involved p38 MAP-kinase-dependent protein synthesis in activated human platelets

S. Lindemann[1], N D. Tolley[2], A S. Weyrich[2], G A. Zimmerman[2]. [1]*Johannes Gutenberg-University Mainz, Department of Medicine II, Mainz, Germany;* [2]*Eccles Institute of Human Genetics, Program in Human Molecular Biology, Salt Lake City, United States of America*

Platelets respond to thrombin or exposed subendothelial matrix at sites of vascular injury by forming hemostatic aggregates that prevent or limit bleeding. Although their hemostatic actions are of paramount importance, platelets also promote the development or progression of atherosclerosis or restenosis after angioplasty. It is generally believed, that these pathophysiologic functions depend largely on the release of preformed mediators. Here, we demonstrate that platelets may also contribute to prolonged inflammatory events by protein synthesis that is regulated by p38 MAP kinase. Among these proteins we further investigated the expression of Interleukin-1beta (IL-1b). Using gene array analysis we found in a previous study that platelets contained numerous megakaryocyte-derived mRNAs. Here, we demonstrated by 35S-methionine-uptake, that platelets translate mRNAs into protein in an activation-dependent fashion, a response that is abrogated when platelets were treated with the p38 MAP-kinase inhibitor SB203580. Following stimulation with PAF [10nM] or thrombin [0.1 U/ml] the IL-1b precursor mRNA was translated into protein (unstimulated control (co): 23±11 pg/ml; PAF [10-7M, 8hrs]: 2374±259pg/ml; thrombin [0.01U/ml, 8 hrs]: 615±120 pg/ml; p<0.05 vs. co). The IL-1b precursor protein was further processed and secreted as active, mature IL-1b. SB 203580 inhibited expression of both forms of IL-1b indicating, that p38 MAP kinase prevented synthesis, not conversion of the IL-1b precursor into the active cytokine. We found that the p38 MAP-kinase was phosphorylated within minutes and remained phosphorylated up to several hours. We then extracted the mRNA binding proteins of activated platelets that were treated with SB203580 or not and separated these by 2-dimensional gel electrophoreses. Among several proteins bound to platelet mRNA, we found that two proteins were bound to the mRNA only when the cells were treated with SB203580. By western blot analysis with a specific antibody, we identified one of these proteins as TIA-R. In conclusion, this study provides evidence that platelets synthesize IL-1b in an p38MAPkinase dependent fashion and that p38 MAP kinase recruits TIA-R to the platelet mRNA to inhibit translation. Regulated protein synthesis in activated platelets may be a mechanism by which platelets can enhance inflammatory outcomes and SB203580 might be a pharmacological approach to influence platelet-induced inflammation in a beneficial way.

2578 Increase in the number of fibrinogen receptors by glycoprotein IIb/IIIa inhibitors

R. Artang[1], G.W. Jurgensen[2], N.J. Frandsen[3], J.D. Nielsen[1], P.E. Bloch Thomsen[3]. [1]*Coagulation Laboratory, Hellerup;* [2]*Hilleroed Hospital, Clinical Chemistry, Hilleroed;* [3]*Gentofte Univ. Hospital, Cardiology, Hellerup, Denmark*

Purpose: Glycoprotein (GP)IIb/IIIa receptor blockade reduces the risk of thromboembolic episodes during percutaneous coronary interventions. Currently three intravenous agents are available: abciximab, eptifibatide and tirofiban. An upregulation of GPIIb/IIIa receptors during treatment with abciximab has been reported both in vivo and in vitro. The aim of this study was to investigate whether eptifibatide and tirofiban have the same effect on platelets.
Methods: After obtaining informed consent, blood from 6 healthy male volunteers (mean age ± SD: 42 ± 8) was drawn. Citrated whole blood was incubated with abciximab in concentrations 0, 1, 2, 3 and 4 μg/ml, epifibatide in concentrations 0, 0.1, 0.5, 1 μg/ml and tirofiban in concentrations 0, 10, 20, 50 and 100 ng/ml, based on previous pharmacokinetic studies of patients receiving recommended doses of each drug. For evaluation of platelet inhibition and number of GPIIb/IIIa receptors, platelets were labeled with FITC-conjugated antibodies against fibrinogen and CD41 (clone SZ22, non-fibrinogen ligand of GPIIb/IIIa receptor), and analyzed by flow cytometry. Mean fluorescence intensities at baseline and at mentioned concentrations were compared using Friedmann Repeated Measures ANOVA test.
Results: Inhibition of platelet fibrinogen binding of >80% was achieved with 2 μg/ml abciximab, 0.5 μg/ml eptifibatide and 50 ng/ml tirofiban. At these concentrations, the mean number of GPIIb/IIIa receptors increased 37 ± 13% (mean ± SD, p<0.01) for abciximab, 10 ± 3.4% (ns) for eptifibatide, and 36 ± 10% for tirofiban (p<0.05) compared to baseline.
Conclusion: While all three GPIIb/IIIa agents inhibit platelet fibrinogen binding effectively at the recommended doses, they have the capability of increasing the number of fibrinogen receptors on platelets in vitro. We have demonstrated for the first time an increase in the number of fibrinogen receptors induced by tirofiban. An increase in the number of receptors may be one of the mechanisms of post-procedural coronary adverse events despite GPIIb/IIIa inhibition. Clinical relevance of this phenomenon requires further investigation.

2579 The central role of platelet activation in determining the mode of presentation of acute coronary syndromes

S.R.O. Kennon[1], M. Macey[2], J. Cooper[3], S. Ramdanay[4], A.D. Timmis[1]. [1]*London Chest Hospital, Cardiology Dpt., London;* [2]*The Royal London Hospital, Haematology, London;* [3]*Charterhouse Square, MRC Epidemiology Unit, London;* [4]*Royal London Hospital, Cardiology, London, United Kingdom*

Background: Clinical studies have shown that in acute coronary syndromes, pretreatment with aspirin favours presentation with unstable angina (UA), while cigarette smoking favours presentation with myocardial infarction (AMI). Although serum markers of platelet activation are increased in patients with acute coronary syndromes but it is not known whether there is different activation in unstable angina and acute myocardial infarction.
Hypothesis: Platelet activation at the time of plaque rupture is a major determinant of the mode of presentation of acute coronary syndromes.
Methods: Patients presenting to the emergency room with acute myocardial infarction and unstable angina were recruited. Blood samples were analysed within 4 hours, for mean platelet component (MPC), a measure of platelet activation derived from flow cytometry utilising a laser source and light scattering technology. MPC reflects the granularity of platelets and is inversely related to the expression of CD62P.
Results: The study group comprised 25 patients with AMI and 64 with UA. The groups were similar as regards age and gender distribution. Mean platelet component was lower in AMI than UA (24.67±1.58 v. 25.86±1.38 g/dl, p=0.001), reflecting significantly greater platelet activation. This difference persisted when the unstable angina cohort was limited to 48 patients at high risk of future cardiac events defined by troponin I concentration >0.1μg/l, or ischaemic ST/T changes on the presenting ECG (24.67±1.58 versus 25.81±1.44 g/dl, p=0.016). Pretreatment with aspirin was less frequent (16.0% versus 68.8%, p<0.0001), and smoking more frequent (48.0% versus 28.1%, p=0.08) in AMI than UA, but in multivariate analysis mean platelet component (odds ratio 0.36; 95% confidence intervals 0.18-0.72) was retained as an independent predictor of diagnosis, despite adjustment aspirin treatment and smoking. Mean platelet volume tended to be higher in AMI than UA (9.4±1.2 versus 9.1±0.9 fl), but the difference was not significant.
Conclusion: This study has shown diagnosis-specific differences in platelet activation in acute coronary syndromes. The finding that platelet activation at the time of presentation was greater in acute myocardial infarction than unstable angina confirms the central role of thrombogenicity in determining the clinical expression of plaque events.

2580 Baseline platelet function in "low responders" to antiplatelet treatment following coronary stent implantation

C. Barrera[1], A. Fernandez-Ortiz[2], D.J. Angiolillo[1], E. Bernardo[1], M.E. Viveros[1], S. Vazquez[1], M. Sabaté[3], C. Macaya[3]. *[1]Cardiovascular Research Laboratory, [2]Coronary Care Unit, [3]Invasive Cardiology Unit, Hospital Clinico San Carlos, Madrid, Spain*

Although most pts undergoing coronary stent implantation (STI) routinely receive double antiplatelet treatment, aspirin plus clopidogrel, a thrombotic risk early after STI still persists. We compared baseline platelet activation and aggregation among pts with low and high inhibition of platelet aggregation (PA) following STI. Methods: PA was assessed before and 24 hrs after STI in 31 consecutive pts using a light transmittance aggregometry after stimuli with 6μM of ADP and 6μg/mL of collagen. GP IIb/IIIa (anti-fibrinogen-FITC) and P-selectin (CD62-PE) platelet surface expression was also measured after stimuli with 2μM of ADP before and 24 hrs after STI using whole blood flow cytometry. All pts were treated with aspirin (100 mg/day) and received a 300 mg loading-dose of clopidogrel at intervention time. During intervention 100 IU/kg of heparin was administered. Pts receiving GP IIb/IIIa inhibitors were excluded. According to the grade of PA upon 6μM ADP stimuli 24 hrs after STI, pts were divided into two groups: G1 (PA>30%) and G2 (PA<30%). Cut-off value of 30% was the median value of our study population and it is a widely used cut-off clinical value to assess platelet inhibition. Time point of 24 hrs is crucial for early coronary thrombosis and at this time full effect of loading-dose of clopidogrel should be observed. Results (mean±SD): G1 and G2 were composed of 13 (10 men;age:63±7y) and 18 (17 men;age:62±11y) pts, respectively. PA upon ADP stimuli 24 hrs after STI was 52,92±16,8% in G1 and 18,67±7,6% in G2 ($p<0.001$). G1 presented a greater PA than G2 even upon stimuli with collagen 24 hrs after STI (55,05±26,34% vs 35,88±20,91%; p=0.032). No differences in baseline PA with ADP (54,76±24% vs 44,91±11,24%; p=0.19) or with collagen (47,10±16,83% vs 42,39±16,32%; p=0.44) were observed between G1 and G2. Therefore, despite antiplatelet treatment, 13 out of 31 (42%) pts had low inhibition of PA 24 hrs after STI. P-selectin expression was 44%±16% vs 42%±19% (P=0.8) at baseline and 27±13% vs 22±15% (p=0.4) 24 hours after STI in G1 and G2, respectively. GP IIb/IIIa expression was 68%±19% vs 51%±23% (p=0.040) at baseline and 57±25% vs 35±29% (p=0.048) 24 hrs after STI. Conclusion: Despite aspirin and clopidogrel treatment, a high proportion of pts undergoing STI may have a poor inhibition of PA early after the intervention. An enhanced GP IIb/IIIa receptor activation at baseline in these pts may help to identify candidates who may obtain the largest benefit from treatment with GP IIb/IIIa receptor antagonists.

2581 The adverse effects of COX-2 inhibitors on cardiovascular disease: fact or fiction

D. Jassal, J.L. Cox. *Halifax, Canada*

Background: At the turn of the new millennium, a new class of anti-inflammatory agents associated with minimal gastric toxicity were introduced, termed the COX-2 inhibitors. A recent subgroup analysis of two randomized trials assessing the efficacy of COX-2 inhibitors suggested that the effects of these agents on prostacyclin synthesis may adversely increase prothrombotic activity, increasing the risk of cardiovascular events. However, no literature to date addresses the safety of COX-2 inhibitors in a specific cardiovascular patient population.

Objective: We examined outcomes in individuals who had previously been taking COX-2 inhibitors and were admitted with an acute coronary syndrome, either unstable angina (UA) or myocardial infarction (MI).

Methods: We utilized a prospective registry-based disease management database, Improving Cardiovascular Outcomes in Nova Scotia (ICONS), to identify all individuals in Nova Scotia, Canada with a discharge diagnosis of acute coronary syndrome (ACS) between January 1, 1999 and December 31, 2000. We identified a cohort of 302 individuals on COX-2 inhibitors and compared them to the total 6829 patients admitted with acute coronary syndrome. Outcome measures including length of hospital stay, in hospital death rate, readmission rates for acute coronary syndrome (ACS) at one year, and one year mortality rates were compared amongst both groups.

Results: The relative percentage of patients on COX-2 inhibitors was 4.4% of a total of 6829 individuals admitted with an acute coronary syndrome between 1999-2000. The mean length of hospital stay was 9.64 days for the total population versus 10.06 days for the COX-2 patients (p=NS). The in hospital mortality rate was identical in both groups at 8.3% (p=NS). Although readmission rates within one year were similar for the COX-2 inhibitor population and the total population at 32.9% and 29.7% respectively (p=NS), patients on the anti-inflammatory medications were more likely to be readmitted with unstable angina within the year, 24.9% vs 17.9% ($p<0.05$). Finally, one year mortality was not statistically higher for those individuals on COX-2 inhibitors.

Conclusion: These findings are particularly pertinent in light of the recent debate of whether COX-2 inhibitors are truly deleterious for those individuals with underlying ischemic heart disease. Although limited, our findings would suggest that these novel anti-inflammatory agents may not increase the risk of an adverse cardiovascular outcome.

2582 Acute resolution of hyperglycemia normalizes platelet responsiveness to nitric oxide in diabetics with acute coronary syndromes

M. Worthley, A.S. Holmes, Y.Y. Chirkov, C.J. Zeitz, J.D. Horowitz. *North Western Adelaide Health Service, Cardiology, Adelaide, Australia*

Background: Diabetics mellitus (DM) is associated with increased mortality in acute coronary syndromes (ACS) when compared with non- DM subjects. The DIGAMI study in DM patients with acute myocardial infarction (AMI) demonstrated that reversal of hyperglycaemia is associated with reductions in 1 year mortality, but no mechanism(s) have been demonstrated for this effect. We now tested the null hypothesis that platelet responsiveness to the anti-aggregatory effects of nitric oxide (NO) donors are independent of BSL.

Methods: DM subjects with ACS (unstable angina or non-Q-wave AMI) and an admission BSL >10mmol/L were enrolled in the study. Subjects were randomized to intravenous (IV) or subcutaneous (SC) insulin administration. Platelet function was assessed by ADP-induced aggregation (Ohms) and its inhibition by the NO donor sodium nitroprusside (SNP, % inhibition of control). This was performed in whole blood and platelet rich plasma (PRP) via impedance aggregometry. Effects on whole blood superoxide (O2-) and platelet cyclic GMP (cGMP) response to SNP were also compared. Data were collected at baseline and after 12 hours of treatment.

Results 47 patients were randomized. Patients were 67±1.8 (SE)years old with an admission BSL of 16.8±1 and an HbA1c of 8.8±.3. On admission 24% of patients were insulin dependent. The effects of therapy in whole blood are shown in Table 1, expressed as change over 12 hrs (delta).There were no significant differences, between the treatment groups when performing the above experiments in PRP. Platelet cGMP response did not differ significantly between the two treatment groups.

delta(0-12hrs)	IV (n=24)	SC(n=23)	Significance
BSL (mmolo/L)	-11.1 ± 1.8	-3.7 ± 1.2	p<0.01
ADP response (Ohms)	0.5 ± 0.4	0.1 ± 0.8	
SNP Response (% inhibition)	15.4 ± 4.8	2.4 ± 3.6	p<0.05
O2- content (mv)	-12.5 ± 5.5	5.7 ± 3.5	p<0.05

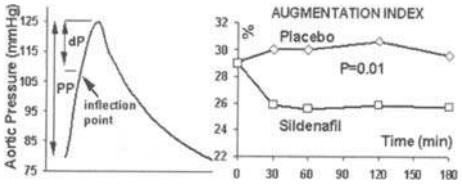
Conclusions: In DM patients presenting with an ACS, more aggressive BSL control with IV insulin significantly enhances the antiaggregatory effects of NO when compared to SC insulin. The 'scavenging' of NO by O2-, rather than stabilization of soluble guanylate cyclase, probably contributes to these findings.

ADVANCES IN HYPERTENSION MANAGEMENT

2593 Sildenafil (Viagra®) improves arterial stiffness in hypertensive patients

C. Vlachopoulos[1], K. Hirata[2], C. Stefanadis[3], P. Toutouzas[3], M. O'Rourke[2].
[1]*Henry Dunant Hospital, Cardiology, Athens, Greece;* [2]*University of New South Wales, Cardiology, Sydney, Australia;* [3]*Athens Medical School, Cardiology, Athens, Greece*

Background: Sildenafil (Viagra®) is a new, effective drug for erectile dysfunction acting on the metabolism of nitric oxide. However, its effects on the cardiovascular system have not been thoroughly investigated. Wave reflection along the arterial tree is an important index of arterial stiffening and cardiac afterload and has been inversely associated with exercise capacity.
Methods: To investigate the effect of sildenafil on arterial wave reflection we studied 17 hypertensive patients (age 72±7 years) in a randomized, double-blind, cross-over fashion (50 mg of sildenafil and placebo). Wave reflection was studied using a validated system (Sphygmocor®) that employs (i) high-fidelity arterial tonometry (Millar tonometer) for the non-invasive registration of radial pulse waveform and (ii) appropriate computer software for pulse wave analysis. Aortic pressure waveform was synthesized from the radial waveform using a generalized transfer function. Augmentation index (=dP/PP %, fig.: waveform) was measured as an index of wave reflection. Inflection point (Pi) was defined with mathematical algorithms. Lower values of augmentation index indicate reduced arterial stiffening and reduced cardiac load and vice-versa.
Results: Sildenafil caused a decrease in aortic systolic and diastolic pressure (by 16.2 and 10.1 mmHg respectively; P<.001 for both). Sildenafil led to a significant decrease in augmentation index indicating decreased effect of wave reflection from the periphery (fig.: trends).



Viagra and wave reflection.

Conclusions: Sildenafil leads to a decrease of wave reflection in hypertensive patients. This finding has important implications for arterial stiffening and the pulsatile load of the heart and may contribute to improved exercise capacity of the patients at intercourse.

2594 Different effects of amlodipine and valsartan on renal haemodynamics in essential hypertension

C. Delles[1], A.U. Klingbeil[1], M.P. Schneider[1], R. Handrock[2], R.E. Schmieder[1]. [1]*University of Erlangen-Nürnberg, Department of Medicine IV, Erlangen, Germany;* [2]*Novartis Pharma GmbH, Nürnberg, Germany*

Objective: Angiotensin AT1-receptor blockers have been found to be renoprotective in hypertensive patients with nephropathy. To elucidate the renoprotective mechanism of AT1-receptor blockers, we compared the effects of the AT1-receptor blocker valsartan with that of the calcium channel blocker amlodipine on renal hemodynamics and microcirculation. **Methods:** Fifty-eight patients (age, 50.2±9.0 years) with mild to moderate essential hypertension were included in a randomized, double-blind study to receive either valsartan (80-160 mg) or amlodipine (5-10 mg). Renal plasma flow (RPF) and glomerular filtration rate (GFR) were measured before and after 8 weeks of treatment. Infusion of NG-monomethyl-L-arginine (L-NMMA; 4.25 mg/kg) was used to assess the contribution of nitric oxide to the perfusion of the renal vasculature. Glomerular hydrostatic pressure (PGlo) and resistances of the afferent (RA) and efferent (RE) arterioles were calculated according to Gomez' formulae. **Results:** Blood pressure control was similar in both groups. RPF did not change with either treatment. In contrast, GFR increased with amlodipine (+8±14 mL/min; p<0.01), but was preserved with valsartan (-0.3±11.3 mL/min; p=n.s.; p<0.05 for comparison between amlodipine and valsartan). Treatment with amlodipine caused a more marked increase in the RE/RA ratio than the one with valsartan (+0.26±0.26 vs. +0.13±0.24, p<0.05) which was paralleled by an increase in PGlo in amlodipine (+1.9±4.3 mmHg; p<0.05) but not in valsartan treated patients (-0.4±4.3 mmHg; p=n.s.). Valsartan maintained the response of RPF to L-NMMA (-44±60 vs. -40±56 mL/min before and after treatment, respectively; p=n.s.), whereas the response of RPF to L-NMMA was reduced with amlodipine treatment (-58±67 vs. -22±55 mL/min, respectively; p<0.05). **Conclusion:** At similar blood pressure control, GFR and PGlo were maintained with valsartan treatment whereas amlodipine leads to glomerular hyperfiltration paralleled by an increase in PGlo. The effects on nitric oxide bioavailability in the renal vasculature contrast between valsartan and amlodipine, too. Both results might account for the favorable renal outcome in patients treated with AT1-receptor blockers.

2595 Chronic angiotensin II receptor blockade reduces sympathetic nerve traffic and improves insulin resistance in obese hypertensives

G. Grassi[1], G. Seravalle[2], F. Quarti[1], R. Dell'Oro[1], F. Arenare[1], G. Mancia[1]. [1]*Hpt. S. Gerardo, Medicina Interna, Monza, Italy;* [2]*Istituto Auxologico Italiano, Cardiology, Milan, Italy*

Objective: Animal studies have suggested that angiotensin II (AII) may exert in obese subjects pro-hypertensive effects by activating sympathetic drive and thus promoting, by adrenergic mechanisms, the occurrence of an insulin-resistance (IR) state. The present study was aimed at testing this hypothesis by examining the effects of chronic AII receptor blockade on muscle sympathetic outflow as well as on insulin sensitivity in obesity-related hypertension.
Design and Methods: In 24 obeses with a mild to moderate essential hypertension (age: 50.3±1.8 yrs, body mass index: 34.3±0.9 kg/m^2, mean arterial pressure, MAP: 111.4±2.0 mmHg, mean±SEM) we measured 24 h ambulatory, clinic and beat-to-beat MAP along with heart rate (HR, EKG) values. Measurements, which also included direct microneurographic assessment of muscle sympathetic nerve traffic (MSNA) as well as evaluation of the IR index (oral glucose overload test), were performed in the no-drug placebo condition and repeated following 12 weeks of either candesartan cilexetil (C, 8/16 mg o.d.) or hydrochlorothiazide (H, 25/50 mg o.d.) daily oral administration, accordingly to a double blind, randomized two parallel groups study design.
Results: Baseline hemodynamic, metabolic and neuroadrenergic values were similar in the two groups. C caused a significant MAP reduction (from 112.5±3.4 to 90.1±3.0 mmHg, p<0.01) coupled with a significant MSNA decrease (from 68.5±3.4 to 55.9±3.2 bs/100 hb, p<0.01) and an improved insulin sensitivity (+24.5±5.1, p<0.05). In contrast, for MAP reductions similar to C (from 110.5±3.2 to 93.1±2.9 mmHg, p<0.01), H did not significantly affect either MSNA (from 68.8±3.5 to 69.6±3.4 bs/100 hb) or insulin sensitivity (-8.7±6.1%).
Conclusions: These data provide direct evidence that renin-angiotensin system partecipates at the sympathoexcitation and at the IR state which characterize obesity-related hypertension. They also show that, at variance from diuretics, A II receptor blockers are capable to exert sympathoinhibitory effects coupled with improved metabolic insulin profile.

2596 Effects of antihypertensive treatment on cardiac and vascular remodelling in older hypertensives: the ICARe Dicomano study

R. Pini[1], M.C. Cavallini[2], L. Staglianò[1], C. Bellotto[1], M. Di Bari[2], N. Marchionni[1], G. Masotti[1], M.J. Roman[3]. [1]*University of Firenze, Critical Care Medicine and Surgery, Firenze, Italy;* [2]*Ospedale Careggi, Gerontology and Geriatrics, Firenze, Italy;* [3]*NYPH-WMC of Cornell University, Medicine, New York, NY, United States of America*

Background: Hypertension is one of the major cardiac and cerebrovascular risk factors. Although there is general consensus on the efficacy of antihypertensive treatment, hypertension is often underdiagnosed and undertreated in older subjects. The aim of the present study is to compare cardiac and vascular changes in treated and untreated older hypertensive subjects.
Methods: Community-dwelling individuals aged >=65 years living in Dicomano, a small town in Italy, underwent extensive clinical examination, echocardiography, carotid ultrasonography and applanation tonometry. In the present analisys we included 225 untreated and 213 treated hypertensive subjects.
Results: Only 20% of the treated subjects had adequate control of blood pressure (<140/90 mmHg). Treated subjects were younger (73±6 vs. 74±7 yrs, p=.026) and had a higher prevalence of comorbidity (history of coronary and cerebrovascular disease: 14% vs. 4%, p<.0001, and 24% vs. 7%, p<.0001, respectively) than untreated subjects. Left ventricular wall thickness and mass index (LVMI) were similar in the two groups. Carotid intimal-medial thickness (IMT) and the number of carotid plaques (0.88±0.17 vs. 0.84±0.17 mm, p=.033, 3±2 vs. 2±2, p=.020) were greater, whereas carotid stiffness index (Beta) was lower (4.55±2.02 vs. 5.35±2.77, p=.003) in treated subjects. To reduce the confounding effect of the non homogeneous distribution of comorbidity in the study population, all subjects with history of cardiac and cerebrovascular diseases were excluded from the subsequent analyses; these subjects were divided into three groups by presence and adequacy of antihypertensive treatment (193 not treated=NT, 22 adequately treated=AT, 108 undertreated=UT). When compared with UT subjects, AT subjects showed significantly lower left ventricular mass and LVMI (131±43 vs. 168±61 g, p=.017 and 77±23 vs. 99±34 g/m^2, p=.008, respectively) while IMT, carotid diameter in diastole, and the number of carotid plaques were similar in the two groups. The stiffness index was significantly higher in the NT group compared with the UT group (5.38±2.88 vs. 4.41±1.84, p=.015).
Conclusions: In our older population, effective anti-hypertensive treatment is associated with a significant reduction in cardiac remodeling. Furthermore, although carotid structural parameters are similar, independent of the presence and efficacy of treatment, carotid artery stiffness is significantly reduced in treated subjects. This study suggests that, in older patients, an effective antihypertensive treatment may reduce the degree of cardiovascular remodeling.

2597 Cardiovascular morbidity in hypertensive patients treated with angiotensin-converting enzyme inhibitors or calcium channel blockers in primary care

G. McInnes[1], D.J. Hole[2], L.S. Murray[1], R. Morton[2], A.F. Lever[1], P.A. Meredith[1], J.L. Reid[1]. [1]*Western Infirmary, Medicine and Therapeutics, Glasgow, United Kingdom;* [2]*University of Glasgow, Department of Public Health, Glasgow, United Kingdom*

In hypertensive patients attending the Glasgow Blood Pressure Clinic, a secondary and tertiary referral centre, treatment with ACE inhibitors (ACEI) is associated with cardiovascular mortality lower than that following calcium channel blocker (CCB) treatment. The objective of this study was to compare cardiovascular morbidity in patients receiving these drug classes in the primary care setting. The United Kingdom General Practice Research Database (GPRD) contains validated demographic, diagnostic and prescription information on over 3 million patients in primary care. From these, we identified a priori a representative sample of 105,965 treated hypertensives eligible for a retrospective cohort analysis. Only those who received ACEI or CCB as first-line therapy and without evidence of cardiovascular disease prior to treatment with a drug of interest were included. Cardiovascular morbidity rates in ACEI and CCB were compared as relative hazard ratios (RHR) with 95% confidence intervals (CI) using Cox proportional hazard model with adjustment for age, gender and year of entry. The results are shown in the table.

Events	ACEI (n = 11249)	CCB (n = 12494)	RHR	95% CI
CHD (incl angina)	946 (8.4%)	1902 (15.2%)	0.63	0.58, 0.68
CHD (excl angina)	509 (4.5%)	1063 (8.5%)	0.91	0.82, 1.02
Cerebrovascular	498 (4.4%)	863 (6.9%)	0.87	0.78, 0.97
LV failure	598 (5.3%)	1009 (8.1%)	0.90	0.81, 1.00

Compared with CCB, first-line treatment of hypertension with ACEI was associated with highly significant reductions in cardiovascular morbidity - 37% for CHD and 13% for cerebrovascular events. Trends in favour of ACEI were seen for CHD even if symptomatic angina was excluded and for LV failure. Since approximately 25% of patients in each group went on to receive a drug from the other class of interest, the findings may underestimate the true difference. In the primary care setting, treatment of hypertension with ACEI is associated with lower cardiovascular morbidity than that following CCB. The results support earlier findings and suggest that observational studies in large well-documented, populations treated in the usual clinical setting may allow differentiation of the cardiovascular protective effects of antihypertensive drugs.

2598 Antihypertensive therapy at the onset of an acute myocardial infarction predicts in-hospital mortality

A. Reikvam[1], K. Landmark[2], E. Kvan[2], I. Aursnes[2]. [1]*Oslo, Norway;* [2]*University of Oslo, Dpt. of pharmacotherapeutics, Oslo, Norway*

Background: Clinical studies have shown that both conventional antihypertensive drugs (thiazide diuretics and beta-blockers) and the newer agents (calcium blockers and angiotensin-converting enzyme (ACE) inhibitors) are almost equally efficacious with regard to effects on blood pressure, and in preventing cardiovascular morbidity and mortality. However, the potential value of these drugs when hypertensive patients (pts) suffer an acute myocardial infarction (AMI) is not known. For practical reasons this issue can not be studied in a clinical trial. We applied an observational study design to investigate whether being on different antihypertensive drugs at the start of symptoms could influence in-hospital death in hypertensive AMI pts.
Methods: Of a total of 898 consecutive pts discharged dead or alive with the diagnosis of AMI (ICD 10 I21/I22), 299 pts reported a history of previous hypertension, and these were included in the study. 16 hospitals participated, and the sampling of pts was done during a three months period in 1999/2000. Variables were entered into a logistic regression model.
Results: The main predictors of death were age and the use of diuretics and calcium blockers, while the use of ACE inhibitors was associated with a significant 58% reduction in mortality (table). Other cardiovascular drugs (beta-blockers, aspirin, warfarin, digitalis) did not influence in-hospital death. Nor did gender, previous coronary heart disease, heart failure, diabetes mellitus nor smoking.

		Adjusted odds ratio	95% confidence interval	P value
Age (n = 299)	>70 years	3.26	1.29-8.24	0.012
Diuretics (n = 116)	yes/no	3.12	1.52-6.41	0.002
Calcium blockers (n = 105)	yes/no	2.26	1.14-4.48	0.020
ACE inhibitors (n = 104)	yes/no	0.42	0.19-0.93	0.033

Conclusions: The present observational study shows that being on ACE inhibitors at the start of symptoms reduced in-hospital death in hypertensive pts suffering an AMI, while diuretics and calcium blockers increased the risk for in-hospital death.

PROGRESS IN PREVENTION OF STROKE

2599 Biochemical composition and echostructure of carotid plaques from symptomatic and asymptomatic patients

I. Goncalves[1], J. Moses[1], L. Pedro[2], N. Dias[2], M. Lindholm[1], J. Fernandes e Fernandes[2], J. Nilsson[1], M. Ares[1]. [1]*Lund University, Wallenberg Lab, Malmö, Sweden;* [2]*Instituto Cardiovascular de Lisboa, Lisbon, Portugal*

As carotid atherosclerotic plaques have been associated with cerebrovascular events, their early detection and characterization with ultrasonography has become more and more relevant. Echolucency, classically related to haemorrhage or lipid, has been associated with higher neurological risk. Nevertheless, the relation between symptoms, echostructure and plaque composition is not fully understood. In this study, biochemical components of carotid plaques were compared between symptomatic and asymptomatic patients, and echolucent and echorich plaques.
Thirty human carotid plaques were snap-frozen immediately after their removal by endarterectomy. Thirteen plaques were associated with ipsilateral hemispheric symptoms. Carotid high-definition ultrasonography (ATL-HDI3000) was performed preoperatively. Images were digitalized and standardized with computer-assisted analysis, being divided into two equal groups: predominantly echolucent or echorich. The total amounts of hydroxyapatite, collagen, elastin, soluble protein and DNA were determined.
Results (table) were normalized and expressed in μg/mg of plaque wet weight, except for hydroxyapatite, in mg/mg of plaque wet weight. Statistical analysis was done using unpaired Student's t-test.

	Symptomatic	Asymptomatic	p	Echolucent	Echorich	p
Hydroxyapatite	4,3±4,2	18,6±21,1	0,04	14,7±19,1	11,5±15,3	NS
Collagen	95,4±27,9	77,7±13,1	0,04	91,7±22,9	69,0±19,0	0,02
Elastin	22,8±6,2	17,6±5,6	0,03	22,1±5,6	16,9±3,6	0,01
Soluble Protein	8,9±2,3	7,0±1,5	0,01	8,1±2,2	7,7±2,3	NS
DNA	73,2±17,1	61,2±11,9	0,03	74,9±13,7	60,5±14,3	0,02

Table I – Normalized results (mean±SD) for plaque wet weight (hydroxyapatite, in mg/mg of plaque wet weight and the other variables in μg/mg of plaque wet weight). NS, not significant.

In conclusion, plaques associated with symptoms contained less hydroxyapatite, more collagen, elastin, soluble protein and DNA. Similar results were also obtained for the echolucent plaques. This study suggests that echogenicity is not necessarily associated with the presence of high levels of collagen and elastin.

2600 Association of gene-gene and gene-environment interactions in atrial fibrillation and sinus rhythm with cerebro-vascular events

R. Winkler[1], B. Klein[1], R. Gök[1], W. März[2], B.R. Winkelmann[3], J. Senges[1], G. Taubert[1]. [1]*Herzzentrum Ludwigshafen, Medizinische Klinik B, Ludwigshafen, Germany;* [2]*Universität Freiburg, Cardiology, Freiburg, Germany;* [3]*Universität Heidelberg, Medizinische Klinik, Kardiologie, Heidelberg, Germany*

Background: Gene polymorphisms (PM), involved in hemostasis and blood pressure regulation have been inconsistently associated with cardiovascular disease either directly or through their association with blood levels of cardiovascular risk factors
Objective: Association of classical risk factors, PM of the renin-angiotensin-aldosteron-system: (angiotensinogen (ANG) 174, ANG 235, ACE insertion/deletion (ID)), and the hemostasis: (factor (F) VII 353, PAI-1 4G/5G), as well as their interactions with cerebro-vascular events (CVE), stratified by sinus rhythm (SR) and atrial fibrillation (AFIB).
Patients and Methods: 3316 patients [62±11 years, 70% male, 59% hypertension (HT), 32% diabetes mellitus (DM), 78% coronary artery disease, SR: n=2946, AFIB=370] of the Ludwigshafen Risk and Cardiovascular Health study. A CVE was defined as TIA, PRIND, or stroke in the medical history (Hx). A multiple regression model (PROC GLM of the SAS package) was used for interaction-analysis.
Results: All PM where in Hardy Weinberg equilibrium. No influence of CAD, gender, PAI-1, d-dimers, and the single PM ANG 174, ANG235, PAI-1 4G/5G on Hx of CVE were seen in both groups. In SR age, hypertension, diabetes mellitus (all $p<0.001$), and in AFIB ACE ID and FVIII353 were associated with a Hx of CVE (all $p<0.05$) (table).

Gene-gene/gene-environment interaction

	SR	AFIB
Hx of CVE, %	7%, n=219	13%, n=49
ANG 174/ FVIII353	<0.0001	n.s.
ANG 235/ FVIII353	<0.005	n.s.
ACE ID/DM	<0.05	n.s.
ACE ID/ANG 174	<0.05	n.s.
ACE ID/PAI4G5G	n.s.	<0.05
ANG235/D-dimer	n.s.	<0.05
PAI4G5G/HT	n.s.	<0.05

Conclusion: 1) Classical risk factors (DM, HT, Age) for a CVE were significant predictors in SR but not in AFIB. 2) Monogenetic influence of the ACE ID and FVII353 genotype in the prediction of a CVE were seen in AFIB. 3) Despite no influence as monogenetic factor, different patterns of gene-gene and gene-environmental interaction were associated with a Hx of CVE in SR vs. AFIB.

2601 The increase recognition of cardiac papillary fibroelastoma. A French multicenter study about 46 cases

R. Roudaut[1], R. Lorillard[2], A. Cohen[2], S. Lafitte[1]. [1]*Hôpital Cardiologique, Pessac, France;* [2]*Société Française de Cardiologie, Filiale Echocardiographie, Paris, France*

Papillary fibroelastoma (PF) are rare, small, benign tumors representing 10% of heart tumors, and the most common valvular tumor. Although they are detected more frequently since the advent of echocardiography and especially transesophageal echocardiography (TEE), there are no guidelines for their management.
This was a retrospective cohort study. Patients were collected from the data bases of the biggest cardiac centers in France (echocardiographic laboratory, surgical department).
The total study group consisted of 46 patients [(20 women, 26 men) mean age 54 ± 12 years] with typical echocardiographic criteria of PF, 35 patients underwent surgery with histologic confirmation. They were valvular tumor in 86% of the cases and intracardiac tumor in 13%. Neurologic events occurred in 81% of the patients and a few patients were asymptomatic. These small tumors were detected by TEE in all cases but TTE was negative in 63% of the cases. This study underlines the leading role of echocardiography and particularly TEE in the diagnosis of FE.
Due to the high risk of embolic events, it seems reasonable to perform surgical removal for left sided PE.

2602 Pregnancy-associated plasma protein: a new marker of carotid plaque vulnerability?

G. Sangiorgi[1], A. Mauriello[2], M. Christiansen[3], F. Pichiorri[2], C. Oxvig[3], G.L. Carbone[4], L.G. Spagnoli[2], R.S. Schwartz[5]. [1]*Istituto Policlinico S.Donato, Cardiovascular Diseases Dept., S. Donato Milanese, Italy;* [2]*II University of Rome, Pathology Dept., Rome, Italy;* [3]*Statens Serum Institute, Department of Clinical Biochemestry, Copenaghen, Denmark;* [4]*Istituto Policlinico S.Donato, Cardiovascular Diseases Dept., S.Donato Milanese, Italy;* [5]*Minneapolis Heart Institute, Department of Cardiovascular Diseases, Minneapolis, United States of America*

Background: Pregnancy-associated plasma protein A (PAPP-A), a proatherosclerotic metalloproteinases, it has been recently recognized as a marker of plaque vulnerability in pts affected by acute coronary syndromes. Also in carotid district, plaque instability has been linked to onset of cerebrovascular events. However, little is known about PAPP-A expression in carotid atherosclerotic disease and if this protein can represent a marker of vulnerable plaque also in the carotid district. **Methods:** Twenty carotid plaques of pts (12 male and 8 female, 68±8 yo) who suffered from stroke formed the base of the study. Echographic and angiographic examination was performed in all cases. Immunohistochemical staining for PAPP-A, smooth muscle cells, CD68 (macrophages) and CD3 (T-lymphocytes) was performed on tissue samples after carotid endarterectomy and graded by semiquantitative analysis. Immunofluorescence confocal microscopy was utilized to confirm PAPP-A cell expression within the plaque. Carotid plaques were divided in four groups: 1) stable plaques (n=5, cap thickness >150 μ and inflammatory cells infiltrate in the cap (ICI) < 25 cells x HPF); 2) vulnerable plaques (n=5, cap thickness < 80 μ and ICI > 25 cells x HPF; 3) ruptured plaques with thrombus (n=5); 4) healed plaques with organized thrombus. **Results:** Angiographic stenosis was similar in all groups (between 65 and 85%). At immunohistochemestry, a strong positivity (+++) for PAPP-A was expressed by macrophage and T-lymphocyte cells in group 2 and 3 in correspondence of the cap, shoulder, and rupture site of the plaque, respectively. Low expression (+) was present in group 1 and 4 (p=.0001). Immunofluorescence confocal microscopy confirmed the expression of PAPP-A by inflammatory cells within the cap and shoulder of the plaque.
Conclusions: Our study suggest that PAPP-A may play a key role in carotid plaque destabilization and rupture. Further serologic studies are necessary to determine if PAPP-A can represents a new target for the prevention of atherosclerotic cerebrovascular disease.

2603 Novel device for percutaneous left atrial appendage transcatheter occlusion (PLAATO) to prevent stroke in patients with atrial fibrillation

H. Sievert[1], M.D. Lesh[2], U. Krumsdorf[3], D. Ogi[4], H. Omran[5], A. Bartorelli[6], T. Trepels[3], K. Billinger[3]. [1]*Frankfurt, Germany;* [2]*University of California, San Francisco, United States of America;* [3]*Cardiovascular Center Bethanien, Frankfurt, Germany;* [4]*Appriva Medical, Sunnyvale, United States of America;* [5]*University Hospital Bonn, Dept. of Cardiology, Bonn, Germany;* [6]*Centro Cardiologico Monzino, Milano, Italy*

Background: Warfarin therapy has been shown to reduce the risk of stroke in patients (pts) with atrial fibrillation. However, it has a narrow therapeutic range and is contraindicated in many. The left atrial appendage is the source of thrombi in > 90%. Occlusion of the left atrial appendage may prevent cardioembolic complications. The purpose of this study was to evaluate the feasibility of the PLAATO in occluding the left atrial appendage. **Patients:** PLAATO was attempted in 17 pts aged between 59 - 78 yrs (mean 70 ± 6) with atrial fibrillation, additional stroke risk factors, and contraindication to warfarin. The left atrial appendage ostial diameter of these pts varied between 12 - 21 mm (mean 17 ± 4). **Methods:** PLAATO™ system consists of a self-expandable nitinol cage covered with a biocompatible membrane. It is delivered through a 12Fr transseptal catheter specially designed to access the left atrial appendage. Animal studies have shown efficacy at sealing the left atrial appendage with complete encapsulation and endothelialization by 1-3 months. The implant has not served as the nidus for new thrombus. Angiography is used to determine the initial device diameter. However, one can collapse the implant and either reposition or remove and replace it with a different size. **Results:** The procedure was successful in occluding the left atrial appendage in all patients. In one patient with a complex left atrial appendage anatomy a hemopericardium developed caused by catheter manipulation before implantation of the device. Pericardiocentesis was performed without sequelae. The procedure was successful in a second attempt for weeks later. There were 4 successful retrievals to change implant size. Devices with diameter of 18 (n=2), 23 (n=4), 26 (n=4), 29 (n=4) & 32 (n=3) mm were ultimately implanted without complications. Transesophageal echocardiography showed the device well seated. Follow up x-rays and echocardiograms revealed stable implants. No thrombi were detected, no complications occurred during follow-up (1-5 months).
Conclusions: (1) Transcatheter closure of the left atrial appendage is feasible; (2) this novel technology may offer an option for pts with AF who are not candidates for anticoagulation; (3) a clinical trial is warranted to show the long term safety and efficacy in reducing stroke.

2604 Rosuvastatin, a new HMG-CoA reductase inhibitor, up-regulates endothelial nitric oxide synthase and protects from stroke in mice

U. Laufs[1], G. Nickenig[1], M. Böhm[1], K. Gertz[2], U. Dirnagl[2], M. Endres[2]. [1]Klinik Innere Medizin III, Geb. 40, Homburg, Germany; [2]Charitee, Experimentelle Neurologie, Berlin, Germany

Background and Objective: HMG-CoA reductase inhibitors (statins) are cholesterol-lowering drugs which reduce the risk of myocardial infarction and stroke. In this study we investigated whether rosuvastatin, a new and relatively hydrophilic HMG-CoA reductase inhibitor, up-regulates endothelial nitric oxide synthase (eNOS) expression and activity and protects from cerebral ischemia in mice.

Methods: Bovine aortic endothelial cells in culture were treated with rosuvastatin for 4 to 48 h and 129/SV mice were administered rosuvastatin s.c. for 10 days. The expression and activity of eNOS were determined by reverse-transcriptase polymerase chain reaction, Western blotting and arginine-citrulline assays. Cerebral ischemia was induced by occlusion of the middle cerebral artery for 2h followed by 22 h reperfusion after which stroke volume was determined.

Results: Treatment of endothelial cells with rosuvastatin up-regulated eNOS mRNA and protein expression in a concentration- and time-dependent manner. In aortas of 129/SV wild-type mice, treatment with 0.2, 2, and 20 mg/kg rosuvastatin significantly upregulated eNOS mRNA by 50%, 142%, and 205%. NOS activity was significantly increased by 75%, 145%, and 320%, respectively. Stroke volume after 2-hour middle cerebral artery occlusion was reduced by 27%, 56%, and 50% (at doses of 0.2, 2 and 20 mg kg-1, respectively). Serum cholesterol and triglyceride levels were not significantly lowered by the treatment.

Conclusions: The new HMG-CoA reductase inhibitor rosuvastatin dose-dependently up-regulates eNOS expression and activity in endothelial cells and protects from cerebral ischemia in mice. The effects are independent of changes in cholesterol levels. Reduction of stroke size by the relatively hydrophilic rosuvastatin was at least as effective as equal concentrations of the lipophilic simvastatin and atorvastatin in this animal model.

THE MANY FACETS OF VESSEL WALL MAINTAINANCY

2613 Paracrine recruitment of mesenchymal cells via VEGF-induced expression of PDGF-B in endothelial cells

B. Witzenbichler, S. Knueppel, K. Warnke, H.P. Schultheiss. *University Hospital Benjamin-Franklin, Cardiology Dept., Berlin, Germany*

Introduction: The formation of capillaries (angiogenesis) and the growth of pre-existing collateral arteries (arteriogenesis) requires not only activation of endothelial cells, but also recruitment and proliferation of mesenchymal cells (pericytes, vascular smooth muscle cells), which form media and adventitia of the vessel wall. From gene targeting experiments it is known that vascular endothelial growth factor (VEGF) as well as platelet derived growth factor (PDGF) play a key role in establishing functionally active vessels, whereas not much data exist regarding the interaction between endothelial and mesenchymal cells, leading to maturation and assembly of the vessel wall. We therefore investigated the influence of angiogenic factors on the expression of PDGF in endothelial cells.

Results: Stimulation of endothelial cells (HUVECs) with VEGF (10-100 ng/ml) led to a marked, dose- and time-dependent induction of PDGF-isoform B, not isoform A at the level of mRNA, as shown by Northern blotting. Basic fibroblast growth factor (bFGF) did not alter expression of PDGF-B, whereas combination with VEGF resulted in a significant induction. These findings were confirmed at the protein level using Western blot. Since PDGF-BB is known to be a strong chemotactic agent for mesenchymal cells, we used conditioned medium from endothelial cells stimulated with VEGF in a microchemotaxis chamber, leading to a strong chemotactic response of mesenchymal cells (10T1/2 fibroblasts and vascular smooth muscle cells) towards the conditioned medium, comparable to the effect of 10 ng/ml PDGF-BB. The use of blocking PDGF-antibody attenuated the cell migration rate to 30%, further addition of HB-EGF-antibody completely abolished the chemotactic response.

Summary: VEGF, but not bFGF, induced expression of PDGF-B isoform in endothelial cells, which is a strong chemotactic agent for mesenchymal cells. VEGF might therefore indirectly participate in maturation and assembly of the vessel wall via this paracrine mechanism.

2614 Essential role of ICAM-1 mediated monocyte migration during arteriogenesis

I. Hoefer[1], N. van Royen[2], J. Rectenwald[3], J. Hua[1], M. Voskuil[2], Z. Abouhamze[3], C.K. Ozaki[3], I. Buschmann[1]. [1]Dept. of Cardiology, Freiburg, Germany; [2]Academisch Medical Centre, Dept. of Cardiology, Amsterdam, Netherlands; [3]University of Florida, Dept. of Surgery, Gainesville, United States of America

Previous studies have shown that blocking of ICAM-1 via monoclonal antibodies abolishes the MCP-1 induced effect on arteriogenesis (collateral artery growth). However, it is not yet clear whether ICAM-1 plays an essential role under physiologic conditions during arteriogenesis. In fact, it seems that it is a matter of numerous cell adhesion molecules (ICAM, VCAM, Selectins), responsible for monocyte transmigration and thus arteriogenesis. Methods: We therefore ligated the right femoral arteries of Selectin -/- mice, showing a defect of all three Selectin isoforms (E-, P-, L-Selectin), ICAM-1 -/- and their appropriate genetic backgrounds. Seven days later both hindlimbs were perfused under maximum vasodilation, combined with the injection of differently labeled fluorescent microspheres. Using FACS-analysis, the microspheres were quantified and perfusion ratios of both hindlimbs were calculated. Results: Results are expressed as perfusion of ligated vs. non-ligated hindlimb. ICAM -/- mice show a significant reduction of perfusion restoration after femoral artery ligation as compared to controls (ICAM-1 -/- 37.5 ± 11.9% vs. C57/BL6 63.8 ± 17.3%; $p<0.05$). The defect of the Selectin isoforms, in contrast, does not lead to a significant reduction of the arteriogenic response to the ligation of the femoral artery as compared to their backgrounds (Selectin -/- 32.4 ± 3.0% vs. Selectin WT 36.9 ± 9.8% p=0.33). Conclusion: A functional defect of only one cell adhesion molecule is usually only of small biological relevance, since others can take its role over. However, this study shows that not Selectin mediated rolling of leukocytes on the endothelium, but firm adhesion to ICAM-1 is essential during arteriogenesis.

2615 Inhibition of endothelial progenitor cell apoptosis via forkhead factor-dependent downregulation of the pro-apoptotic protein Bim

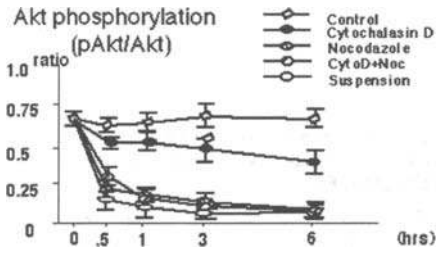
C. Urbich[1], A.M. Zeiher[2], S. Dimmeler[2]. [1]University of Frankfurt, Molecular Cardiology, Frankfurt, Germany; [2]University of Frankfurt, Molecular Cardiology, Frankfurt, Germany

Circulating bone marrow-derived endothelial progenitor cells (EPCs), which originate from CD34-positive hematopoietic stem cells, are involved in postnatal neovascularization. Transplantation of cultivated EPCs or CD34-positive cells enhances neovascularization and improves cardiac function. In hematopoietic cells, the forkhead transcription factors play an important role in apoptosis induction via the regulation of down-stream targets like the pro-apoptotic protein Bim. Therefore, we investigated the involvement of Bim in EPC apoptosis. EPC apoptosis was induced by H2O2 and determined by FACS analysis of annexin-positive cells. EPCs were isolated by density gradient centrifugation with Biocoll from peripheral blood of healthy subjects and cultured for 3 days before stimulation. H2O2 dose-dependently induces apoptosis of EPCs (500 μM: 288±94% of control). Consistent with apoptosis induction the number of differentiated EPCs was reduced after 48 h of H2O2 treatment (50±3% of control) as determined by counting dual-stained cells positive for lectin and DiLDL as a marker for EPCs. Because statins promote the phosphorylation and activation of the pro-survival kinase Akt, we analysed the effect of statins on the reduction of EPC number and apoptosis. Coincubation with atorvastatin (0.1 μM) significantly prevents the reduction of EPC number by H2O2 (178±2% of control; $p<0.05$). In addition, atorvastatin (0.1 μM) significantly reduces EPC apoptosis induced by H2O2 (288±94% vs. 146±31% of control; $p<0.05$). The anti-apoptotic effect of atorvastatin could be reversed with the PI3K-inhibitor Ly294002 (273±8% of control). Because the pro-apoptotic forkhead transcription factors (AFX, FKHR, FKHRL1) are phosphorylated and thereby inactivated by the PI3K/Akt pathway, we analysed the effect of atorvastatin on the phosphorylation of AFX. Atorvastatin (0.1 μM) induces the phosphorylation of AFX. In addition, atorvastatin profoundly reduces the expression of the forkhead-regulated pro-apoptotic Bcl-2-family member protein Bim in EPCs after 24 h (37±8% of control) in a PI3K-dependent manner and inhibits the H2O2-induced upregulation of Bim (165±14% vs. 112±19% of control), suggesting a potential involvement of Bim in EPC apoptosis. Taken together, these results provide insights into the beneficial effects of statins. Atorvastatin reduces apoptosis of EPCs induced by oxidative stress, inactivates the forkhead factor AFX and downregulates the expression of the pro-apoptotic protein Bim.

2616 Cooperative control of Akt phosphorylation and apoptosis by cellular cytoskeletons (CSKs) in capillary endothelial cells

Y. Numaguchi, D.A. Flusberg, D.E. Ingber. *Children's Hospital-HMS, Surgical Research, Boston, United States of America*

Capillary endothelial cells can be switched between growth and apoptosis by modulating their shape using micropatterned adhesive islands (Chen et al., Science 1997; 276:1425-1428). To examine whether cytoskeletal filaments like actin and tubulin contribute to this apoptotic respons, we carried out chronospatial analysis of PI3 kinase-Akt signaling pathway and apoptosis rate as well as cellular morphometry with CSK disrupting drugs. The cell shape and intracellular changes were visualized in living cells with YFP-actin or GFP-tubulin. Disruption of microfilaments or microtubules using cytochalasin D (Cyto D; 1μg/mL) or nocodazole (NOC 10μg/mL) led to levels of apoptosis in capillary cells equivalent to that demonstrated by inducing cell rounding using micropatterned culture surfaces containing small (< 20 μm diameter) circular adhesive islands (CytoD:NOC:island=12%:20%:18%). Simultaneous disruption of microfilaments and microtubules led to more pronounced cell rounding and to enhanced levels of apoptosis approaching that observed during anoikis in fully detached cells (CytoD+NOC:suspended=48%:55%), indicating that these two cytoskeletal filament systems can cooperate to promote cell survival. Western blot analysis revealed that the protein kinase, Akt, which is known to be critical for control of cell survival became dephosphorylated during cell rounding induced by disruption of the cytoskeleton, and that this was accompanied by a decrease in bcl-2 expression and an increase in caspase activation.



Akt phosphorylation after attachment.

This ability of the cytoskeleton to control capillary endothelial cell survival should be important for understanding the relationship between extracellular matrix turnover, cell shape changes, and apoptosis during angiogenesis inhibition.

2617 Endothelial progenitor cells modulate vascular re-endothelialization and neointima formation. Effect of HMG CoA reductase inhibition

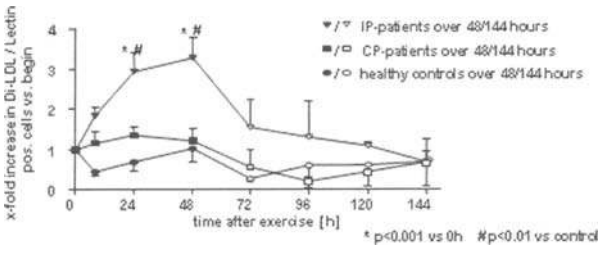
N. Werner, J. Priller, U. Laufs, M. Endres, M. Böhm, U. Dirnagl, G. Nickenig. *Universitätskliniken des Saarlandes, Medizinische Klinik und Poliklinik, Homburg-Saar, Germany*

Background: Both, atherosclerosis and restenosis after vascular injury are characterized by endothelial dysfunction and apoptosis, inappropriate endothelialization and neointima formation. Bone-marrow-derived endothelial progenitor cells have been implicated in neovascularization resulting potentially in adult blood vessel formation e.g. in the heart subjected to myocardial infarction. Despite the anticipated stem cell plasticity, the role of bone-marrow-derived endothelial progenitor cells has not been clarified in vascular lesion development.
Methods and Results: We investigated vascular lesion formation in mice which had undergone transplantation of bone-marrow transfected by means of retrovirus with enhanced green fluorescent protein. Carotid artery vascular injury was induced resulting in profound neointima formation. Fluorescent microscopy and immunohistological analysis revealed that circulating endothelial progenitor cells derived from the bone marrow are decisively involved in re-endothelialization of the vascular lesions. Treatment with an HMG CoA reductase inhibitor, rosuvastatin 20 mg/kg/d enhanced the circulating pool of endothelial progenitor cells by 5-fold, propagated the advent of bone-marrow-derived endothelial cells in the injured vessel wall and, thereby, accelerated re-endothelialization and significantly decreased neointima formation.
Conclusions: Vascular lesion development initiated by endothelial cell damage is moderated by bone-marrow-derived endothelial progenitor cells. HMG CoA reductase inhibition promotes bone marrow-dependent re-endothelialization and diminishes vascular lesion development. These findings may help to establish novel pathophysiological concepts and may enable future therapeutic strategies of various cardiovascular diseases.

2618 Increase of circulating endothelial progenitor cells in patients with coronary artery disease after reversible exercise-induced ischaemia

K. Lenk[1], V. Adams[1], D. Lenz[2], A. Tarnok[2], S. Erbs[1], S. Gielen[1], G. Schuler[1], R. Hambrecht[1]. [1]*University of Leipzig, Heart Center, Cardiology, Leipzig, Germany;* [2]*University of Leipzig, Heart Center, Pediatric Cardiology, Leipzig, Germany*

Increasing evidence suggests, that endothelial progenitor cells (EPC) play an important role in postnatal neovascularization. As animal studies propose ischemia seems to be one of the main triggers for the release of EPC's from the bone marrow. Aim of this study was therefore to analyse the effect of a maximal stress test on the number of EPC's in patients with coronary artery disease (CAD) and exercise-induced myocardial ischemia (ischemic patients, IP, n=16) versus CAD-patients without exercise-induced ischemia (control patients, CP, n=6) and healthy subjects (HS, n=6).
The concentration of EPC's was analyzed by FACS-analysis and cell culture assay in blood samples drawn before and up to 144h after the ergometer test. The amount of EPC's among the adherent cells was determined by analyzing Di-LDL and FITC-labeled lectin double positive stained cells by Laser Scanning Cytometry (Fig.1). Plasma concentrations of VEGF, b-FGF, TNF-alpha and GM-CSF were determined by ELISA.
Circulating EPCs increased in IP with a maximum after 24-48h (cell culture: 3.3±0.6fold increase, p=0.001 vs. baseline, p=0.01 vs. CP/HS; FACS: 3.1±0.5fold increase, p=0.001 vs. baseline, p=0.01 vs. CP/HS) and returned to baseline levels within 72h. In CP and HS no increase in EPCs was detectable. VEGF levels in IP reached a maximum after 2h (4.0±1.1fold increase, p=0.001 vs. baseline, p=0.03 vs. CP/HS) whereas no change was observed in CP and HS. The deltas of VEGF and EPC were significantly correlated (r=0.77; p<0.001).



In conclusion, the present study demonstrates for the first time that a short episode of myocardial ischemia in CAD patients is sufficient to induce a considerable increase in the number of circulating EPC's. This rise seems to be related to the previous increase of plasma VEGF.

SIGNAL TRANSDUCTION PATHWAYS IN CARDIAC HYPERTROPHY AND FAILURE

2619 Cardiac hypertrophy due to pressure overload correlates with increased active cardiac elongation factor-2 in senescent rats

D. Jaeger[1], K. Pönicke[2], I. Heinroth-Hoffmann[2], K. Werdan[1], U. Müller-Werdan[1]. [1]*Department of Internal Medicine III,* [2]*Institute of Pharmacology, Martin-Luther University, Halle, Germany*

Eucaryotic elongation factor-2 (eEF-2), a cytosolic GTPase of 857 amino acids, is a key protein of peptide-chain elongation during protein synthesis. Endogenous ADP-ribosylation at a unique posttranslationally modified histidine residue, called diphthamide,leads to its inactivation. A close relationship between protein synthesis (PS) and the amount of eEF-2 has been demonstrated for several tissues and cell systems. Furthermore an involvement of eEF-2 in the slowing down of bulk PS during ageing has been proposed. Therefore we studied the influence of experimental cardiac hypertrophy on total and active (i.e. not endogenously ADP-ribosylated) eEF-2 in cardiomyocytes (CM) from adult rats in correlation with cardiac PS and ageing.

Methods: Left ventricular (LV) hypertrophy was induced in 4 week old Wistar rats by stenosis of the suprarenal abdominal aorta (AOB). Sham-operated animals underwent the identical procedure except the hemoclip (SOP). CM were isolated according to the LANGENDORFF method at 8, 20 and 52 weeks after OP. PS of the CM was assessed using [3H]-phenylalanine incorporation. Active eEF-2 was measured after specific labelling of cytosolic extracts of the CM with Pseudomonas exotoxin A catalyzed [32P]ADP-ribosylation and SDS-PAGE,total amount of eEF-2 was detected by immunoblot.

Results: LV hypertrophy was confirmed by a significantly increased heart weight of the old AOB rats (1.88±0.1g;n=7)compared to 8 weeks postoperative AOB (1.43±0.13g;n=3)and old SOP rats (1.38±0.08g;n=6). Basal PS continually decreased in both groups (AOB and SOP 8 weeks postop. 1726±28 and 1648±36 dpm; AOB and SOP senescent 814±46 and 602±53 dpm respectively). PS was significantly higher in AOB compared to SOP only in the senescent animals ($p<0.05$). Active eEF-2 was elevated by 153% in the old-aged AOBs compared to SOPs ($p<0.05$). An age dependent decline in active eEF-2 in SOPs could not be demonstrated. These results were confirmed by immunoblot.

Conclusions: The positive correlation of active eEF-2 with the increased heart weight and the PS of senscent AOB rats compared to old-aged SOP rats points at an involvement of eEF-2 in the hypertrophic reaction of the heart due to pressure overload. Old and young adult rat hearts showed a different reaction pattern of eEF-2 in this stress situation.

2620 Activation of distinct signal transduction pathways in hypertrophied hearts by pressure and volume-overloads

T. Miyamoto, Y. Takeishi, H. Takahashi, T. Shishido, M. Itoh, I. Kubota. *Yamagata Univ. Sch. of Medicine, 1st Dept. of Internal Med., Yamagata, Japan*

Background: Chronic pressure- and volume-overloads result in morphologically and functionally distinct types of cardiac hypertrophy. A key role of mitogen-activated protein (MAP) kinase family in cardiomyocyte hypertrophy has been demonstrated in in vitro studies using neonatal cardiomyocytes and in vivo pressure-overload hypertrophy. However, signal transduction pathways leading to eccentric cardiac hypertrophy induced by volume-overload have not been rigorously investigated. Thus we examined the phosphorylation activities of 3 subfamilies of MAP kinases including extracellular signal-regulated kinase (ERK1/2), p38 MAP kinase, and c-Jun NH2 terminal kinase (JNK) and Akt in rabbit hearts with volume-overload. Methods: Volume-overload was induced by shunt formation between the left common carotid artery and the external jugular vein. Subtotal ascending thoracic aortic banding was performed in rabbits and these were used as a model for pressure-overload hypertrophy. Phosphorylation activities of ERK1/2, p38 MAP kinase, JNK, and Akt were examined by Western blotting with phospho-specific antibodies. Results: Chronic volume-overload increased left ventricular weight (4.1 ± 0.2 vs. 6.2 ± 0.3 g, $P < 0.01$) with ventricular cavity dilatation (12.8 ± 0.5 vs. 17.5 ± 0.5 mm, $P < 0.01$), and relative wall thickness was decreased indicating eccentric cardiac hypertrophy. Chronic pressure-overload increased left ventricular weight ($P < 0.01$) with no cavity dilatation, and relative wall thickness was increased. In rabbit hearts with concentric hypertrophy by ascending thoracic aortic stenosis, ERK1/2 ($P < 0.05$), p38 MAP kinase ($P < 0.01$) and Akt ($P < 0.05$), but not JNK, were activated 1 day and 1 week after banding surgery and the activity was returned to normal levels after 4 weeks. However in rabbit hearts with eccentric hypertrophy by volume-overload, none of ERK1/2, p38 MAP kinase and JNK were activated from 1 day to 12 weeks after shunt formation. Akt was predominant in volume-overloaded hearts, and the activation of Akt was sustained from 1 day to 12 weeks after shunt surgery ($P < 0.01$). Conclusion: These results suggest that different mechanical stresses activate distinct signaling pathways, which may lead to different types of cardiac hypertrophy.

2621 Inhibition of extracellular signal-regulated kinase prevents progressive left ventricular remodelling in hypertensive heart failure

R.A. de Boer[1], S. Pokharel[2], M. Flesch[3], A.J.H. Suurmeijer[4], F. Boomsma[5], W.H. van Gilst[6], D.J. van Veldhuisen[1], Y.M. Pinto[2]. [1]*University Hospital, Cardiology, Groningen, Netherlands;* [2]*University Hospital, Cardiology, Maastricht, Netherlands;* [3]*Universitat zu Koln, Klinik III fur Innere Medizin, Cologne, Germany;* [4]*University Hospital, Pathology Dept., Groningen, Netherlands;* [5]*University Hospital Dijkzigt, COEUR/Department of Internal Medicine, Rotterdam, Netherlands;* [6]*University of Groningen, Clinical Pharmacology, Groningen, Netherlands*

Background: Mitogen-activated protein kinases (MAPKs) are activated in response to neurohormonal activation in left ventricular (LV) hypertrophy and heart failure. We studied whether inhibition of MAPKs is effective in preventing LV dysfunction and remodeling in a model with angiotensin II-driven LV dysfunction.

Methods: We monitored LV function, neurohormones, and activation of MAPKs in homozygous REN2 rats at different time-points (6, 10, and 13 weeks). Then, we treated REN2 rats before the onset of heart failure (7-11 weeks), with placebo, an AT1 receptor blocker (ARB, candesartan), an extracellular signal-regulated kinase (ERK) inhibitor (Tyrphostin A46), or a p38 MAPK inhibitor (SB 239063). We studied LV function, neurohormonal profile, MAPK activity, and LV histological morphometry (fibrosis and microvessel density).

Results: LV hypertrophy (LVH) was present in REN2 rats at all time-points, and LV dysfunction progressed to heart failure between 10 and 13 weeks. Blood pressure was elevated after 6 and 10 weeks, but normalized after 13 weeks. Plasma neurohormones (renin, N-ANP) were elevated. ERK was activated at early time points (6, 10 weeks); this abated during heart failure. P38 MAPK was not activated. Treatment with the ARB prevented LVH and RVH, normalized LV end-diastolic pressure (LVEDP) and dP/dt, N-ANP levels, hampered fibrosis, and restored microvessel density (all: $P<0.05$). ERK inhibition reduced LVH and LVEDP ($P<0.05$), and markedly reduced fibrosis and restored microvessel density (both $P<0.01$). Myocardial ERK activation was blocked by ERK inhibition. The P38 MAPK inhibition reduced LVH ($P<0.05$), however no effects on other outcome parameters were observed.

Conclusions: ERK is activated in this model of LVH and heart failure. Treatment with an ERK inhibitor is efficacious in preventing LV remodeling, and its effects resemble the effects of the ARB. Especially, fibrosis was reduced and microvessel density was restored, which indicate that the observed ERK activation may not be confined to the cardiomyocytes, but may also be present in fibroblasts and endothelial cells.

2622 Decreased activation of the JAK2–STAT3 signaling pathway in patients with end-stage dilated cardiomyopathy

E.K. Podewski[1], D. Hilfiker-Kleiner[1], A. Hilfiker[1], H. Morawietz[2], A. Lichtenberg[3], K.C. Wollert[1], H. Drexler[1]. [1]*Medizinische Hochschule Hannover, Department of Cardiology, Hannover, Germany;* [2]*Martin-Luther-University, Department of Pathophysiology, Halle-Wittenberg, Germany;* [3]*Medizinische Hochschule Hannover, Thoracic and Cardiovascular Surgery, Hanover, Germany*

Interleukin-6 (IL-6) related cytokines signaling via the common receptor subunit gp130 and activation of the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway provide a critical myocyte survival pathway. Little is known, regarding the activation of this signaling pathway in the myocardium of patients with end-stage dilated cardiomyopathy (DCM).

We have performed a comprehensive expression analysis in left ventricular myocardium derived from patients with end-stage DCM (n=10) and non-failing (NF) donor hearts (n=5) concerning IL-6 related cytokines (IL-6; leukemia inhibitory factor, LIF; cardiotrophin-1, CT-1), receptors (gp130; LIF-receptor, LIFR; IL-6-receptor, IL-6R), signal transducers (JAK2; STAT1; STAT3) and signal transduction inhibitors (suppressors of cytokine signaling, SOCS-1 and SOCS-3) (table).

IL-6	LIF	CT-1	IL-6 receptor	LIF receptor	GP130	JAK2	STAT1	STAT3	SOCS1	SOCS3
-60%**	+48%*	-21%	-7%	-17%*	+20%	-9%	-15%	-58%**	+70%*	-40%**

Altered protein-expression in failing versus non failing heart (STAT: Signal transducer and activator of transcription, SOCS: suppressor of cytokine signaling, CT-1: cardiotrophin 1. *$p<0,05$, **$p<0,01$)

In addition, tyrosine phosphorylation (i.e. activation) of JAK2 (-72%, $p<0.01$) and STAT3 (-53%, $p<0.01$) were significantly reduced in end-stage DCM, whereas STAT1 tyrosine phosphorylation was unchanged.

Conclusion: Signaling through gp130 and JAK-STAT is profoundly altered in patients with end-stage DCM. Most notably, protein expression and tyrosine phosphorylation of STAT3 and protein expression of SOCS3 are significantly reduced, suggesting altered STAT3 dependent transcription in end-stage dilated cardiomyopathy.

2623 Differential regulation of mitogen-activated protein kinases in the failing human heart in response to mechanical unloading

M. Flesch[1], K.B. Margulies[2], D.L. Mann[3]. [1]University of Cologne, Dept. of Medicine III, Cologne, Germany; [2]Temple University, Cardiovascular Research Group, Philadelphia, United States of America; [3]Baylor College of Medicine, Winter's Heart Failure Center, Houston, United States of America

Background: Mechanical unloading of the heart with a left ventricular assist device (LVAD) leads to favorable changes in the biology of the failing cardiac myocyte. To determine a potential mechanism for these improvements, we examined the regulation of mitogen-activated protein kinases (MAPKs) in the failing heart in the presence and absence of LVAD support.
Methods and Results: We examined the degree of activation (ie, phosphorylation) of p44/42 extracellularly regulated kinase, p38 kinase, and c-Jun N-terminal kinase (JNK1/2), and the corresponding activity levels of these MAPKs in myocardial samples obtained from 11 patients with LVAD support and in 11 patients without LVAD support. MAPK activity was also examined in an additional 6 patients from whom paired samples were obtained before and after LVAD support. The activity of p44/42 and JNK1/2 were reduced significantly, whereas p38 activity levels were significantly increased after LVAD support. We examined functional parameters that are linked to MAPK activation, namely cardiac myocyte hypertrophy and apoptosis. Both cardiac myocyte cell size and the incidence of cardiac myocyte apoptosis were significantly reduced after LVAD support.
Conclusions: Mechanical unloading of the failing heart leads to differential regulation of MAPKs. These changes in MAPK activity are associated with changes in myocyte hypertrophy and viability, suggesting a potential mechanistic basis for some of the observed salutary changes after LVAD support.

REVASCULARIZATION THERAPY IN THE ELDERLY

2625 Acute coronary syndromes in the elderly: insights from the GRACE registry

W. Lankes[1], D. Gulba[1], J. Johnson[2], J. Forth[1] on behalf of The GRACE Investigators. [1]Krankenhaus Düren, Innere Medizin I, Düren, Germany; [2]U Mass Med School, Center for Outcomes Research, Worcester, United States of America

Elderly patients are believed to be at high risk of acute coronary syndromes (ACS) but an optimal strategy for treatment is still under debate.
Methods: The Global Registry of Acute Coronary Events (GRACE) collects data from 10,000 cases of ACS worldwide each year. We analysed treatment and outcomes of the first 8,564 ACS patients aged 65 and over.
Results: Patients >= 75 years were treated significantly less aggressively than younger patients, but had a significantly higher rate of death and major bleeding (table). In multivariate models adjusting for potential confounders the odds ratios(OR 95% confidence interval) for patients >= 75 years vs. those 65 to 75 for death and major bleeding remained unchanged and significant, the ORs were 1.90 (1.58, 2.29) and 1.55 (1.24, 1.93), respectively. Elderly patients with renal insufficiency appear to be at a high risk, with creatinine >1.29 being a strong predictor for death OR 3.22 (2.69, 3.86) and major bleeding OR 1.97 (1.58, 2.46). Mortality was lower, when aspirin OR 0.45 (0.35, 0.57), or low molecular weight heparin (LMWH) OR 0.67 (0.56, 0.80) are used. Major bleeds occur more frequently with the use of GPIIb/IIIa inhibitors OR 2.08 (1.58, 2.74), PCI OR 1.90 (1.47, 2.47) and unfractionated heparin OR 1.55 (1.21, 1.98), while under LMWH therapy major bleeds occurred significantly less OR 0.68 (0.54, 0.86).

		Age group		P-value
		≥75 years	65-75 years	
Treatment	GpIIb/IIIa	13.5%	16.9%	<0.0001
	Thrombolytics	11.9%	16.1%	<0.0001
	Cardiac Cath	37.5%	51.7%	<0.0001
	PCI	21.1%	28.1%	<0.0001
	CABG	4.4%	7.8%	<0.0001
Outcomes	Hospital Death	10.6%	5.3%	<0.0001
	Major Bleed	5.5%	3.7%	<0.0001

PCI - percutaneous coronary intervention; CABG - coronary artery bypass grafting.

Conclusion: These data show that the benefits of modern antithrombotic/antiplatelet therapies and interventional cardiac procedures extend to the population >75 years of age, and that such therapies should probably be used on a wider scale than at present.

2626 Treatment and outcome in an unselected elderly population with acute myocardial infarction: 6-month follow-up results

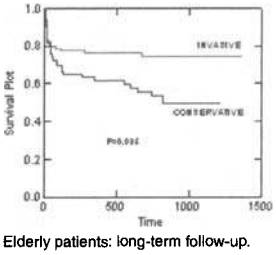
N. Carrabba[1], A. Barchielli[2], G M. Santoro[1], G. Corti[1], F. Ferrante[1], M. Maci[2], N. Marchionni[1], E. Buiatti[3]. [1]Careggi Hospital, Florence, Italy; [2]Health Unit, Florence, Italy; [3]Tuscany Health Agency, Florence, Italy

Background: Reperfusion treatment (RT) is considered particularly beneficial in higher risk subgroups, including the elderly. Primary PTCA (P-PTCA) is the most frequent modality of RT in the Florence area (Italy). Scanty data exist about the use of P-PTCA and the outcome in an unselected elderly population.
Methods: Data are derived from the AMI-Florence Registry, a prospective observational registry including all the Florence area residents who experienced AMI from March 1, 2000 to February 28, 2001 and were admitted to hospital within 24 hours from symptom onset. The analysis concerning the 806 patients (pts) with ST-elevation AMI included in the registry is presented.
Results: Of these pts, 368 (46%, mean age: 58 yrs) were <70 yrs (Group 1) and 438 (54%, mean age: 79 yrs) were >=70 yrs (Group 2). No difference was observed in time from symptom onset to hospital admission between groups. RT was used in 73% of Group 1 pts (P-PTCA in 93%) and in 51% of Group 2 pts (P-PTCA in 90%) (p=.001). Of the Group 2 pts directly admitted to the 2 centres with P-PTCA facilities, 73% underwent RT (99% with P-PTCA) while only 39% of the Group 2 pts admitted to the 5 hospitals without invasive facilities were treated with RT (78% with P-PTCA, performed after patient transfer) (p=.001). At multivariate analysis age >=70 yrs was negatively associated with the use of RT (OR: 0.52, 95%CI: 0.35-0.74). In pts not treated with RT, in-hospital mortality was 7% in Group 1 and 20% in Group 2 (p=.004); 6-month mortality was 10% and 30%, respectively (p=.001). In pts treated with RT, in-hospital mortality was 1% in Group 1 and 11% in Group 2 (p=.001), 6-month mortality was 3% and 17%, respectively (p=.001). At multivariate analysis age >=70 yrs was associated with a reduced probability of survival (OR: 0.33, 95%CI: 0.19-0.57). The use of RT showed a protective effect in Group 2 pts (OR: 1.62, 95%CI: 0.99-2.64), while it did not show a significant effect in Group 1 pts (OR: 1.45, 95%CI: 0.42-5.07).
Conclusion: Even in a setting where P-PTCA is the preferred modality of RT, elderly pts are less likely to undergo RT, particularly if they are admitted to a community hospital without invasive facilities. The results suggest a protective effect of RT in pts >=70 yrs.

2627 Surgical revascularization and percutaneous coronary intervention, in the setting of myocardial infarction, are more efficacious in the elderly

J.C. Nicolau[1], R.T. Ladeira[2], L.M. Baracioli[2], M. Franken[2], L.F.B.C. Seguro[2], J. Brum[3], M. Sprafka[3], J.A.F. Ramires[2]. [1]São Paulo, Brazil; [2]Heart Institute (InCor) - HCFMUSP, Acute Coronary Disease Unit, São Paulo, Brazil; [3]Procter & Gamble Pharmaceuticals, Cincinnati, United States of America

Little is known, especially in the elderly, about the role of surgical myocardial revascularization and percutaneous coronary intervention (invasive procedures - IP) in the long-term follow-up of pts with acute myocardial infarction (AMI), aim of this study.
Methods: we analyzed 481 pts with AMI included prospectively and consecutively in a databank and followed for up to 4 years (mean survival time 3.15 y). During the in-hospital phase, 309 pts were submitted to IP (64.2%), and 151 (31.4%) were older than 69 years. Pearson Chi-square was utilized for the in-hospital analysis; Kaplan-Meier estimator and log-rank test were utilized in the long-term follow-up analysis.
Results: (a) In-hospital analysis: for the elderly population, the mortality rate was 21.8%; the mortality rates for the subgroups submitted to IP (n=85) or treated conservatively were, respectively, 18.8% and 24.2% (OR=0.78, p=0.53); for pts younger than 70 y, the mortality rate was 5.5%; the mortality rates for the invasive (n=224) or conservative subgroups were 6.2% and 4.7%, respectively (OR=1.35, p=0.58). (b) Long-term follow-up analysis: the survival rates for invasive and conservative groups in the whole population were, respectively, 83.1% ± 2.3 and 70.6% ± 3.8 (p=0.007); in the subgroup of pts older than 69 y the survival rates were 74.8% ± 4.8 and 49.7% ± 7, respectively (p=0.035); in the subgroup of pts younger than 70 y, the survival rates were 86.3% ± 2.5 and 83.1% ± 3.9 (p=0.7). Sixty-three pts were treated with primary angioplasty (24 and 39, respectively, for the elderly and younger groups). The exclusion of these pts did not modified the main results.



Elderly patients: long-term follow-up.

Conclusion: In conclusion, in the long-term follow-up post-AMI, the invasive strategy was more efficacious in elderly patients.

2628 Is the early hazard of revascularisation for chronic coronary artery disease in elderly patients balanced during long-term follow-up?

M. Pfisterer on behalf of the TIME Investigators. *University Hospital Basel, Cardiology, Basel, Switzerland*

Background: The Swiss multicenter Trial of Invasive versus Medical therapy in Elderly patients (TIME) showed, that patients 75 years of age or older with chronic angina benefit significantly more from invasive (INV) than from optimal medical (MED) therapy regarding quality of life (QoL) and outcome after 6 months, although at a non-significant excess in early mortality.
Aim/Methods: To assess the long-term risk/benefit ratio of INV therapy in these patients, all 282 patients, age 80±4 years, surviving the first 6 months (140 randomized to INV and 142 to MED therapy) were followed prospectively after 12 months for QoL (angina severity by Canadian Cardiac Society class, Rose score; general health by SF-36; daily activity by Duke Activity Score Index) and major adverse clinical events (MACE: death, infarction, hospitalisation for acute coronary syndrome ± (repeat) revascularisation).
Results: Angina and QoL improved significantly after 6 and 12 months for both INV and MED therapy vs. baseline ($p<0.01$ each), but the difference in QoL between treatments in favour of INV patients noted after 6 months disappeared after 12 months due to 46% MED patients crossing over to revascularisation. The benefit in angina and QoL of MED patients without revascularisation remained significantly lower than that of INV patients after 6 and 12 months ($p<0.05$). Mortality for each 6 months period (0-6 and 7-12 months) decreased in INV patients by 66% from 8.5% to 2.9%, whereas it stayed unchanged in MED patients (4.1% and 4.2%). MACE rates were significantly higher for MED patients after 6 months (49% vs. 19% INV, $p<0.001$), a difference which increased to 72% (MED) vs. 28% (INV) after 12 months ($p<0.0001$).
Conclusions: Both treatment strategies led to a persistent improvement in angina and QoL, but the difference in favour of INV therapy after 6 months disappeared after 12 months due to an increasing rate of revascularisations in MED patients. The small early mortality hazard of INV therapy was reversed during months 7-12 and the overall advantage of INV therapy in reduction of MACE even increased. Thus, the benefits of INV compared to MED therapy outweigh the early risks during late follow-up.

2629 Ischaemic heart disease in the elderly and referal patterns for revascularisation

R. snowdon[1], R. Lowe[2], R A. Perry[2]. [1]*The University of Liverpool, Medicine, Liverpool, United Kingdom;* [2]*Cardiothorasic Centre (Liverpool) NHS, Cardiology, Liverpool, United Kingdom*

Demographic analysis continues to show a disproportionate increase in the size of the elderly population. IHD is responsible for 25% of medical admissions within this age group. While being more likely to be intolerant of medical therapy, these patients are believed to be less likely to receive revascularisation.
Objectives: To establish the incidence of IHD in the elderly presenting acutely to hospitals in the Merseyside & Cheshire zone and to investigate referral patterns for revascularisation in the elderly.
Method: Data on the number of acute adult medical admissions from 1/4/99 to 30/3/00 broken down by age and diagnosis was obtained from 11 hospitals in the Merseyside & Cheshire zone. Data on angiography and revascularisation was obtained by searching the procedures databases at the Cardiothoracic Centre Liverpool, which is the sole tertiary referral center for the zone.
Results: Over one year there where 125,755 acute medical admissions of which 56,692 (45%) where over the age of 70yrs and 22.5% where due to IHD. See table for a breakdown by age of the number of admissions due to IHD, coronary angiograms, PTCA & CABG performed.

Coronary angiograms & revascularisation

Age	Admissions with IHD	Corronary Angiograms	PTCA	CABG
All Adult	28,314	3354	924	1034
>70yrs	14,200(50%)	638 (19.0%)	114(12.3%)	226(21.9%)

Conclusion: An elderly patient with IHD is markedly less likely to be referred for angiography, however once an angiogram has been performed the likelihood of going on to receive CABG is similar to that in younger patients. The number of PTCAs is relatively reduced which we believe is due to the high incidence of multi vessel disease. Given that the chance of revascularisation is only marginally less (9.1%) we believe there is a case for lowering the threshold for angiogrophy in this group of patients.

2630 Is coronary revascularisation underused among older people? – Prospective findings from the ACRE study

S. Gnani[1], N.K. Fitzpatrick[1], A.M. Crook[1], A. Timmis[2], P.G. Magee[2], H. Hemingway[3]. [1]*KCW Health Authority, Research and Development, London, United Kingdom;* [2]*Barts and the London NHS Trust, Cardiac Directorate, London, E2 9JX, United Kingdom;* [3]*University College London Med School, Dept Epidemiology and Public Health, London WC1E 6BT, United Kingdom*

Objective: To determine whether coronary revascularisation is underused in older patients, using appropriateness ratings as a marker of clinical need.
Design: Prospective cohort study with 2.5 years follow up. A nine member expert panel rated the appropriateness of revascularisation independently of patient age.
Setting: Tertiary cardiac centre in the City and east London.
Patients: 4020 consecutive patients undergoing coronary angiography in the Appropriateness of Coronary Revascularisation (ACRE) study. There were no exclusion criteria. There were 2601 patients aged <65 years, 1162 aged 65-74 years and 250 aged 75-84 years; median age 62 years.
Main outcome measures: Coronary revascularisation, all cause mortality.
Results: Among the 1353 patients in whom CABG was deemed appropriate, older compared to younger patients were equally likely to undergo CABG (patients aged 75-84 years vs <65 years hazard ratio 1.29, 95% confidence interval(CI) 0.97-1.71). All cause mortality was higher among patients for whom CABG was deemed appropriate but who underwent medical management compared to those who received CABG: the hazard ratios were 2.83 (95%CI 1.60-5.01) in patients aged <65 years, 4.62 (95%CI 2.54-8.40) in patients aged 65-74 years and 7.29 (95%CI 2.19-24.23) in patients aged 75-84 years after adjustment for number of diseased vessels, left ventricular function and Parsonnet operative risk score. The absolute risk differences in these three age groups were 8.3%,18.3% and 35.3% respectively. Coronary angioplasty among patients in whom it was deemed appropriate was performed at a lower rate in patients aged 65-74 years compared to patients aged <65 years, hazard ratio 0.69 (95%CI 0.54-0.90).

Age group	Medical		CABG		Medical:CABG
	Number of deaths	Absolute risk (%)	Number of deaths	Absolute risk (%)	
<65	27	13.17	21		
65-74	31	24.41	17		
75-84	9	42.86	4		

Conclusions: The mortality impact of underuse of CABG may be greater among older patients in relative and absolute terms. With the lack of randomised trials of revascularisation among older age groups, appropriateness ratings offer a useful method of investigating age inequalities in treatment.

GENDERS DIFFERENCES IN THE DIAGNOSIS AND TREATMENT OF CARDIOVASCULAR DISEASE

2631 Gender differences in the treatment of coronary heart disease?

R. Videbaek[1], S. Paaske Johnsen[2], J. Videbaek[3]. [1]*Rigshospitalet, Cardiac Cath Lab, Medical department B, Copenhagen, Denmark;* [2]*University of Aarhus, Institute of Epidemiology, Aarhus, Denmark;* [3]*Danish Heart Foundation, Copenhagen, Denmark*

It has been suggested that women are under diagnosed and under treated for coronary heart disease in relation to men. We therefore analysed a consecutive group af daily routine patients, referrred to the cath. lab. with suspicion of, or established diagnosis of coronary heart disease. All patients came from a well defined geographical area and follow up with respect to death is 100% complete, with the longest follow up period of 6 years.

The material represents 2.651 patients, 794 women mean age 63 year (SD 11,7) and 1.857 men mean age 61 year (SD 10,9). The proportion of acute examinations were 33,1% among the females and 32,4% among the males.

Coronary pathology: The patients were divided in to 3 groups. Group 1 consisted of patients with normal coronary arteries. Group 2 of patients with light to moderate (diffuse insignificant or 1-2 vessel) disease. Group 3 of patients with severe (3 vessel and/or left main) disease. 20.5% of the women vs. 4.5% of the men ($p<0.001$) had normal coronary arteriograms. 60.3% of the women vs. 62.4% of the men had light to moderate disease (ns). 19.1% of the women vs. 33.1% of the men had severe disease ($p<0.001$)

Treatment: Revascularisation of patients in group 2 and 3 was performed as either PCI or CABG. 67.2% of the women vs. 75.8% of the men in group 2 was revascularised ($p<0.001$). This significant difference is due to the fact that the men had more 2 vessel disease than the women in this group (data not shown). In group 3 with severe disease 89.5% of the women vs. 86.4% of the men was revascularised (ns).

Survival: Within the 3 different groups of coronary pathology there was no difference in survival between women and men. After revascularisation the relative risk of death (men vs. women) was 0.98 (95 CI 0.68-1.42) after correction for age, coronary pathology, acute procedure and year of treatment.

Conclusion: In our material of unselected routine patients, we find no evidence of under treatment of women with coronary heart disease, but women have a lesser degree of disease when examined. For equal degree of disease, women and men were treated alike, and with the same outcome with respect to survival.

2632 In-hospital management of acute myocardial infarction in France: is there a gender bias?

J.P. Cambou[1], P. Guéret[2], H. Ghobrial[3], G. Hanania[4], D. Blanchard[5], J.M. Lablanche[6], L. Vaur[3], N. Danchin[4] on behalf of the USIC registries investigators. [1]*Inserm U 518, Toulouse, France;* [2]*CHU Mondor, Cardiologie, Créteil, France;* [3]*Aventis, Paris, France;* [4]*Cardiology Dept., Paris, France;* [5]*Clinique St Gatien, Cardiologie, Tours, France;* [6]*CHU Lille, Cardiologie, Lille, France*

The possibility of a "sex bias" in the management of patients with coronary artery disease is controversial. We conducted a nation-wide in 369 intensive care units representing more than 3/4 of all French ICUs in November 2000, in order to asses "real world" management and outcome of patients with acute myocardial infarction (AMI). A total of 2320 patients with AMI < 48 hours from symptom onset were included. There were 1692 men (73%) and 628 women (27%). Women were older than men (73 ± 13 vs 63 ± 14 years, $p<0.0001$). Risk factors differed markedly, hypertension 40% vs 63%, current smoking 33% vs 4%, known hyperlipidemia 40% vs 13%, diabetes mellitus 18% vs 28% in men and women, respectively. Women had less previous history of myocardial infarction (13% vs 20%), previous PTCA (5% vs 11%), previous CABG (2.6% vs 4.9%), peripheral artery disease (6% vs 10%), but more history of congestive heart failure (8.8% vs 5.6%). Reperfusion therapy by either intravenous thrombolysis or PTCA was used more seldom in women (36% vs 46%, $p< 0.0001$). Heparin, nitrates, calcium antagonists, and ACE-inhibitors were used as often in men and women. In contrast, GP IIb/IIIa blockers (20% vs 12%), beta-blockers (74% vs 63%) and statins (49% vs 34%) were used more often in men, while diuretics (23% vs 36%) were used more often in women.

Using multivariate regression analysis, however, most classes of medications were not influenced by gender. In particular, gender was not an independent predictor of reperfusion therapy, antiplatelet agents, and beta-blockers. The same was true for diuretics, digitalis, and intravenous dobutamine. Only statins (relative risk: 0.72; 95% CI/0.59-0.88) and GP IIb/IIIa blockers (relative risk: 0.74; 95% CI: 0.56-0.98) remained negatively correlated with female sex. During the hospital stay, 62% of men and 45% of women underwent a PTCA procedure ($p< 0.0001$); this difference remained statistically significant after multivariate adjustment (RR: 0.77; 95% CI: 0.63-0.95).

Conclusion: women admitted for AMI are 10 years older on average than men. As evidenced by multivariate analyses, this age difference explains most of the differences in their management compared to men. A "sex bias", however, cannot be formally excluded as regards the use of PTCA during the initial hospital stay.

2633 Use of revascularisation procedures in women after acute coronary events: results from the French nation-wide PREVENIR Survey

V. Bongard[1], O. Grenier[2], J. Ferrières[1], N. Danchin[2], C. Cantet[1], E. Amelineau[3], J.P. Cambou[1]. [1]*INSERM U558, Department of Epidemiology, Toulouse, France;* [2]*Georges Pompidou Hospital, Department of Cardiology, Paris, France;* [3]*Bristol-Myers Squibb, Paris, France*

There are controversial data about gender differences in the management of coronary artery disease. In a large sample, we compared the use of revascularisation procedures after acute coronary events, in French men and women, at the end of the nineties.

Methods: An observational survey was carried out in 149 intensive cardiac care units, evenly distributed in France. Seventy seven centres included 1334 patients in January 1998 and 72 other centres included 1292 patients in May-June 1999. Eligible patients were consecutive patients admitted for myocardial infarction (MI) or unstable angina in one of the participating centre and who were alive at discharge. Data were retrospectively collected from medical records after discharge (age, previous medical history, cardiovascular risk factors, left ventricular ejection fraction (LVEF) and therapeutic management of the acute coronary event).

Results: The sample was composed of 1921 men (73.2%) and 705 women (26.8%). Women were significantly older than men and less frequently admitted in a university hospital. Arterial hypertension and reduced LVEF were significantly more prevalent in women, whereas smoking was significantly more prevalent in men. Among patients admitted for MI, 79 women (19.3%) and 382 men (32.5%) were treated with pre-hospital or in-hospital thrombolysis, $p<0.0001$ for Chi 2 test. During the hospitalisation, percutaneous transluminal coronary angioplasty (PTCA) was performed in 164 women (40.1%) and 587 men (50.0%) admitted for MI ($p<0.001$) and in 104 women (35.1%) and 354 men (47.5%) admitted for unstable angina ($p<0.001$). In multiple logistic regression, adjustment variables were assessed by backward analysis among age, previous history of coronary artery disease, cardiovascular risk factors, LVEF and year and centre of inclusion (university hospital, general hospital or private clinic). The adjusted female-to-male odds ratio (OR) for the use of thrombolysis was 0,65 (95% confidence interval [0.49-0.87]). The adjusted OR for the use of PTCA was 0.72 [0.54-0.96] in patients admitted for unstable angina and 0.97 [0.75-1.25] in patients admitted for MI.

Conclusion: Women were less likely than men to receive thrombolysis for myocardial infarction and to be treated with PTCA when admitted for unstable angina. Although these results could reflect gender differences in the prevalence of contra-indications, an authentic discrimination against women in the management of coronary artery disease cannot be excluded.

2634 Health status outcomes of CABG patients one year post-surgery: are there gender differences?

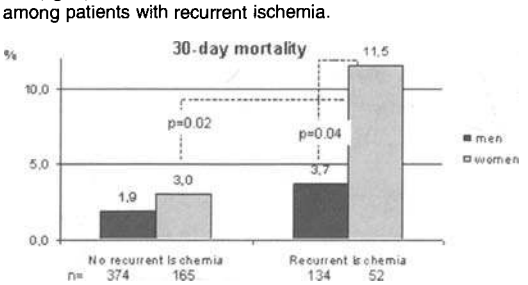
H.M. McGee[1], A. Tynan[1,4], E. McGovern[2], E. Shelley[3], D. Tolan[2], V. Young[2]. *[1]Royal College of Surgeons in Ireland, Dept. of Psychology, Dublin, Ireland; [2]St. James's Hospital, Keith Shaw Unit, Dublin, Ireland; [3]Royal College of Surgeons in Ireland, Dept. of Epidemiology, Dublin, Ireland; [4]GlaxoSmithKline, Healt Outocmes Dept., Dublin 16, Ireland*

Introduction: This study evaluated health outcomes of coronary artery bypass patients (CABG) patients. Gender-specific outcomes were compared since research indicated differences in other cardiac groups.
Method: CABG patients (n=280;76% male) in three centres were interviewed prior to surgery. Follow-up questionnaires were posted to study participants at six weeks, six months and one year post-surgery. The questionnaire assessed symptoms (Seattle Angina Questionnaire) physical functioning (Duke Activity Scale Index), general health status (SF-36) and mental health (Hospital Anxiety and Depression Scale).
Results: Significant improvements were found from pre-surgery to one year post-surgery scores across all dimensions assessed; most improvement took place by 6 months. Adjusting for age, men had significantly higher levels of physical functioning and energy and lower levels of pain than woman prior to surgery ($p<0.01$). Six weeks post-surgery there was one significant difference; men reported higher levels of physical functioning ($p<0.01$). At six months post-surgery, in addition to better physical function, men reported better mental health and less pain ($p<0.01$). At one year post-surgery men reported significantly higher levels of physical functioning and general health status and lower frequency of angina and depression ($p<0.01$).
Conclusions: While male CABG patients reported better physical functioning than their female counterparts at all stages, there were few other differences between the groups either prior to surgery or at six weeks post-surgery. By six months post surgery, the experiences of both groups began to diverge with men performing better. At one year post-surgery this divergence continued with male CABG patients outperforming females in both rate and extent of recovery. This was represented by significantly better scores across a range of functional, health status, symptom and mental health measures. The clinical significance of age adjusted gender differences needs further evaluation.

2635 Signs of failed reperfusion or recurrent ischaemia – Worse for women?

P. Johanson[1], T. Jernberg[2], A-M. Svensson[3], B. Lindahl[2], L. Wallentin[2], M. Dellborg[3]. *[1]Duke Clinical Research Institute, Durham, United States of America; [2]UAS, Dept. of Cardiology, Uppsala, Sweden; [3]SU/ÖSTRA, Clin. Exp. Research Lab., Göteborg, Sweden*

Introduction: Gender-differences in symptoms, signs and treatment of acute myocardial infarction have previously been suggested. We set out to investigate whether risk-stratification by ST-analyses may be done equally good in men and women. ST-segment resolution (ST-res) is a good predictor of both reperfusion and prognosis in patients with ST-elevation infarction (STEMI). Furthermore, ST-reelevations have been associated with worse outcome.
Methods: 864 patients with STEMI but without bundle branch block were included in the ST-monitoring substudy of the ASSENT 2 and ASSENT PLUS trials. Bad quality-, short-, and lost recordings were excluded, leaving 752 patients (527 men and 225 women) to analyse. Patients received either t-PA or TNK and were ST-monitored for 24 hours (h) with either vectorcardiography (n=571) or 12-lead ST-monitoring (n=181). ST-data were analysed blindly by two independent observers. We used 50% ST-res within 60 min as cut-off for early ST-res. Late, recurrent ischemic episodes were defined as any re-elevations after 4h, >50uV, lasting 2 min or more.
Results: Total 30-day mortality was 4.2% (n=32), significantly higher in women (6.7%) than men (3.2%), p=0.03. Median time to 50% ST-res did not differ in women and men (77 vs. 77.5 min), neither did maximal ST-elevation.
Women and men reaching 50% ST-res had equal (1.1 vs. 1.5%) 30-day mortality, whereas women with low-grade ST-res had significantly higher mortality (10.4 vs. 4.3%) p=0.01. Women with recurrent ischemia also were at higher risk (fig. 1). Women were older than men, this difference was less pronounced among patients with recurrent ischemia.



Conclusion: Signs of failed reperfusion or recurrence of ischemia when treating STEMI should alert us, particularly if the patient is female.

2636 Acute coronary syndromes in young premenopausal women. Is the prognosis so good?

O. Diaz-Castro[1], E. Torrecilla[1], S. Quintela[2], M. Bravo[2], M. Martinez[1], F. Calvo[2], J. Goicolea[2]. *[1]Madrid, Spain; [2]Hal. Meixoeiro, Cardiology, Vigo, Spain*

Background: There are few data about clinical profile and both in-hospital and long-term prognosis of acute coronary syndromes in young premenopausal women.
Methods and Results: We studied 162 consecutive women less than 55 years old (95 premenopausals and 67 postmenopausals), admitted to the cardiology department for acute chest pain in whom the diagnosis of acute myocardial infarction or unstable angina with confirmed coronary disease was finally made. Myocardial infarction was present in 69% of patients and angina in 31%. Premenopausals presented significantly more prevalence of smoking, less prevalence of hypertension, hypercholesterolemia and less extensive coronary disease than postmenopausals (18,5% vs. 39% of multivessel disease).
The onset of myocardial infarction coincided with the menstrual phase of the cycle in 48% of premenopausals (probability significantly higher than expected by choice, p=0,001).
In-hospital prognosis was good (Killip III-IV 11%, mortality rate 2.1%). Long-term follow-up was made with a median time of 40 months. Although mortality rate was low, there was a high incidence of readmissions (23% at one year in premenopausals vs 37% in postmenopausals, p=ns) being recurrent unstable angina and heart failure the most frequent causes.
Conclusions: Young premenopausal women with acute coronary syndromes have different clinical profile than young but postmenopausal ones. Most women present one vessel disease with low mortality rates but with very frequent readmissions. Temporal association between menstruation and onset of AMI was found in premenopausal patients.

PROGRESSIVE NEW STRATEGIES FOR THE TREATMENT OF MYOCARDIAL INFARCTION

2661 Autologous stem cell transplantation for myocardial regeneration in patients undergoing coronary artery bypass grafting

C. Stamm[1], B. Westphal[1], B. Kleine[2], M. Petzsch[3], C. Beythien[3], C. Nienaber[3], M. Freund[2], G. Steinhoff[1]. *[1]Universität Rostock, Klinik für Herzchirurgie, Rostock, Germany; [2]Universitaet Rostock, Hämatologie und Onkologie, Rostock, Germany; [3]Universität Rostock, Kardiologie, Rostock, Germany*

Objective: Undifferentiated stem cells may be able to regenerate infarcted myocardium. Although experimental data are promising, feasibility and safety of myocardial stem cell transplantation in humans is unknown. Here, we report our initial experience with a phase-I study of human bone marrow-derived stem cell transplantation in conjunction with coronary artery bypass grafting (CABG).
Methods: Six patients (age 63 ± 7 yrs) have been enrolled in the study since July 2001. Principal inclusion criteria were: 1. acute myocardial infarction less than 3 months ago, 2. presence of a distinct area of infarcted myocardium not amenable to revascularization, 3. elective CABG operation indicated to treat ischemia of other LV wall areas, and 4. patient consent and approval by the institutional review board. Autologous, pluripotent stem cells positive for CD 133 (1 x 10E6) were isolated from the patients bone marrow aspirate one day prior to surgery, and were directly injected in the infarct border zone during the CABG operation.
Results: All patients survived the operation without major complications and have been discharged with significantly improved NYHA class. Follow-up ranges between 2 weeks and 7 months and comprises 24 patient months. Szintigraphic imaging at follow-up indicated improved myocardial perfusion in all patients, including the areas with preoperatively absent perfusion that were treated with stem cells. LV dimensions (LVEDV 149±45 vs. 137±28ml, p=0.02; LVEDV 54±4 vs.48±6mm, p=0.2) and LV ejection fraction (37±9 vs. 50±6%, p=0.05) as assessed by echocardiography have improved in all patients, as well as contractility in the previously akinetic infarct area. To date, there is no evidence of new ventricular arrhythmia or neoplasia.
Conclusion: Based on our initial experience, stem cell transplantation for myocardial regeneration can be safely performed in humans. There is evidence of improved revascularization and contractility of infarct areas, but further studies are needed to clearly determine the clinical benefit.

2662 Preliminary experience of catheter based transendocardial delivery of autologous skeletal myoblasts for cellular cardiomyoplasty

P.C. Smits[1], L. Maat[2], R.C.H Lee[1], D. Poldermans[1], R.J. van Geuns[1], P.A. Cummins[1], W.J. van der Giessen[1], P.W. Serruys[1]. *[1]Department of Cardiology, Thoraxcentre, Rotterdam, Netherlands; [2]Erasmus Medical Center, Department of Thoracic Surgery, Rotterdam, Netherlands*

Present therapy of heart failure after MI is focussed on medication to conserve left ventricle (LV) rest function. Cell based myocardial repair by autologous skeletal myoblasts is a novel and promising therapeutic option that has the potential to improve systolic and diastolic LV function.

Methods: Six patients, age 54±12 years (mean±std), were enrolled in this pilot safety feasibility study. All patients were symptomatic of heart failure, NYHA class 2-3, after a large Q wave anterior wall infarction. In all patients the infarct was more than 1 year ago and the residual LVEF was between 20-45%.

At baseline, a muscle biopsy was taken from the quadriceps muscle. From this muscle biopsy skeletal myoblasts were isolated and cultured for cell culture expansion. After cell culturing for 2-3 weeks, 4 patients received cellular implants in the akinetic, non-viable infarcted area by an injection catheter under fluoroscopy and NOGA guidance. On average 182 million cells (range 25-300 million), 60% myoblasts by Desmin staining (range 12-85%) were transendocardially injected by 14 injections (range 9-18) of 0.3 ml per injection.

Results: No adverse events occurred during or after the biopsy and cell transplantation procedure. All treated patients were discharged the next day after cell transplantation. To date, 6 months follow up of the first patient shows a modest improvement of LVEF by ventriculography, blood pool scintigraphy, MRI and tissue doppler imaging compared to base-line assessment. No arrythmias have been recorded. We will report on our initial experience and follow-up results in this on-going study.

2663 Thrombectomy followed by elective stent implantation in ST elevation myocardial infarction. Results from the TASMI study

E. Garcia[1], M. Valdés[2], A. Alvarez[1], R. Moreno[3], M. Abeytua[1], T. Díaz[1], J. Soriano[1], A. Barrio[1]. *[1]Hospital Gregorio Marañón, Interventional Cardiology Dept., Madrid, Spain; [2]Hospital Virgen de la Arrixac, Murcia, Spain; [3]Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain*

Effective myocardial reperfusion after stent implantation in patients with ST-elevation myocardial infarction (STEMI) is sometimes jeopardized by distal embolization and microvascular occlusion. Thrombus removal prior to stent implantation should reduce the risk of embolization of the thrombotic material. We report the results from a multicenter prospective registry of mechanical reperfusion in STEMI using the X-Sizer thrombus removal device followed by routine stent implantation.

Patients and methods: TASMI (Thrombectomy and Stent implantation in Myocardial Infarction) study is a prospective multicenter registry that includes patients with STEMI treated with mechanical reperfusion using the X-Sizer thrombus removal catheter system followed by routine stent implantation within 12 hours from symptoms onset. This study specially focuses on the epicardial flow and myocardial perfusion determined by the TIMI flow and Myocardial Blush Score, respectively.

Results: In 104 patients (61±9 years, 88% male) with STEMI < 12 hours from symptoms onset, thrombectomy with the X-Sizer device was attempted before stent implantation without prior balloon angioplasty. Out of them, 49% had anterior location MI. TIMI flow pre procedure was 0-1 in 74%. TIMI flow 3 post X-Sizer and before stent implantation was achieved in 69% patients. A total of 148 stents were implanted at a mean pressure of 14 atm. After stent implantation, TIMI flow 3 was obtained in 93% patients, and TIMI flow 2 in 6%. Myocardial blush 3 score was achieved in 55% of the patients at the end of the procedure. IIb/IIIa blockers were used in 14%, and the procedure was performed with the help of intraortic balloon pump implantation in 8%. During hospitalization, there were no deaths, 1 patient suffered a non-fatal reinfarction and 1 had a non disabling ischemic stroke. Outcome at 30 days after discharge was: death 0%, non-fatal reinfarction 0%, target vessel revascularization 0%, stroke 0%, and congestive heart failure 2%. Six month clinical and angiographic evaluation will be ready for presentation in August.

Conclusion: Thrombectomy using the X-Sizer device followed by routine elective stent implantation in patients with STEMI is safe and effective, with excellent clinical outcome in the TASMI study. With similar epicardial flow it seems to be able to obtain better myocardial perfusion than conventional stent implantation without prior thrombus removal. Randomized trials will determine the role of the X-Sizer Catheter System in STEMI.

2664 Comparison of immediate results of primary percutaneous coronary intervention versus facilitated percutaneous coronary intervention in acute myocardial infarction

D. Dudek, T. Rakowski, W. Mielecki, M. Kuta, J. Legutko, S. Bartus, K. Zmudka, J S. Dubiel. *Jagiellonian Univ., Inst. of Cardiology, Krakow, Poland*

Primary PCI is a preferred therapy for acute myocardial infarction (MI). Adjunctive use of Gp IIb/IIIa blockers before intervention improves microvascular reperfusion. It is postulated that combination therapy of Gp IIb/IIIa blockers and half dose lytics followed by immediate PCI (Facilitated PCI) could further improve clinical outcome of patients with acute MI.

Methods: The aim of this study was to compare immediate clinical and angiographic results of treatment of consecutive non-shock patients with acute MI within 12 hrs of chest pain onset using Primary PCI (n=143; group 1) or Facilitated PCI (n=200; group 2). In group 1 pts were transferred to catheterization laboratory within 90 minutes and abciximab was given immediately before PCI at operators' discretion (48% of pts). In group 2 the transfer time to catheterization laboratory was > 90 min. All pts received i.v. bolus of 60U/kg heparin, 15 mg/35mg alteplase and abciximab at the remote hospital and were immediately transferred to angiography/PCI.

Results: there was no difference in baseline characteristics of patients in both groups. In group 1 door to needle time was 17±9 min and in group 2 remote hospital door to needle time was 158±61 min (transport time of 97±39 min). In baseline angiography TIMI 3 flow was present in 17% vs. 71% (p<0,0001), corrected TIMI frame count (cTFC) was 86±29 vs. 35±30 (p<0,0001) in group 1 and 2 respectively. Major adverse cardiac events occurred with similar frequency (death 3.5% vs. 3.5%; recurrent MI 0.7% vs 1%, rePCI 0.7% vs 1.5%; urgent bypass surgery 0% vs. 0%). However, there were 1% intracranial bleeding and 3% other severe bleeding complications in group 2. After PCI TIMI 3 flow was achieved in 93% vs. 92%, cTFC 20±12 vs. 20±13, TIMI Myocardial Perfusion Grade (MPG 3+2) in 65% vs 68% in group 1 and 2 respectively.

Conclusions: Patients after combined lytic therapy could undergo immediate PCI (Facilitated PCI) with procedural success rate similar to Primary PCI despite of substantial time delay to mechanical reperfusion. There was no differences in angiographic parameters of reperfusion after PCI despite of much higher frequency of open arteries before PCI in group 2. Bleeding complications occurred with high frequency in pts subjected to Facilitated PCI.

2665 Enoxaparin attenuates the rise in Von Willebrand factor in patients with ST-segment elevation myocardial infarction treated with fibrinolysis: results from ENTIRE-TIMI 23

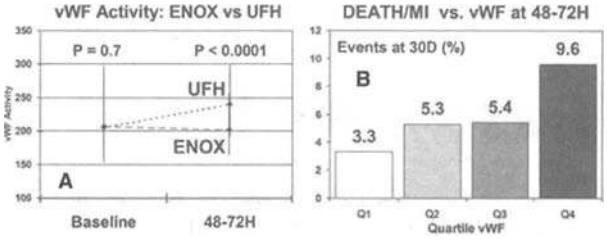
D.A. Morrow[1], N. Rifai[2], F. Bigonzi[3], J.P. Bassand[4], G. Pisapia[3], C. Hecquet[3], F. Van de Werf[5], E.M. Antman[1]. *[1]Brigham & Women's Hospital, Cardiovascular Division, Boston, USA; [2]Childrens Hospital Medical Center, Dept. of Laboratory Medicine, Boston, USA; [3]Aventis, Croix-de-Berny, France; [4]University Hospital Jean-Minjoz, Dept. of Cardiology, Besançon, France; [5]UZ Gasthuisberg, Department of Cardiology, Leuven, Belgium*

Von Willebrand Factor (vWF) is an important participant in platelet aggregation and may promote re-thrombosis early after fibrinolysis for ST-elevation MI (STEMI). Enoxaparin blunts the rise in vWF compared with unfractionated heparin (UFH) in patients (pts) with unstable angina. Little is known about the effect of enoxaparin on vWF in STEMI.

Methods: We measured vWF activity at baseline and at 48-72 hr in pts with STEMI treated with enoxaparin or UFH as adjunctive therapy for fibrinolysis (full dose TNK or 1/2-dose TNK + abciximab).

Results: Samples were available for vWF determination at both baseline and 48-72 hr in 356 pts (74%) from ENTIRE. vWF activity is presented as median [interquartile range]. Baseline vWF was similar in pts treated with UFH (202 [158-294]) vs. enoxaparin (206 [152-260]), p = 0.7). In contrast, levels of vWF at 48-72hr were higher in pts treated with UFH (240 [192-309]) compared to enoxaparin (203 [165-250], p < 0.0001, Fig A). A trend toward higher rates of death or MI was observed among patients with higher vWF activity at 48-72 hours (p-trend = 0.08) (Fig B).

Conclusions: Compared with UFH, adjunctive therapy with enoxaparin attenuates the rise in vWF activity after fibrinolysis for STEMI. This favorable effect of enoxaparin may underlie in part the reduction in death or MI observed in recent clinical trials of enoxaparin vs. UFH in STEMI.



OUTCOMES AFTER PERCUTANEOUS CORONARY INTERVENTION: THE CHALLENGE REMAINS

2677 Direct comparison of CABG and unprotected left main coronary artery stenting: immediate and medium term results

M. Boccalatte, N. Mulvihill, M. Loutfi, E. Salengro, B. Farah, J.P. Bounhoure, J. Fajadet, J. Marco. *Clinique Pasteur, Unité de Cardiologie Interventionelle, Toulouse, France*

Coronary artery bypass surgery (CABG) is currently the gold standard treatment for left main coronary artery (LMCA) disease. Recent data have demonstrated encouraging immediate and long term results of unprotected LMCA stenting (S) in selected patients. To date there has not been a clinical trial involving direct comparison between these revascularisation strategies for LMCA disease. We have evaluated the in-hospital and mid term outcome in patients with significant (> 50%) LMCA disease treated by CABG or S.

Methods and Results: Between Jan 2000 and Dec 2001, 187 consecutive patients underwent revascularization for symptomatic LMCA disease, 115 by CABG and 72 by S. Patients treated by S were at higher surgical risk: female (10.7% vs 6.4%, p=0,002), age (74±9 vs 66±9 years, p= 0.0001), renal impairment (5.3% vs 1.6%, p=0.003), impaired respiratory function (7.5% vs 2.1% p=0.0001) and clinical presentation with unstable angina (65% vs 35% p=0.014). The 2 groups were well matched in terms of diabetes (10% vs 14%, NS), previous MI (7.5% vs 8%, NS) and mean LVEF (57±14% vs 59±13%, N.S.). MACE were defined as total mortality, cardiac death, non fatal MI and target lesion revascularisation (TLR). There were 3 in hospital deaths (1 S, 2 CABG), 7 MI (4 S, 3 CABG) 2 strokes (0 S, 2 CABG). At a mean follow up of 331± 207 days there were 14 further deaths (9 S, 5 CABG, p=0.048) however, only 8 were cardiac (4 S, 4 CABG,p=NS). There were 4 cancer related deaths in the S group. The malignancy had been diagnosed prior to revascularisation in all 4 cases. There were 13 and 3 TLRs, p=0.01 respectively in the S and CABG groups. Kaplan-Meier analysis revealed cardiac death free survival at 1 year of 92±0.3% vs 91±0.3%(mean ± SEE) for S vs CABG, p=NS, and MACE free survival of 76±0.5% vs 90±0.4%, log rank p=0.02 respectively.

Conclusion: The immediate and medium term survival following unprotected LMCA stenting was equivalent to CABG. The longer term outcome of S was limited by the need for TLR. Stenting offers an excellent alternative to CABG in patients with relative contraindications to surgery.

2678 The French registry of left main coronary artery treatment

M. Silvestri[1], P. Labrunie[1], T. Lefevre[2], K. Khalife[3], G. Bayet[4], M.C. Morice[2], M. Bedossa[5], A. Chmait[6]. *[1]U.C.V, Marseille, France; [2]Institut Hospitalier Jacques Cartier, Institut Cardiovasculaire Paris Sud, Massy, France; [3]Hôpital Bon Secours, Metz, France; [4]Clinique Générale, Istres, France; [5]Hôpital Pontchaillou, Rennes, France; [6]CHU, Hôpital Cardiologique, Lille, France*

Background: CABG is the established treatment for unprotected left main coronary artery lesions (LMCA). However, this strategy should be reconsidered in view of new refinements in PCI with stenting. As a consequence, PCI is now proposed as an alternative to CABG in some centers.

Methods: A prospective registry was set-up in 12 French high-volume centers in order to evaluate their approaches in patients with LMCA.

Results: From May to December 2001, 342 consecutive Pts were included, age 69+11years, female gender 24%, unstable angina 43%, 3 vessel disease 41%, distal LMCA 56%, EF 57±15%. Based on their demographic data, Pts were classified as good candidates for surgery in 63%, poor in 32% and contra-indicated in 5%. Treatment choice was CABG in 48%, PCI in 39% and medical in 13%. The main clinical characteristics were similar in the CABG and PCI groups except for an excess of poor candidates for surgery in the PCI group (49 vs 13%, p=0.003). Angiographic data were also similar except for more RCA lesions in the CABG group (47% vs 27%, p=0.05). Complete revascularization was achieved in 77% for CABG using 1.7±2.0 grafts (43% arterial) vs 67% for PCI (p = NS). In the PCI group, 86% of patients were pre-treated at least 3 days before with the antiplatelet association of thienopyridin and aspirin. Anti Gp2b3a were started pre-procedure in 12% and during in 6%. An intra-aortic balloon pump was inserted pre-procedure in 30%. PCI was performed via the femoral route in 92% and radial in 8% using 6 Fr guides in 69%, 7 Fr in 16% and 8 Fr in 15%. Before stent implantation, rotational atherectomy was used in 6.2% and cutting balloon in 3.1% of cases. Left main stents were deployed without predilatation in 62% of cases (1.1±0.4 stents, diameter 3.8±0.3 mm, length 11.5±3.5 mm, inflation pressure 15.1±3.1 atm.). Kissing balloon inflation was performed in distal LMCA in 55% of cases. Angiographic success was obtained in all cases. The left main MLD increased from 1.24±0.57 to 3.70±0.69 mm and % stenosis decreased from 71.1±14.1 to 6.5±9.2%. In hospital MACE were 4.8% in the CABG group including death in 4.2% (cardiac 1.8% and non cardiac 2.4%) and Q-wave-MI (0.6%) and 0.7% in the PCI group (non Q-wave-MI 0.7%, no Death, no emergency CABG). Length of stay was 14±8 days in the CABG group vs 5±3 in the PCI group (p<0.001).

Conclusion: Despite unfavorable characteristics, the PCI group for LMCA is associated with excellent in-hospital outcome and a trend towards a lower mortality rate than the CABG group. The 6-month follow-up of the entire cohort will be presented at the meeting.

2679 One-year outcomes of unprotected and protected left main stenting in the current era

N. Meneveau[1], B. Klugherz[2], S. Hashemi[2], R. Wilensky[2], J. Johnston[3], F. Schiele[1], J.P. Bassand[1]. *[1]Department of Cardiology, Besancon, France; [2]University Pennsylvania Health System, Department of Medicine, Philadelphia, United States of America; [3]Pittsburgh, United States of America*

Background: Although coronary artery bypass surgery is the accepted treatment for left main coronary artery (LMCA) disease, improved coronary interventional techniques may facilitate a percutaneous approach. Data regarding patient outcomes following left main stenting remain limited.

Methods: We retrospectively reviewed outcomes among 135 consecutive patients who underwent protected or unprotected LMCA stenting at least one year prior to follow-up. Outcomes of one-year survival, myocardial infarction (MI), target-lesion revascularization (TLR), and the combined major adverse clinical event (MACE) rate were computed. Several demographic and procedural variables were tested in univariate and multivariate prediction models.

Results: Of 135 patients with a mean age of 68±10 years and mean ejection fraction 48±10%, 94(70%) underwent protected (left coronary artery grafted) and 41(30%) underwent unprotected LMCA stenting. Cardiogenic shock was present in 6% of patients. Glycoprotein 2B/3A receptor antagonists were used in 58 patients (43%). One-year clinical follow-up was obtained in 95% of patients. Survival at one year was 88% for all patients (protected 95% and unprotected 71%), TLR 21%, and the one-year MACE rate was 34%. For the 8 patients with cardiogenic shock, one-year survival was 50%. In a multivariate analysis, predictors of mortality included cardiogenic shock (odds ratio [OR] 6.0, 1.0-34.9, p=0.05) and unprotected LMCA stent (OR 3.3, 1.4-7.6, p=0.06). Congestive heart failure was a univariate predictor of survival (OR 3.3, 1.1-9.6, p=0.03). No univariate predictors of TLR were identified.

Conclusion: In the setting of protected LMCA disease, percutaneous intervention has an excellent one-year survival. Survival is reduced following unprotected LMCA stenting in a selected population felt to be poor surgical candidates. In contrast to previous outcomes analyses of patients undergoing coronary stenting, diabetes is not a predictor of left main TLR or MACE. Target-lesion revascularization for left main stents is similar to stenting of other large coronary arteries.

2680 A comparison of stenting with angioplasty for isolated stenosis of the left anterior descending coronary-artery: five-year clinical follow-up

F. Versaci, A. Gaspardone, F. Tomai, I. Proietti, L. Altamura, A. De Fazio, M. Iamele, A.S. Ghini. *European Hospital TorVergata Univ., Cardiology, Rome, Italy*

We have previously demonstrated that in a trial that carried out 120 symptomatic patients (pts) with isolated stenosis of the proximal left anterior descending coronary artery, primary stent implantation, as compared with balloon angioplasty (PTCA), resulted in better clinical and angiographic results at one year. The aim of this study was to establish whether the early favourable results are maintained over 5-year follow-up.

Data at five years were determined from hospital-wide clinical database. Major clinical events (death, myocardial infarction, and target lesion revascularization) were analysed according to the intention to treat analysis.

Cardiovascular mortality was significantly higher in PTCA group compared with stent group (13% vs 5%; p=0.04); myocardial infarction was not significantly different in the 2 study groups (15% vs 12%, p=0.43). In the PTCA pts, 20% underwent target lesion revascularization (TLR) versus 8% of pts in stent group (p=0.04). At five years, the event-free survival rate (80% vs 67%; p=0.05) was significantly better in stent group compared with PTCA.

Conclusions: In patients with isolated stenosis of the proximal left anterior descending coronary artery, 5-years clinical follow-up confirms a better clinical outcome in stent compared with PTCA group.

2681 Stent implatation in proximal left anterior coronary: ostial versus nonostial lesions

W. Pimentel, Wilson Pimentel, Maéve Barros, Edson Bocchi. *Instituto do Coração de Campinas, Cardiac Catheterization, Campinas, Brazil*

Background: The presence of a left anterior descending(LAD)coronary ostial lesion poses a special management problem,since is more likely to be associated with high incidence of restenosis.
Methods: We performed an analysis between 1996 and 2001 for all patients(pts)who underwent PTCA with stent for treatment of proximal LAD disease:Group(G)I=451pts nonostial; G II=159pts ostial lesions. Demographic, clinical and angiographic fartors were similar in both groups.
Results: see table

Initial(in-cath.lab.)%	G I	G II	p-value
procedural success	98	97	NS
acute closure	0.7	0.1	NS
CABG	0.7	1.3	NS
QMI	1.0	1.3	NS
death	0.7	1.3	NS
Two-years FU%			
MACE	17	28	<0.05
TVR	10	21	<0.05

Conclusions: Coronary stenting in proximal ostial LAD lesions resulted in equivalent in-cath.lab. results when compared to proximal nonostial LAD lesions; however, the long-term FU was caracterized by higer incidence of MACE and TVR.

2682 Evaluation of different approaches to stenting true bifurcation lesions

T. Lefevre[1], Y. Louvard[1], M.C. Morice[1], P. Dumas[2], C. Loubeyre[3], O. Tavolaro[2]. *[1]Institut Hospitalier Jacques Cartier, Institut Cardiovasculaire Paris Sud, Massy, France; [2]Clinique du Bois de Verrières, Institut Cardiovasculaire Paris Sud, Antony, France; [3]Hôpital Claude Galien, Institut Cardiovasculaire Paris Sud, Quincy, France*

Background: Various approaches have been proposed for stenting true bifurcation lesions but no large studies have compared these different approaches.
Methods: The purpose of this study was to retrospectively evaluate the immediate results and mid term outcome of different approaches that were used for treating "true bifurcation lesions" (type 1) with stents. All patients had been prospectively included in a prospective single center observational database since January 1996 with 7-month follow-up and coronary angiogram in cases of clinical or stress test ischemia.
Results: Among 936 bifurcation lesions consecutively included, 474 (51%) were type 1. Patients were 64+12 yrs old, 85% male, 40% unstable angina and 10% acute MI (cardiogenic shock was excluded). A total of 1.98+0.79 vessels were dilated during the index procedure. Systematic T stenting, stenting the side branch first (Type A treatment) was used in 19% of cases. Stenting of the main branch with provisional T stenting of the side branch (Type B) was used in 74% of cases, "Culotte" stenting (type C) in 3% and others in 4%. The clinical characteristics were similar in each group. Main characteristics and results are summarized in the table below.

	Type A	Type B	Type C
Patients (n)	88	354	14
T-shape lesion (%)	33.0†	18.6	7.1
Main branch stenosis (%)	82.9±12.2†	75.1±17.0	78.8±14.1
Side branch stenosis (%)	80.7±17.5†	65.4±24.1	62.0±12.1
Main branch tubular stent (%)	72.8†	93.1	50.0*
Side branch stent (%)	100†	32.6	100*
Kissing Balloon (%)	66.3†	85.0	61.5*
Total procedure time (min)	75±15†	66±29	90±28*
In-hospital MACE (%)	8.0	4.5	35.7*
Total 7-month MACE (%)	29.3†	16.9	44.4*
Target vessel revascularization (%)	22.8†	12.8	18.2

†p<0.05 type A vs B, *p<0.05 type C vs B

Conclusion: Preliminary results of this study show that provisional T stenting of the side branch is the least time-consuming strategy associated with a lower rate of MACE and TVR compared to other strategies.

IMPACT OF THE REDEFINITION OF MYOCARDIAL INFARCTION

2683 Myocardial infarction redefined: impact of new troponin-based criteria on diagnosis and outcome of acute coronary syndromes

S. Wilson[1], N. Sekhri[1], K. Foo[1], C. Knight[2], A. Suliman[1], K. Ranjadayalan[1], A.D. Timmis[2]. *[1]Newham Healthcare Trust, Cardiology Dept., London, United Kingdom; [2]London Chest Hospital, Cardiology, London, United Kingdom*

Background A change from enzymatic to troponin-based diagnostic criteria for acute myocardial infarction (AMI) has been recommended by the Joint ESC/ACC Committee. This will produce parallel changes in the diagnostic frequency and risk profile of AMI, but the magnitude and direction of these changes have not been defined.
Aims To compare the diagnostic frequency and outcome of AMI according to old (CK-based) and new (troponin-based) diagnostic criteria in patients with acute coronary syndromes.
Methods 964 patients with acute coronary syndromes were studied. Serial CK and 12 hour troponin I/T concentrations were obtained, the dignostic cut-offs being 400 IU/l and 0.1 μmol/l, respectively. Rates of left ventricular failure (LVF) and hospital death were calculated according to old (CK-based) and new (troponin-based) diagnostic criteria.
Results Of the 964 patients, 297 (30.8%) fulfilled old CK criteria and 481 (49.9%) new troponin criteria for AMI. Among patients fulfilling old CK criteria, rates of ST shift and Q wave development were 79% and 77%, compared with 65% and 26% among patients fulfilling new troponin criteria. Accordingly, rates of LVF and hospital death were 22.2% and 7.4% when diagnosis was based on old CK criteria, but fell to 17.3% and 4.6% when diagnosis was based on new troponin criteria. However, when analysis was restricted to 242 patients in the upper quartile range of troponin concentrations (>=8.4 μmol/l), rates of LVF and hospital death were substantially higher (21.5% and 7.0%, p<0.001).
Conclusion Application of new troponin-based criteria increases by 62% the proportion of acute coronary syndrome patients diagnosed with AMI and simultaneously reduces the risk of LVF and hospital death by 22% and 38%, respectively. Only when the diagnosis of AMI is restricted to patients with troponin concentrations in the upper quartile range (>=0.84 μmol/l) do complication rates become comparable to those seen in patients with AMI based on old enzymatic criteria.

2684 The new definition of myocardial infarction: what does it change in the routine daily care of patients?

M. Cassin[1], F. Macor[1], E. Cervesato[1], D. Rubin[2], F. Marciano'[1], F. Antonini Canterin[1], C. Burelli[1], G.L. Nicolosi[1]. *[1]A.O. S. Maria degli Angeli, Cardiology Dept., Pordenone, Italy; [2]A.O. S.Maria degli Angeli, Clinical Pathology, Pordenone, Italy*

Introduction: In the year 2000 the new definition of myocardial infarction has been approved and published (ESC/ACC). The aim of the present study was to analyze the clinical impact of applying this new definition.
Methods: the decisional level for myocardial infarction by using the CK-MB values was that recommended by the WHO criteria (CK-MB mass greater than 5 ng/ml), whereas the one for troponin I levels, obtained according to the suggested methodology approved by the ESC/ACC joining group, was first subjected to clinical validation at our institution and then defined at 0.13 ng/ml.
Results: In the year 2000, 760 consecutive patients were admitted for acute coronary syndrome. Of these, 359 (227 males aged 63(12) years and 132 females aged 76(11) years) had a final diagnosis of myocardial infarction with traditional criteria and 401 patients (255 males aged 64(10) years and 146 females aged 71(10) years) had a final diagnosis of unstable angina. By applying the new definition of myocardial infarction the additional number of patients with myocardial infarction was 155, with an increase of 43% compared to the classical definition. In this group of patients the use of anti-thrombotic therapy and diagnostic tools (echocardiography, exercise test, coronary angiography) was similar to that observed in the patients with non ST elevation myocardial infarction with classical criteria.
Conclusions: the new definition of myocardial infarction caused in our institution a 43% increase of this diagnosis compared to the traditional definition. The use of diagnostic resources and therapeutic strategies did not show any significant differences between patients with classical NSTEMI and with the new definition of MI. The social and economic impact of this significant increase should be carefully taken into account.

2685 The impact of redefining myocardial infarction on caseload in a large British teaching hospital

G A. Large[1], D. Gray[2], J R. Hampton[2]. [1]*University Hospital Nottingham, Department of Cardiovascular Medicine, Nottingham, United Kingdom;* [2]*University Hospital Nottingham, Department of Cardiovascular Medicine, Nottingham, United Kingdom*

Background: A joint European Society of Cardiology/American College of Cardiology (ESC/ACC) committee recently recommended that acute myocardial infarction (AMI) be redefined. We conducted a prospective observational study of all suspected cases of AMI admitted to a large British teachng hospital over six months, to determine the impact of applying of the new definition in practice.
Methods: A study population was assembled using the 'hot pursuit' methodology. A record of clinical features, serial electrocardiographic appearances and biomarker assay results was kept. The population was then divided into three groups by diagnostic category (1. AMI by 'traditional' modified W.H.O. criteria. 2. AMI by the 'new' ESC/ACC criteria only. 3. MI Excluded.). Each group was followed to determine rates of in-patient investigations, therapeutic interventions and outcomes.
Results: There were 1348 admissions with suspected AMI during the study period. 385 cases (28.6%) were defined as AMI by 'traditional' criteria. A further 240 cases (17.8%) of AMI were identified by the 'new' definition. Compared with patients attracting the traditional diagnosis of MI, those satisfying the new definition only were more likely to undergo in-patient coronary angiography - and revascularisation - (15.4% v 6.2%) but despite this, spent less time in hospital (mean length of stay 4.8 days v 5.8 days). In patient case fatality rate was 7.1% v 12.8%.
Conclusions: Widespread adoption of the re-definition of AMI in clinical practice will dramatically increase the number of patients labelled with the diagnosis, accompanied by, as yet, unquantified social and psychological sequelae. The additional cases make high demands for early, aggressive management; possibly leading to reduced length of hospital stay and have a relatively low early fatality rate.

2686 Prognostic implications of the new definition for non-ST-segment elevation acute myocardial infarction

C. Aguiar, J. Ferreira, R. Teles, K. Reis-Santos, R. Seabra-Gomes. *Hospital Santa Cruz, Cardiology Dept., Carnaxide, Portugal*

Background: A consensus document of the ESC/ACC has recently redefined acute myocardial infarction (AMI): acute coronary syndromes (ACS) with cardiac troponin (cTn) elevation but normal CK-MB levels are included in the category AMI. We evaluated the clinical and prognostic implications of this new definition.
Methods: We studied 315 patients hospitalised due to non-ST-elevation ACS and presenting cTnI elevation with or without CK-MB elevation in serial measurements performed every 6 hours during the first 24 hours after admission. Patients were divided into two groups: (1) "classic" AMI – patients presenting CK-MB elevation; (2) "redefined" AMI – typical rise and fall of cTnI with normal CK-MB levels. We compared these groups with respect to baseline clinical characteristics, in-hospital management (pharmacological therapy and myocardial revascularization procedures) and 30-day outcome (study endpoint was defined as death or re-MI occurring during the first 30 days after admission).
Results: Overall, 154 patients presented cTnI elevation with persistently normal CK-MB – "redefined" AMI – and 161 patients presented CK-MB elevation – "classic" AMI. Thus, the new definition for AMI increased the number of patients considered to have a non-ST-elevation AMI by 96%. Patients of the group "redefined" AMI were older (odds ratio 1.89; 95% IC: 1.04 - 3.44; p=0.038), less frequently treated with glycoprotein IIb/IIIa inhibitors (odds ratio 0.44; 95% IC: 0.25 - 0.77; p=0.004) and more frequently with calcium channel blockers (odds ratio 2.22; 95% IC: 1.09 - 4.53; p=0.028). The 30-day endpoint rate was 11.4% for the entire study population. Thirty-day outcome was similar for both groups of patients (11.8% endpoint rate for "classic" AMI versus 11.0% for "redefined" AMI), even after adjustment for the differences detected: the adjusted odds ratio for the 30-day risk of death or re-MI in the "redefined" AMI patients was 0.90 (95% IC: 0.44 - 1.82; ns).
Conclusion: The new AMI definition approximately doubled the number of patients having a final diagnosis of non-ST-elevation AMI. Patients considered to have positive-cTn unstable angina and those considered to have non-ST-elevation AMI, according to previous definitions, showed similar short-term outcomes. These results strengthen the importance of cTn measurements for risk stratification in patients with ACS and selection of those who may most benefit from aggressive management.

2687 Comparative outcome of chest pain unit versus coronary care unit management of acute coronary syndromes without ST-segment elevation

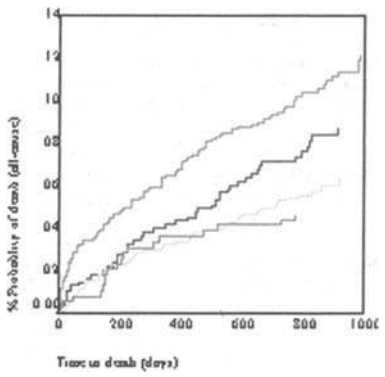
A. Conti[1], B. Paladini[1], S. Toccafondi[1], S. Magazzini[1], M. Zanobetti[1], L. Di Felice[2], C. Francois[2], G. Berni[2]. [1]*Chest Pain Unit, Emergency Department, Florence, Italy;* [2]*Emergency Department, Careggi Hospital, Florence, Italy*

Background: In patients (pts) with acute coronary syndromes without ST elevation (unstable angina, UA; non ST elevation myocardial infarction, NSTEMI) treatment with GP IIb/IIIa receptor blockers associated with early invasive strategy significantly reduce the incidence of composite coronary events (CE), but benefits vary among subsets of patients (pts). Chest pain unit (CPU) management of these pts and selection for angiography may represent an alternative solution to coronary care unit (CCU) admission.
Patients and Methods: During 2001, 142 consecutive pts (mean age 71 y, range 44-92, male 66%) with UA or NSTEMI were treated with GP IIb/IIIa antagonist in addition to standard pharmacologic therapy. Patients were randomly assigned to CPU-management(angiography depending on: recurrent angina, troponin I > 0.10 ng/l, ST-segment elevation < 0.1 mV or depression, EF < 40%) or CCU-management (early invasive strategy encouraged). Patients were followed-up for CE in-hospital and at 6 months.
Results: The two subsets of CPU-pts (n=73) and CCU-pts (n=69) shared similar baseline features, troponin levels, TIMI risk score, and presence of UA or NSTEMI on admission. PTCA was performed in 33% CPU-pts versus 49% CCU-pts (P<.05); CABG in 5.5% versus 5.8% (P=ns). Direct discharge rate was also similar (13.7% from CPU versus 14.5% from CCU; p=ns). During in-hospital stay, CPU-pts had recurrent angina, AMI and death in 29%, 4%, and 0% respectively versus 22%, 0%, and 1.4% of CCU-pts (P=ns). At 6-month follow-up, 14% CPU-pts suffered CE, versus 17% CCU-pts (P=ns). Management in CPU or in CCU did not show significant difference in CE rate (during in-hospital and at 6 months) when pts were divided in subsets according to TIMI risk score <4 (n=82) or TIMI score =/>4 (n=60).
Conclusions: Management in CPU of pts with UA and NSTEMI is a safe, effective alternative to CCU management and does not increase the likelihood of in-hospital and short-term recurrence of CE. The management is specially attractive for those hospital without availability of angiography facilities.

2688 Importance of classifying angina severity: prospective findings from the ACRE study

N.K. Fitzpatrick[1], S. Gnani[1], G. Feder[2], A.M. Crook[1], N. Walker[1], P. Magee[3], A. Timmis[3], H. Hemingway[1]. [1]*Kensington & Chelsea and Westminster H, Dept. of Research and Development, London;* [2]*Dept. of General Practice, London, United Kingdom;* [3]*Cardiac Directorate, Barts and the London NHS Trust, London, United Kingdom*

Background: Although the prevalence of angina remains high, the importance of grading angina severity is unclear. **Objective:** To determine the extent to which functional severity of angina is associated with angiographic findings, quality of life, revascularisation rates and mortality. **Design:** Prospective, population-based study with 2.5 year follow-up. Angina severity was assessed with the Canadian Cardiovascular Society (CCS) scale. **Setting:** Barts & the London NHS Trust, London, UK. **Patients:** 4020 consecutive patients undergoing coronary angiography in the Appropriateness of Coronary Revascularisation (ACRE) study. **Main outcome measures:** SF-36, Seattle Angina Questionnaire (SAQ), revascularisation rates, non-fatal myocardial infarction, mortality.
Results: Higher CCS class was linearly associated (p for linear trend <0.001) in age adjusted analyses with impaired left ventricular dysfunction, higher number of diseased vessels and worse health functioning, to a similar extent in younger and older (over 75) patients. Higher CCS class was associated with higher revascularisation rates (p <0.001; CCS IV vs I HR: 1.99, 95%CI 1.40-2.83 for angioplasty and 1.98, 1.46-2.69 for bypass graft), worse all cause mortality (p <0.001; CCS IV vs I: 1.69, 0.90-3.18) and non-fatal myocardial infarction. These effects were independent of age, sex, smoking, history of hypertension, diabetes, diseased vessels, left ventricular dysfunction and revascularisation status.
Conclusion: CCS class was linearly associated with angiographic findings, quality of life, revascularisation rates, survival and non-fatal myocardial infarction. These findings support the usefulness of grading symptomatic status among angina patients angina with this simple four level scale.



Probability of death by CCS class.

ANTIPLATELET THERAPY – RISKS AND BENEFITS

2689 Beneficial effect of a 24-48 hr "cool-down" period with tirofiban before coronary angiography in high risk patients with non-ST-segment elevation acute coronary syndromes

A.W.J. van 't Hof[1], F. Zijlstra[1], J.H. Dambrink[1], K. Miedema[2], H. Suryapranata[1], J.C.A. Hoorntje[1], A.T.M. Gosselink[1], M.J. de Boer[1] on behalf of the Zwolle Myocardial Infarction Study Group. [1]*Cardiology,* [2]*Clinical Chemistry, Isala Klinieken Zwolle, Zwolle, Netherlands*

Background: Recent studies show that an aggressive strategy of early angiography and revascularisation may improve outcome in high-risk non-ST elevation ACS-patients. However, only few studies have addressed the effect of timing of angiography and the effect of pre-treatment with a glycoprotein 2b/3a blocker. **Patients and Methods:** From April 2000 to Dec 2001, 220 pts with unstable angina, Braunwald class 3, with >1 mm ST depression or a positive trop T (>0.05 ng/ml) were randomised to very early (<12 hrs) angiography (group A) without 2b/3a treatment or to angiography after 24-48 hrs pre-treatment with tirofiban (group B, 0.4 μg/kg/30 min,/0.1 μg/kg/min for 24 hrs). From Jan 1,2001, tirofiban was given at a higher dose (10 μg/kg bolus/0.15 μg/kg/min) with continuation of treatment for at least 12 hrs in case PTCA was performed. Enzymatic infarct size (LDHQ48) was assessed by the area under the LDH release curve from at least 5 measurements over a period of 48 hrs. All angiography films of patients were analysed by an independent core-lab, unaware of treatment modality. **Results:** 75% of pts had elevated trop T on admission or 3 hrs thereafter. Median time to angiography was 6 (grp A) and 51 hrs (grp B). During initial hospitalisation, revascularization was performed in 75% (PTCA: 61%, CABG:14%, grp A) and 77% (PTCA: 58%, CABG: 19%, grp B) of pts.

	Group A (N=109)	Group B (N=111)	P-value
TIMI 2 or 3 pre PTCA (%)	43/65 (66)	53/65 (82)	0.04
Corr TIMI frame count post PTCA (SD)	23 (14)	18 (8)	0.05
LDHQ48 (SD)	407 (471)	242 (353)	0.004
low dose tirofiban/24 hrs	417 (443)	281 (407)	0.11
high dose tirofiban/48 hrs	398 (501)	211 (303)	0.02
negative troponin T	278 (499)	191 (260)	0.88
positive troponin T	412 (441)	257 (369)	0.004

Conclusion: An initial "cool-down" period with 24-48 hrs treatment with tirofiban is associated with a smaller enzymatic infarct size and improved angiographic outcomes, compared to immediate angiography without 2b/3a pretreatment. These benefits are more pronounced in troponin-positive patients and in pts in whom high dose tirofiban was continued until angiography.

2690 Ticlopidine and aspirin versus aspirin alone in the treatment of the acute coronary syndromes without persistent ST elevation (TICASA)

J. Stepinska, Z. Sadowski, K. Zawilska, S. Niemczyk, M. Banaszewski. *National Institute of Cardiology, CCU, Warsaw, Poland*

Aggregation of platelets is the pathophysiologic basis of the acute coronary syndromes. TICASA is a polish multicenter, randomized, placebo controlled prospective trial. Rationale to the study was to use lower doses of the two antiplatelet agents acting in the two different mechanisms to improve antiplatelet action and to decrease side effect as compare with the standard doses. The aim of the study was to compare the efficacy and safety of aspirin (ASA) 100 mg with ticlopidine (TIC) 250 mg versus ASA alone in the treatment of the unstable angina. Randomization was performed in a double-blind manner by coordinating center. 454 with unstable angina were randomized to TIC 250 mg or placebo group. Intravenous heparin was to be given as a bolus dose of 5000 U followed by infusion 1000 U/h with APTT range 50-70 sec. All patients received first dose 300 mg ASA, than 100 mg per day. The primary end point was a composite of death, myocardial infarction, recurrent ischemia or hospitalization in 30 days and 3 months. The secondary end points included bleeding and other side effects. There was no difference in the base-line characteristics of the groups. A sample consisting of 454 patients in the two groups would provide the study with 80 percent power to detect a reduction of 13% (or an absolute reduction of 10 percent) of the composite end point in the 3 months incidence, assuming an event rate of 70% in the placebo group. Incidence of the components of the composite end point was not different between groups in 30 days and 3 months. The incidence of the composite end point at 30 days for the TIC group was 37,9% and for the placebo group was 43,9% (NS), at 3 months 66,9% and 76,9% (p<0,05) and 13,1% relative risk reduction. The incidence of minor and mild bleeding was similar in two groups (11,6% vs 13,4% and 4% vs 2,6%). Serious or life-threatening bleeding occurred only in TIC group - 3 patients (1,3%) but strokes only in placebo group - 3 patients (1,3%). **Conclusions:** Concomitant therapy ASA 100mg and TIC 250 mg decreased composite endpoint (death, myocardial infarction, recurrent ischemia and rehospitalization) after 3 months therapy. The treatment was safe and well tolerated.

2691 The risks versus benefits of clopidogrel treatment in acute coronary syndrome patients overall, and those undergoing CABG: the CURE trial

K.A.A. Fox[1], S.R. Mehta[2], F. Zhao[2], B. Gersh[3], S. Yusuf[2]. [1]*The Royal Infirmary of Edinburgh, Cardiology, Edinburgh, United Kingdom;* [2]*McMaster University, Hamilton, Canada;* [3]*Rochester, United States of America*

Among the 12,562 ACS patients in CURE 9.3% of those randomized to clopidogrel experienced cardiovascular death, MI or stroke vs 11.4% for placebo (RR 0.80, 95% CI 0.72-0.90, <0.001). 2072 patients underwent CABG with the effects of clopidogrel being consistent with the overall benefits; 147/1011 (14.5%) clopidogrel vs 172/1061 (16.2%) placebo sustained the primary end point (RR 0.89, CI 0.71-1.11). Similar benefits were seen among the 1013 patients who underwent CABG surgery during the initial hospitalization (RR 0.78, 95%CI 0.57 -1.08). For the entire study there was a 1% excess of major bleeding but no significant excess of life threatening bleeding (2.1% clopidogrel vs 1.8% placebo, p=0.13) or haemorrhagic strokes. For those undergoing CABG a non significant excess of 1 patient per 100 experienced life threatening bleeding with clopidogrel. This apparent excess was confined to those continuing the study drug within 5 days prior to CABG (7.8% clopidogrel vs 5.0% placebo, within 7 days of CABG, RR 1.55, CI 0.93-2.57). However, there was no significant excess using the TIMI criteria for major bleeding (see table) or GUSTO criteria or severe/life threatening bleeding, even among those continuing drug within 5 days of CABG (≤5 days 3.2 vs 5.5, >5 days 2.9 vs 2.4 placebo vs clopidogrel, both ns).

CURE:Adjudicated bleeding after CABG

	Stop≤5days				Stop>5 days			
	Plac (%)	Clopid (%)	RR	95%CI	Plac (%)	Clopid %	RR	95%CI
Life threat	24(5.04)	34(7.80)	1.55	0.93-2.57	19(4.19)	17(3.73)	0.89	0.47-1.69
Other Major	6 (1.26)	8(1.83)	1.46	0.51-4.16	5(1.10)	3(0.66)	0.60	0.14-2.48
TIMI Major	13(2.73)	11(2.52)	0.92	0.42-2.04	11(2.42)	8(1.75)	0.72	0.29-1.78

Nevertheless, the more inclusive CURE criteria for major bleeding revealed 7.4% placebo vs 11.9% clopidogrel (p=0.02). The results indicate that the increase in bleeding risk with CABG is confined to those treated with clopidogrel in the preceding 5 days. Treating 1000 patients in the CURE protocol results in 28 fewer deaths, MIs or strokes in 22 patients, against an excess of 6 patients requiring transfusion and a trend for 1 patient experiencing life threatening bleeding following CABG. The excess risks of bleeding are not observed in those discontinuing clopidogrel >5days prior to surgery. Overall, these data indicate that the benefits of clopidigrel clearly outweigh the risks.

2692 Aspirin dose and bleeding events in the CURE study

R.J.G. Peters[1], F. Zao[2], B.S. Lewis[3], K.A.A. Fox[4], S. Yusuf[2] on behalf of the CURE Investigators. [1]*Academic Medical Center, Cardiology, Amsterdam, Netherlands;* [2]*Mc Master University, Canadian Cardiovascular Collaboration, Hamilton, Canada;* [3]*Lady Davis Carmel Medical Center, Cardiology, Haifa, Israel;* [4]*Royal Infirmary, Cardiology, Edinburgh, United Kingdom*

Introduction: There is limited information on the optimal dose of aspirin (ASA) in patients with acute coronary syndromes (ACS). In the CURE study, 12,562 patients with a non-ST segment elevation ACS were randomized between placebo and clopidogrel (Clop) for a mean of 9 months. Study drug was given on top of ASA, which was dosed according to local practice. The CURE protocol recommended 75-325 mg daily. In-hospital, almost all patients received heparin. We retrospectively investigated relationships between ASA dose and bleeding.

Methods: Patients were divided into 4 groups of ASA dose: <100 mg, 100-150 mg, 151-300 mg and >300 mg daily. Relative risks were adjusted for gender, weight, hypertension, TIMI risk score, angiography, percutaneous coronary intervention and bypass surgery.

Results: Adjusted rates of major or life threatening bleeding are shown below:

	Placebo		Clop		Clop/Placebo	
ASA dose (mg)	N	%	N	%	RR	95% CI
<100	19	1.92	27	2.82	1.47	0.82-2.63
100-150	64	2.24	91	3.19	1.42	1.04-1.95
151-300	46	3.32	65	4.63	1.40	0.96-2.02
>300	40	3.77	48	4.65	1.23	0.82-1.86
Adjusted p-value		0.057		0.042		

Adjusted odds ratios for highest versus lowest ASA dose groups: placebo 1.7 (95% CI 0.9-3.0), Clop group 1.5 (95% CI 0.9-2.4). There was no evidence of increasing efficacy against cardiovascular death, myocardial infarction or stroke with increasing ASA dose. The benefit of Clop was consistent across the ASA dose groups, without evidence of heterogeneity. The incidence of minor bleeding did not show a clear ASA dose response.

Conclusion: Bleeding risks with ASA are dose dependent. In order to reduce the risk of bleeding it would be prudent to use an ASA dose of 75-100 mg, especially since such patients are on multiple antithrombotic agents.

2693 Bleeding in relation to abciximab use in non ST-segment elevation acute coronary syndromes without early coronary revascularisation. Results of the GUSTO IV-ACS trial

T. Lenderink[1], E. Boersma[2], P. Armstrong[3], R. Califf[4], J. Scherer[5], E. Barnathan[6], L. Wallentin[7], M.L. Simoons[2]. [1]*Leiden, Netherlands;* [2]*University hospital, Cardiology, Rotterdam, Netherlands;* [3]*Alberta university, Edmonton, Canada;* [4]*Duke University, Durham, United States of America;* [5]*Eli Lilly, Indianapolis, United States of America;* [6]*Centocor, Malvern, United States of America;* [7]*University hospital, Upsala, Sweden*

Treatment with the glycoprotein IIb/IIIa receptor antagonist abciximab reduces the risk of thrombotic complications, in conjunction with percutaneous coronary interventions (PCI), but also has been associated with higher bleeding rates. We investigated the bleeding risk in patients with a non ST-elevation acute coronary syndrome (NSTE-ACS) without early coronary revascularisation.

Methods and Results: In the GUSTO IV–ACS trial 24 hour or 48 hour infusion of abciximab was compared to placebo in 7800 patients with NSTE-ACS. During study drug administration 2% of the patients underwent a revascularisation procedure. A bleeding event according to the TIMI classification was seen in 1507 patients (98 major, 215 minor and 1194 insignificant). Spontaneous bleeding was seen in 911 patients. The other 596 patients had their event in conjunction with a procedure (catheterisation, PCI or CABG). However more and higher severity bleeding occurred when percutaneous coronary intervention or CABG followed catheterisation. Significant predictors for all bleeding events as found with multivariable analysis were: low molecular weight heparin (LMWH) (OR:4.9, 95%CI: 4.1-5.9), duration of abciximab infusion (OR:2.8, 95%CI: 2.3-3.3 for 24 h and (OR:3.8, 95%CI: 3.2-4.6 for 48 h infusion), region of hospitalisation (OR:4.9, 95%CI: 4.0-5.9 for patients treated in North America), inotropics given during hospitalisation (OR:3.2, 95%CI: 2.3-4.6), age over 70 years (OR:1.8, 95%CI: 1.6-2.1), female gender (OR:1.5, 95%CI: 1.3-1.7), and performance of CABG or PCI (OR:4.7, 95%CI: 1.2-19.2). Weight was not a significant predictor. The most important predictors for spontaneous bleeding in this population were the same.

Conclusions Treatment with abciximab in patients with non-ST-elevation acute coronary syndrome is, with regard to bleeding risk, safe. Major bleedings and stroke are rare. Guidelines for use of abciximab in PCI are also applicable here as well as dosing guidelines for LMWH, as many patients with NSTE-ACS will undergo an intervention and thus bleeding events associated with the intervention might be prevented.

2694 Platelet inhibition during tirofiban treatment in patients with acute coronary syndromes

R. Curtin[1], M. Dooley[1], D. Cox[1], J.B. Foley[2], D.J. Fitzgerald[1]. [1]*Royal College of Surgeons in Ireland, Department of Clinical Pharmacology, Dublin, Ireland;* [2]*St. James's Hospital, Department of Cardiology, Dublin, Ireland*

Background: early studies of GPIIb/IIIa antagonists suggest that greater than 80% receptor occupancy, with nearly complete inhibition of platelet aggregation is necessary to prevent platelet-induced coronary thrombosis. Treatment with tirofiban in acute coronary syndrome (ACS) patients reduces the risk of death, MI or refractory ischaemia at 30 days and 6 months. However, the platelet inhibitory effects of tirofiban in an ACS population remain undefined.

Methods: this is an interim analysis of 18 patients (planned total of 30) with unstable angina or non-ST-segment-elevation MI who were randomised to varying durations (24, 48, 72 and 96 hours) of tirofiban, administered as a bolus dose of 10μg/kg over 3 minutes followed by a maintenance infusion of 0.1μg/kg/min. Platelet function was measured at baseline, 6, 24, 48, 72 and 96 hours. Receptor occupancy was measured by flow cytometry (Biocytex kit). Platelet aggregation to ADP 20μM and closure time on the PFA-100 were also assessed.

Results: mean receptor occupancy on treatment was 77.5%(95%CI 74.8-80.1%). Only 30 of 55 sampling times on treatment showed receptor occupancy of > 80% and only 5 of 17 patients had > 80% receptor occupancy at all timepoints on treatment. Mean inhibition of ADP-induced platelet aggregation was 80.2% (95%CI 77.5-83.0%). Only 40 of 60 sampling times on treatment showed > 80% inhibition of platelet aggregation and only 6 of 18 patients had > 80% inhibition of platelet aggregation at all timepoints on treatment. Lower levels of receptor occupancy and inhibition of platelet aggregation were not related to a particular sampling time. Closure times on the PFA-100 correlated strongly with ADP-induced platelet aggregation (R^2=0.96), but this point-of-care assay appears overly sensitive to the inhibitory effects of GPIIb/IIIa antagonists, reaching maximum values at 60-70% inhibition of ADP-induced platelet aggregation.

Conclusion: Many ACS patients fail to achieve adequate levels of platelet inhibition while undergoing treatment with a standard regimen of tirofiban. Higher or tailored doses of tirofiban may be necessary to achieve levels of platelet inhibition that have been previously shown to optimally inhibit coronary thrombosis. In addition, the PFA-100 does not appear to be an ideal point-of-care assay for monitoring GPIIb/IIIa antagonism.

MANAGEMENT OF PATIENTS AFTER HEART TRANSPLANTATION

2695 Allograft vasculopathy surveillance and timing of coronary angiographies by tissue Doppler imaging and electron beam computed tomography

M. Dandel[1], F. Knollmann[2], E. Wellnofer[3], M. Hummel[1], S. Kapell[1], R. Hetzer[1]. [1]*German Heart Institute of Berlin, Thoracic and Cardiovascular Surgery, Berlin, Germany;* [2]*Charite, Campus Virchow-Klinikum, Strahlenklinik, Berlin, Germany;* [3]*German Heart Institute of Berlin, Cardiology Dept., Berlin, Germany*

Background: Although most transplant centers perform coronary angiograms annually for screening, these surveillance studies often fail to detect transplant coronary artery disease [TxCAD] prior to a clinical event. Routine coronary angiographies for TxCAD surveillance are also risky, especially for renal failure due to chronic renal impairment induced by cyclosporine. Thus, the non-invasive timing of coronary angiographies would be more beneficial than the recommended routine annual screening. After promising results for early TxCAD diagnosis obtained separately with pulsed-wave tissue Doppler imaging [PW-TDI] and electron beam computed tomography [EBCT], we assessed the value of both methods in combined use for TxCAD monitoring.

Methods: Throughout 18 months, 198 consecutive patients (post-transplant times: 1 -16 years) underwent PW-TDI wall motion analysis and EBCT for coronary calcification detection before coronary angiography. With PW-TDI we measured the systolic and diastolic wall motion peak velocities Sm and Em, the systolic and diastolic times TSm (from onset of first heart sound to Sm) and TEm (from onset of second heart sound to Em), and also the systolic and diastolic wall accelerations Sm/TSm and Em/TEm. Coronary calcifications were quantified by the Agatston scoring system. EBCT and PW-TDI data were tested for relationships with angiographic findings.

Results: The systolic peak velocity (Sm) and Agatston score (AS) showed the highest diagnostic values. We found significant differences (p=0.0001) between patients with and without proximal stenoses of great epicardial coronary vessels for both AS and Sm. Definite cut-off values for AS and Sm enabled highly diagnostic conclusions. The negative predictive values for relevant coronary stenoses (>50% occlusion) of Sm velocities above 9 cm/s and AS values below 50 (93.3% and 91.1% respectively) allow the exclusion of relevant stenoses in these patients. The positive predictive values for coronary stenoses of Sm and AS evaluated separately were lower. Nevertheless, using both Sm and AS together we obtained several functions that enable diagnostic decisions with probabilities of between 88 and 90%. Among these, Fishers' classification functions appeared most suitable for patient selection to coronary angiography on the basis of PW-TDI and EBCT findings.

Conclusions: Serial PW-TDI and annual EBCT are reliable for timing of cardiac catheterizations. They facilitate earlier detection of TxCAD and enable patients with a high risk for catheterization to be spared unnecessary routine angiographies.

2696 Long-term benefits of treatment with mycophenolate mofetil and low-dose cyclosporine in chronic cyclosporine induced nephrotoxicity

V. Sanchez[1], J.F. Delgado[2], J.M. Morales[3], M.A. Gomez[2], P. Escribano[2], L. Cea-Calvo[2], A. Forteza[4], C. Saenz de la Calzada[2]. [1]*Hospital Doce de Octubre, Cardiology Dept., Madrid, Spain;* [2]*Hospital Doce de Octubre, Cardiology, Madrid, Spain;* [3]*Hospital Doce de Octubre, Nephrology, Madrid, Spain;* [4]*Hospital Doce de Octubre, Cardiac Surgery, Madrid, Spain*

Cyclosporine (CsA) induced nephrotoxicity is a major limitation in heart transplant patients (HTp). CsA dose reduction can leads to substantial early improvement in renal function. However, there aren't controlled studies that confirm if this maintenance therapy can be long term beneficial in HTp. Our aim was to study long-term benefits of therapy with low dose of CsA and mycophenolate mofetil (MMF) in HTp with CsA induced nephrotoxicity and analyze the mean related factors.

Patients and methods: Twenty-five adult HTp (mean post-HT 41.7 SD 25.7 months) were included in our retrospective analysis (22 men, mean age 58.84 SD 7.96 years.) CsA nephrotoxicity was defined as serum creatinine level (Cr) > 2 mg/dl at least in two determinations one month apart, excluding other causes of renal disease. Patients were switched from azathioprine to MMF (1-3 gr/d), followed by a stepwise reduction of CsA dosage aiming 50% of the pre-switch CsA blood level. Renal function (glomerular filtration rate (GFR) and Cr) was monitored every 3 months. Analysis of variance for repeated measures was performed for analyze renal function improvement along the time and multiple logistic regression was used to analyze variables that could be related.

Results: Mean follow-up was 30 SD 13 months (range 9-54). Results are shown in table. CsA level was the unique independent variable associated with renal function improvement (partial R^2 0.4), without influence of MMF dose, time postHT, age or sex. Renal function experimented a quickly improvement after conversion to MMF in first three months ($p < 0.001$) reaching a plateau, but without further significant improvement over the course of time.

Cyclosporine induced nephrotoxicity

	Baseline	End of follow up	p value
Cr (mg/dl)	2.37 SD 0.5	1.59 SD 0.4	< 0.0001
GFR (ml/min)	36.77 SD 10.01	54.98 SD 13.8	< 0.0001
CsA (ng/ml)	158.9 SD 69.71	85.9 SD 38	< 0.001

Cr: creatinine; GFR: glomerular filtration rate; CsA: cyclosporine; SD: standard desviation

Conclusions: CsA induced nephrotoxicity is not a progressive and irreversible disease. Reduction CsA levels and association with MMF is useful for long-term renal function improvement and could avoid terminal chronic renal failure. Unique significant factor associated with this improvement is the reduction of CsA level.

2697 Two years angiographic and clinical follow-up after coronary artery stenting in heart transplant recipients

C. Tron[1], M. Redonnet[2], H. Eltchaninoff[1], F. Bouchart[2], C. Nafeh-Bizet[2], J.P. Bessou[2], A. Cribier[1]. [1]*Hôpital Charles Nicolle, Service de cardiologie, Rouen, France;* [2]*Hôpital Charles Nicolle, Cardiac surgery, Rouen, France*

Cardiac allograft vasculopathy (CAV) remains the major cause of late death following heart transplantation (HT). Although the safety of coronary artery stenting in this indication has been recently reported in small series of patients, long-term follow-up data after coronary stents implantation in transplanted patients are lacking.

Methods: Since December 94, 16 patients (Pts) aged 55 ± 14 with documented severe ischemia underwent implantation of 21 coronary artery stents at a mean of 94 ± 33 months (32 to 161) after HT. Mean EF was 57 ± 9% and 13/16 Pts had multivessel disease. All Pts received aspirin (100 mg/d) and thienopyridine (for 1 month) after stenting. Quantitative coronary angiography (QCA, Phillips DCI) was performed before and after stent implantation and at a systematic 6 month angiographic control. Pts were then followed clinically every 2 months and angiographically every 12 months.

Results: 1 stent was implanted in 11 Pts and 2 stents in 5 Pts. Location of stenting was: LAD in 12 cases, LCX in 6 and RCA in 3. Indication for stenting was elective in 58%, or due to unsatisfactory acute results (16%) or restenosis (26%) after balloon angioplasty. Mean stent length was 15 ± 6 mm (7 to 34 mm). Mean balloon size was 3.0 ± 0.2 mm and mean inflation pressure was 9 ± 2 atm. Percent diameter stenosis decreased from 71 ± 14% at baseline to 26 ± 13% after stent implantation ($p<0.05$). Procedural success was 100%. At 6-month follow-up, the angiographic restenosis rate (%DS>50%) was 56% in 17/21 stents controlled. During a mean follow-up of 28 ± 24 months (2 to 86) after stent implantation, a total of 23 revascularization procedures were required in 8 Pts for in-stent restenosis or treatment of new lesions. Five/16 Pts (31%) died, 2 of non cardiac cause.

Conclusion: Coronary stenting in CAV is a palliative procedure followed by the need for multiple revascularization procedures and a high mortality rate during follow-up. However, it might remain the best therapeutic option before potential retransplantation in this life-threatened population.

2698 Is introduction of mycophenolate mofetil and reduction of cyclosporine valuable in renal dysfunction after heart transplantation? (IMPROVED-study)

C.E. Angermann[1], S. Störk[1], A. Costard-Jäckle[2], T.J. Dengler[3], G. Tenderich[4], R. Schwarz[5], A. Rahmel[6], F. Wagner[7], B. Haaff[8], H. Nägele[9], K. Pethig[10] on behalf of the IMPROVED-Study Group. [1]*Med. Poliklinik, Universität Würzburg, Cardiology, Würzburg, Germany;* [2]*Christian-Albrechts-University, Clinic for Cardiothoracic Surgery, Kiel, Germany;* [3]*Universität Heidelberg, Cardiology, Heidelberg, Germany;* [4]*Ruhr-Universität Bochum, Cardio-Thoracic Surgery, Bad Oeynhausen, Germany;* [5]*Rheinisch-Westf.Technische Hochschule, Medizinische Klinik I, Aachen, Germany;* [6]*Universität Leipzig, Herzzentrum Leipzig, Leipzig, Germany;* [7]*Herz-Kreiskreislaufzentrum Dresden, Dresden, Germany;* [8]*Westpfalz-Klinikum Kaiserslautern, Kaiserslautern, Germany;* [9]*Universitätsklinikum Hamburg-Eppendorf, Herzchirurgie, Hamburg, Germany;* [10]*Med. Hochschule Hannover, Klinik f. Thorax-/Herz-/Gefäßchirurgie, Hannover, Germany*

Background and Aim: Cyclosporine (CyA)-associated nephrotoxicity is a major concern in heart transplant recipients (HTR). This prospective multicenter study investigated whether introduction of the non-nephrotoxic immunosupressant mycophenolate mofetil (MMF, target level 2-4 µg/ml) after withdrawal of azathioprine (aza) followed by subsequent stepwise reduction of CyA (target level 50 ng/dl) improves impaired renal function in HTR as assessed by serial serum creatinine (Cr)-measurements. Secondary endpoints included safety and tolerability of MMF/low-dose-CyA and the influence of the initial degree of renal impairment and of comorbidity with diabetes mellitus.

Subjects: HTR >6 months pop. with Cr ≥1.7 mg/dl for ≥6 months and standard immunosuppression with CyA/aza/steroids were eligible. The treatment arm (T) included 109 and the control arm (C) 52 HTR. Study duration was 6 months.

Results: T and C did not differ in age (58.7±8.2 vs 59.5±6.6 years), sex (8% vs 11% female), pre-transplant Cr (1.3±0.5 vs 1.3±1.3 mg/dl), and Cr at time of inclusion (2.4+07 vs 2.2+06 mg/dl). During the study, Cr deceased from 2.4±0.7 to 2.1±1.0 mg/dl ($p<0.0001$) in T, but remained unchanged in C (2.2±0.6 vs 2.2±0.7 mg/dl). In the 12 months preceding the study, a negative regression slope of serial reciprocal Cr values (1/Cr) vs time indicated significant deterioration of renal function over time in both T and C. With MMF/low-dose-Cya the slope became positive in T indicating progressive renal improvement(difference of slopes: $p<0.0001$). This effect was observed in all T-subgroups (Cr 1.7-2.2, 2.3-2.8, 2.9-3.5 and, to lesser extent, >3.5 mg/dl) and in both diabetic and non-diabetic HTR. In C, the negative trend also stopped (difference of slopes: $p<0.04$). Adverse events were observed in T in 60.9% (80.0% in C; NS). 19 HTR were excluded from analysis for different reasons (2 in C). Myocardial biopsies obtained in T (not in C) at MMF/CyA target levels showed 3 rejections grade 1B, 1 grade 2, and 3 grade 3A, the latter reversible with therapy.

Conclusion: Over a wide range of Cr-levels, CyA-associated chronic nephrotoxicity in HTR proved partially reversible even in diabetics with MMF/low-dose-CyA. Long-term observation must clarify whether this renal improvement will postpone/prevent end-stage renal failure in HTR. Due to the risk of occasional moderate rejections initial graft monitoring is mandatory with this regimen. Cr-monitoring with unchanged immunosuppression did not have the same effect, but attenuated progression of renal dysfunction in the 6 month study period.

2699 Sildenafil decreases central arterial wave reflection amplitude and reduces aortic pressure and systolic stress in cardiac transplant recipients

W. Nichols, D. Edwards, R. Aggarwal, J. Estrada, J. Aranda, J. Hill, R. Schofield. *University of Florida, Cardiovascular Medicine, Gainesville, Florida, United States of America*

Objective: Cardiac transplantation is associated with increased arterial stiffness and hypertension which may contribute to cardiovascular complications. Arterial stiffening increases arterial pulse wave velocity and causes early return of reflected pressure waves to the proximal aorta from peripheral reflecting sites which augments systolic blood pressure and increases left ventricular afterload and systolic stress. The aim of this study was to determine if sildenafil, a type 5 phosphodiesterase inhibitor, influences central systolic arterial wave reflection and alters aortic blood pressure and systolic stress in cardiac transplant recipients (CTR) with stable post-transplant hypertension (HTN) taking concomitant antihypertensive medication. Methods: High-fidelity radial artery pressure waveforms were recorded non-invasively by applanation tonometry in 10 hypertensive CTR (age 55±6.0 years) and aortic pressure waveforms generated using a mathematical transfer function. Aortic augmentation index (measure of wave reflection amplitude), time delay of the reflected pressure wave and tension time index (TTI, measure of systolic stress and myocardial oxygen demand) were calculated. After baseline recordings, sildenafil (50 mg) was administrated and recordings collected every 15 minutes for 60 minutes. Results: Sildenafil influenced a significant decline in augmentation index from 7.0±12 to 0.0±13% (mean±SD, $P < 0.01$) and a delay in reflected wave travel time from 54±3.7 to 61±10 msec ($P<0.03$). Maximum modification in wave reflection occurred at 30 to 45 minutes and was associated with a decline in aortic systolic pressure from 120±8.2 to 111±8.4 mm Hg ($p<0.004$) and TTI from 2831±233 to 2630±224 mm Hg sec/min ($P<0.01$). Heart rate was 91±11 b/min at baseline and did not change with sildenafil. Conclusions: Sildenafil delays return of the reflected pressure wave from the periphery to the heart, reduces its amplitude and, therefore, decreases aortic blood pressure and systolic stress in hypertensive CTR taking other antihypertensive vasodilator medication. These changes, which are likely due to decreased arterial stiffness and pulse wave velocity, influence a decline in left ventricular afterload and myocardial oxygen demand.

2700 High rejection score is an independent predictor of cardiac allograft vasculopathy: a single center 15-year study and risk factor analysis

A.L.P. Caforio[1], F. Tona[1], A. Belloni Fortina[2], S. Piaserico[2], A. Gambino[3], G. Thiene[4], D. Casarotto[3], S. Iliceto[1]. *[1]University of Padua, Cardiology, Dept Exp Clin Med, Padua, Italy; [2]University of Padua, Dermatology Dept., Padua, Italy; [3]University of Padua, Cardiovascular Surgery, Padua, Italy; [4]University of Padua, Pathology Dept., Padua, Italy*

Cardiac allograft vasculopathy (CAV) may represent a form of chronic allograft rejection. However, the link between acute rejection and CAV has remained elusive, as well as the relative contributions of donor and recipient immune and nonimmune risk factors as predictors of CAV.

Methods: We performed multivariate analysis of risk factors for CAV in 361 heart transplantation (HT) patients, 312 male, aged 50 ± 12 years (yrs) mean follow-up 7.2 yrs, on double or triple therapy. Rejection scores (RS) on endomyocardial biopsy were calculated (International Society for Heart and Lung Transplantation grades: 0=0; 1A=1; 1B=2; 2=3; 3A=4; 3B=5; 4=6) in the first year and during the whole follow-up. RS including only severe grades (= or >3A) were also calculated. Selective coronary angiography was performed yearly after HT and CAV onset was defined as any lesion = or >10%. The coronary tree was divided into 17 traits and a CAV severity/diffusion index was calculated for each patient summing up the scores assigned to all lesions (10% stenosis=1; 20%=2; 30%=3; 40%=4; 50%=5; 60%=6; 70%=7; 80%=8; 90%=9; 100%=10). Multivariate analysis (Cox regression) for CAV onset and severity/diffusion included: donor age, sex, and weight; recipient sex and age at HT, pre-HT diagnosis in the recipient; hypertension, diabetes and hyperlipidemia post-HT; number of treated rejections and RS at 1st year and total; immunosuppressive drug dosage (mg/Kg) at 3, 6, 12 months (mo).

Results: Overall survival post HT was 84%, 75% and 62% at 1, 5, and 10 yrs. The incidence of CAV (Kaplan-Meier) was 2% at 1 year, 22% at 5 and 39% at 10 yrs. Multivariate analysis showed, as risk factors for CAV onset, older (>32 yrs) donor age ($p<0.0001$, RR=9.9), male donor sex ($p<0.001$, RR=3.2), high (>0.15) RS for severe grades ($p<0.02$, RR=2.01), high Cyclosporin at 3 mo ($p<0.02$, RR=1.9). Risk factors for CAV severity/diffusion were higher (>68 Kg) donor weight ($p<0.01$, RR=7.5), high prednisone dosage at 1 yr ($p<0.0001$, RR=21.1), ischemic heart disease pre-HT ($p<0.002$, RR=9.7).

Conclusions: High rejection score was an independent predictor for CAV onset, as well as known risk factors such as older donor age and male sex. Predictors of CAV severity/diffusion were mainly non immune features. This strongly suggests an immune-mediated basis for CAV onset as well as non-immune modulation of CAV progression.

BETA BLOCKER THERAPY IN HEART FAILURE: CURRENT THOUGHTS

2701 Randomized comparison on the effects of metoprolol or carvedilol on myocardial substrate utilization in chronic heart failure

A. Al-Hesayen, E. Azevedo, J. Parker. *Mount Sinai Hospital - U of Toronto, Medicine Dept., Toronto, Canada*

Background: The benefits of beta-blocker therapy in congestive heart failure (CHF) is well documented. Surprisingly, the pathophysiological basis for this benefit is not clearly established. Evidence from animal models of CHF suggests that therapy with beta-blockers can improve cardiac efficiency and energy substrate utilization by reducing cardiac free fatty acid (FFA) utilization and increasing cardiac lactate consumption. Furthermore, it is possible that selective versus nonselective beta-blockers have differential impacts on cardiac metabolism

Methods: This was a randomized, double blind study, designed to compare the effects of 4 months of therapy with metoprolol versus carvedilol on myocardial substrate utilization in patients with CHF. After randomization, patients were instrumented with Swan-Ganz, coronary sinus, and arterial catheters for measurement of hemodynamics and myocardial FFA and lactate extraction. Patients were then started on a beta-blocker and up-titrated to 50mg bid of metoprolol or 25mg bid of carvedilol. After 4 months of therapy, hemodynamics and transcardiac substrate extraction measurements were repeated.

Results: Eleven patients (age 54 ± 3yrs, LVEF 18 ± 2%) were randomized to carvedilol and 11 patients (age 54 ± 4yrs, LVEF 21 ± 3%) were randomized to metoprolol. Neither drug caused a significant change in cardiac filling pressures, mean arterial pressure, or cardiac index. Both drugs caused a significant reduction in heart rate (-8 ± 3 bpm metoprolol; -16 ± 3 bpm carvedilol; $P < 0.05$ vs baseline for both). Carvedilol caused a significant reduction in FFA extraction (0.12 ± 0.02 mmol/L vs 0.1 ± 0.02 mmol/L, $P < 0.05$) and tended to increase lactate extraction (0.24 ± 0.05mmol/L vs 0.35 ± 0.08mmol/L, $P < 0.08$)

By contrast, metoprolol caused no change in FFA extraction (0.09 ± 0.02mmol/L vs 0.11 ± 0.03 mmol/L, P = NS) and caused a significant reduction in lactate extraction (0.18 ± 0.03 mmol/L vs 0.11 ± 0.04mmol/L, $P < 0.05$).

Conclusion: Chronic carvedilol therapy in CHF patients had a beneficial effect on myocardial substrate extraction with a shift from FFA to lactate utilization. This shift could lead to an improvement in myocardial efficiency in carvedilol treated patients compared to those treated with metoprolol. The clinical significance of these differential effects awaits the results of randomized clinical trials

2702 Effect of beta-blockade on activation of the renin-angiotensin-aldosterone system in chronic heart failure

W.H. Fung[1], S. Chan[1], T.G. Yandle[2], A.M. Richrds[2], M.G. Nicholls[2], J.E. Sanderson[1]. *[1]The Chinese University of Hong Kong, Medicine & Therapeutics, Shatin, NT, Hong Kong; [2]Christchurch School of Medicine, Medicine, Christchurch, New Zealand*

Background: Beta-blockers are known to suppress renin release in hypertension and lower levels in patients taking ACEIs. However, it is not entirely clear what is the effect of additional beta-blockade on renin and aldosterone levels in severe heart failure (HF) patients taking ACEIs over the longer term. It has been postulated that beta-blockers may obviate the need for ACEIs in heart failure or reduce their effectiveness.

Methods: 49 pts with chronic HF were given metoprolol 50mg bd or carvedilol 25mg bd (50%) after a 4 week dose titration period in addition to standard therapy with diuretics and ACEIs in a prospective trial. Samples for plasma rennin activity (PRA), and aldosterone were taken at baseline, 4, 12 and 52 weeks after starting therapy.

Results: Treatment with either beta-blocker significantly lowered PRA at 4 weeks compared to baseline (-2.0±0.6 nmol/L/hr, p=0.006), but at 12 weeks this had reduced to -1.1±0.6 nmol/L/hr (p=0.08), and at 52 weeks PRA was not significantly different from baseline (+1.05±0.6 nmol/L/hr, p=0.13). Aldosterone levels did not change significantly from baseline at 4 or12 weeks although there was a non-significant trend for lower levels at 52 weeks(aldo baseline 232 ±154 pmol/L, 52 weeks 192±100 pmol/L, p=0.09). There were no sig difference between metoprolol and carvedilol.

Conclusions: these results indicate that the suppressive effect of beta-blockers on plasma renin activity in HF pts already on an ACEI is temporary and there is no significant effect on serum aldosterone levels. Therefore patients on beta-blockers still need to continue with an ACEI or ARB as well as an aldosterone antagonist.

2703 Efficacy of bisoprolol, β1-selective adrenoblocker, in chronic heart failure patients with increased cytokine level

L. Olbinskaya, S. Ignatenko. *Moscow Medical Sechenov Academy, Internal Medicine and Clinical Pharmac, Moscow, Russian Federation*

Activation of cytokine system may develop in the patients with chronic heart failure (CHF). TNFa is one of the biochemical markers of this state. In order to investigate pharmacological effects of b-adrenoblockers as neurohomonal-modulating agents in CHF with increased cytokine level, we performed an open randomized comparative trial.

Methods: 38 male CHF patients with increased TNFa level aged under 60, II-IV NYHA functional classes (FC), ejection fraction (EF) <30% received 24-weeks treatment with either traditional pharmacotherapy of CHF with ACE inhibitors (2nd group) or the same with 10 mg o.d. bisoprolol, b1-selective adrenoblocker,(1st group). We evaluated NYHA FC, hemodynamic state (heart rate (HR), blood pressure (BP) level), heart morphofunctional parameters (end systolic and diastolic volume (ESV, EDV), EF), exercise capacity and TNFa plasma level.

Results: The NYHA FC was diminished more significantly in the 1st group pts. It was decreased from 3.5+0.53 to 2.25+0.46 ($p<0.001$) in the 1st gr and from 3.43+0.53 to 2.57+0.98 ($p<0.01$) in the 2nd one. The best beneficial influence on hemodynamic, morphofunctional parameters and exercise capacity was more significantly in the 1st gr too (the results are in the table).

Changes in hemodynamic parameters

	HR, %	SBP, %	DBP, %	ESV, %	EDV, %	EF, %
1 group	- 22.6**	-13.6**	-14.5**	-16.6**	-8.3*	+17.7**
2 group	-6.1*	-8.3*	-4.26*	-8.4*	-3.7	+9.7*

* - $p<0.01$; ** - $p<0.001$ compared with baseline

Exercise capacity (EC) increased from 27.5+10.35 Wt to 47.5+18.32 Wt ($p<0.0001$) in the 1st group and from 25.7+9.76 to 31.43+15.74 Wt ($p<0.01$) in the 2nd one. The TNFa plasma level diminished from 12.37+6.00 to 2.24+1.28 pg.ml-1 ($p<0.0001$) in the 1st group and from 14.88+8.77 to 6.3+3.8 pg.ml-1 ($p<0.005$) in the 2nd one.

In conclusion, the addition of bisoprolol to traditional pharmacotherapy of CHF in the patients with increased cytokine level significantly improves the quality of life, left ventricular function, hemodynamic parameters and exercise capacity. All these changes were accompanied with the decreasing of TNFa plasma level.

2704 Effect of carvedilol on major clinical events in patients with severe heart failure and an extremely depressed ejection fraction

H.A. Katus[1], M. Tendera[2], P. Mohacsi[3], M.B. Fowler[4], A.J.S Coats[5], H. Krum[6], E.B. Roecker[7], M. Packer[8] on behalf of the COPERNICUS Study Group. *[1]Lubeck University, Cardiology Dept., Luebeck, Germany; [2]Silesian School of Medicine, Cardiology Dept., Katowice, Poland; [3]University Hospital Bern, Cardiology Dept., Bern, Switzerland; [4]Stanford University Medical Center, Cardiology Dept., Stanford, United States of America; [5]Royal Brompton Hospital, Cardiology Dept., London, United Kingdom; [6]Monash University, Clinical Pharmacology Medicine Dept., Prahran, Australia; [7]University of Wisconsin, Madison, United States of America; [8]Columbia Presbyterian Medical Center, Circulatory Physiology, New York City, United States of America*

Background: Despite the demonstrated survival benefit of beta-blockers in heart failure (HF), many physicians avoid the use of these drugs in patients with extremely depressed LV function in the belief that they will not respond favorably or may be adversely affected by treatment.

Methods: Of the 2289 patients with severe HF enrolled in the COPERNICUS trial, 371 patients had a baseline LV ejection fraction ≤ 15%. These patients had a lower mean systolic blood pressure (117 vs 125 mm Hg) and were more likely to be treated with digitalis (73% vs 65%) than patients with higher EF (both $P<0.002$) but were otherwise similar in their baseline characteristics. Both subgroups of patients were randomized to placebo (PBO) or carvedilol (CRV) for up to 29 months.

Results: Shown below are 1-year Kaplan-Meier rates and risk reductions with CRV (Cox model). The effects of CRV on all-cause mortality and on the risks of death or hospitalization (for any reason or for a specific cause) in patients with EF ≤ 15% were similar to those seen in patients with higher EF. CRV reduced the risk of permanent discontinuation of study drug in patients with EF ≤ 15% (by 32%) and in those with higher EF (by 19%).

Conclusion: CRV is effective and well tolerated even in patients with severe HF symptoms and an extreme depression of LV systolic function.

	Ejection fraction ≤ 15%			Ejection fraction > 15%		
	PBO (n=191)	CRV (n=180)	Change in risk	PBO (n=942)	CRV (n=976)	Change in risk
All-cause mortality	23.8%	18.9%	-30%	17.4%	9.7%	-36%
Death or hospitalization for worsening HF	46.3%	30.3%	-39%	36.0%	24.6%	-28%
Death or cardiovascular hospitalization	52.1%	34.6%	-41%	39.4%	29.4%	-23%
Death or any hospitalization	59.9%	47.2%	-33%	50.7%	40.4%	-21%

2705 Patients with dilated cardiomyopathy with attenuated elevation of cardiac sympathetic activity are poor responder to carvedilol therapy

N. Sasaki[1], Y. Yasumura[1], Y. Ishida[2], A. Hanatani[1], S. Nakatani[1], M. Yamagishi[1], M. Kitakaze[1], K. Miyatake[1]. *[1]Cardiology, [2]Radiology, National Cardiovascular Center, Osaka, Japan*

Because reverse remodeling by carvedilol lasts for at least one year, non-responders to carvedilol determined at 4 months after its administration can belong to the responders determined at one year. We studied the charcteristics of responders and non-responders to investigate the mechanism of left ventricular reverse remodeling. One hundred and eighteen patients (pts) with dilated cardiomyopathy were enrolled. Before, at 4 months and 1 year after the onset of carvedilol (20mg/day) therapy, cardiac function (left ventricular ejection fraction (EF) determined by radionuclide ventriculography), cardiac sympathetic nerve activity (cSNA), and plasma brain natriuretic peptide (BNP) concentrations were determined. cSNA was assessed by myocardial uptake of metaiodobenzylguanidine (MIBG) calculated as the heart/mediastinal activity ratio (H/M). Storage and release of MIBG was also calculated as percent myocardial MIBG washout rate (WR). Low H/M or high WR suggests the enhanced cSNA. Responders were defined as the patients with improved EF by more than 5 units. Baseline EF (26±10 vs 26±8%), plasma BNP concentrations (158±163 vs 163±159pg/ml), and early H/M before carvedilol therapy did not differ between the non-responders (29pts) and responders (63pts) determined at 4 months. However, the baseline value for delayed H/M of non-responders was larger (2.06±0.44 vs 1.88±0.35) and WR was smaller (43.1±12.2 vs 49.5±11.2%) than those of the responders. Baseline value for EF of non-responders (10pts) determined at 1 year was slightly larger (32±8 vs 25±9%), BNP was smaller (64±47 vs 171±176pg/ml), delayed H/M was larger (2.40±0.48 vs 1.93±0.36), and WR was further smaller (39.1±9.5 vs 48.4±11.8%) than those of the responders (47pts). Conclusions: Patients with dilated cardiomyopathy and attenuated elevation of both baseline cSNA and BNP may receive less benefit from reverse remodeling by carvedilol therapy.

2706 Prescription rate and safety of betablockers in heart failure patients with or without diabetes

M. Bobbio[1], S. Ferrua[1], C. Opasich[2], M. Porcu[2], D. Lucci[2], M. Scherillo[2], L. Tavazzi[2], A.P. Maggioni[2] on behalf of BRING-UP Investigators. *[1]Ospedale Molinette, Div. Univ. di Cardiologia, Torino; [2]ANMCO Res. Ctr., Florence, Italy*

Background: Physicians are still concerned to prescribe beta-blockers (BB) in diabetic patients (pts).

Methods: We evaluated the applicability, the safety profile, and the outcome of BB use in pts with heart failure (HF) enrolled in an outcomes research study, planned by the Italian Association of Hospital Cardiologists (ANMCO). Pts were followed-up for 1 year. During 1 month, 3091 pts were enrolled by 202 Cardiological centres: 25% of the recruited pts were already on BB treatment, 28% started treatment at the enrolment visit, and 47% were not started on BB. The present analysis refers to the pts with complete 1 year follow-up (96.5%).

Results: Diabetic pts (21.8%) were older (66±9 vs 63±12 yrs; $p<0.0001$), with a higher prevalence of female (33 vs 25%; $p=0.001$), they had higher NYHA class (III-IV: 38 vs 33%; $p<0.01$), and mean heart rate (80±14 vs 77±15 bpm; $p<0.0001$) than pts without diabetes. No difference of mean EF was observed between the two groups. A lower rate of pts with diabetes was already on BB at enrolment visit (23 vs 27%; $p<0.05$), however the same rate of diabetic and non-diabetic pts started BB during the study. Adverse reactions leading to BB permanent discontinuation were not significantly different in diabetic and non-diabetic pts (26.5% vs 22.7%, NS). The overall 1-year mortality for the total population and split by BB use and diabetes is shows in the table.

1-year mortality	BB	No BB	RR [95%CI]	Total
Total population	8%	17%	2.17 [1.76-2.67]	12%
Diabetic	11%	21%	2.26 [1.77-2.90]	16%
Non-diabetic	7%	16%	1.87 [1.28-2.79]	11%

The Cox multivariate analysis showed that advanced age, NYHA class III-IV, higher heart rate, lower systolic blood pressure, EF < 30% and diabetes are independent risk factors for 1-year mortality, while the use of BB was a protective factor in both diabetics and non-diabetics.

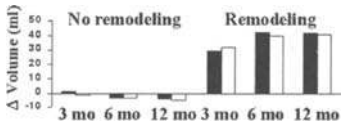
Conclusions: This outcomes research study showed that: - BB were largely prescribed in HF pts with or without diabetes; - the safety and tolerability profile of BB was similar in diabetics and non-diabetics; - the relative reduction of 1-year survival and hospitalisation rates obtained by BB was similar in pts with or without diabetes. Therefore, to deny BB treatment to diabetic pts is not reasonable.

NEW DEVELOPMENTS IN THREE-DIMENSIONAL ECHOCARDIOGRAPHY

2726 Left ventricular remodelling after myocardial infarction assessed by 3D echocardiography

H.F.J. Mannaerts, J.A. van der Heide, O. Kamp, C.A. Visser. *VU Medical Center, Cardiology, Amsterdam, Netherlands*

Background: Left ventricular (LV) volumes, assessed by 3 D echocardiography (3DE) are 2 to 3 times more accurate compared to 2 D echocardiography. Therefore serial individual changes in LV volume can be measured more accurately.
Aim: Accurate assessment of LV remodeling after myocardial infarction (MI) using 3DE.
Methods: 3DE was obtained prospectively in 32 consecutive patients post MI, starting at 5 ± 3 days after the event (baseline), and at 3, 6 and 12 months. The TomTec Freehand® method in conjunction with an ATL 5000®, were used with second harmonic imaging, using the apical window. LV volumes were measured off-line with TomTec Echo-Scan® software. Remodeling was defined as an end-diastolic volume (EDV) or end-systolic volume (ESV) increase of > 10% from baseline.
Results: 18 non-remodelers and 14 remodelers could be identified. Baseline EDV, ESV and ejection fraction (EF) were, respectively, 95.2 ± 25.2 ml, 54.5 ± 19.4 ml, and 43.6 ± 7.7% in the non-remodelers, and 94.8 ± 25.8 ml, 57.5 ± 18.8 ml, and 40.7 ± 7.9% in the remodelers. At 12 months EDV, ESV and EF were respectively 92.1 ± 28.9 ml, 48.7 ± 20.2, and 48.0 ± 6.9% (p = NS for all) in the non-remodelers, and 137.2 ± 56.7 ml (p = 0.001), 87.4 ± 49.6 ml (p = 0.007), and 40.3 ± 13.2% (p = NS)in the remodelers. In this group there was no significant increase (delta) in volumes after 3 months (see figure; black = EDV, white = ESV).



Change in volume (ml) from baseline.

Conclusions: 3 DE can accurately discriminate between non-remodelers and remodelers after MI. In the former there was no significant volume or EF change during the entire follow-up of 12 months, whilst in the latter there was a significant volume increase from baseline to 3 months, without a significant increase thereafter.

2727 Analysis of regional left ventricular endocardial wall area. A novel free hand three-dimensional Doppler tissue imaging parameter in coronary artery disease

C. Breburda, M. Nandalur, P. Rahko. *Univ. of Wisconsin/ Clinical Science C, Medicine, Madison, WI, United States of America*

The assessment of regional left ventricular (LV) wall function using Doppler tissue imaging (DTI) is a promising new technique, yet its quantitation is one-dimensional and its diplay transmural only. Furthermore 70% of regional myocardial contraction occurs at the level of the endocardium, which currently can only be imaged as a cross-section by pulsed Doppler and 2-D DTI.
We thus hypothesized, that free-hand three-dimensional (3-D) DTI is feasible and reveals qualitative and quantitative information about the function of a whole endocardial wall area, a novel parameter for the assessment of regional LV function. We also hypothesized, that differences can be seen between normal and hypokinetic wall segments in patients with coronary artery disease.
Method: 18 patients with coronary artery disease (8 f, 10 m, age 60 ± 16, EF 58 ± 14%) were imaged with two-dimensional Color DTI using a Sequoia echo unit interfaced with a free-hand 3-D (TomTec) system. The endocardial surfaces of the basal and mid lateral and septal left ventricular wall segments were reconstructed in 3-D. Segmental 3-D DTI velocities of the endocardial areas were measured throughout the cardiac cycle and compared with the standard 2-D gray scale (ASE) wall motion score by two independent observers using qualitative visual assessment.
Results: Color 3-D DTI velocity patterns of endocardial wall areas were reconstructed (n=146 total). In normal wall segments (n=90) the velocity patterns of the 3-D endocardial area were more homogeneously distributed than in hypokinetic wall segments (n=56). Peak (mean) systolic velocities were 1.14 ± 0.44 mm/sec (0.37 ± 0.17); peak (mean) diastolic velocities were - 1.66 ± 0.98 mm/sec (-0.51 ± 0.28) respectively. There was a strong correlation between peak systolic and diastolic 3-D endocardial wall area velocities (y = 0.62x + 0.72, r = 0.71, p = 0.0002) and between systolic wall acceleration of the endocardial 3D DTI area and 2-D gray scale wall motion score (r = 0.8, p = 0.007).
Conclusions: 1) Free-hand 3-D Color Doppler tissue imaging is feasible and provides endocardial wall area velocities as well as velocity patterns. 2) Qualitative and quantitative differences between the motion patterns of the endocardial area of normal and hypokinetic left ventricular wall segments can be identified. 3) 3-D free hand DTI may have the potential to provide new insights into regional LV wall function and thus may provide a new technique for the diagnosis of coronary artery disease.

2728 Left ventricular volume measurements with and without Optison for left ventricular opacification – The "endocardial wall" concept revisited

J. A. van der Heide, H.F.J Mannaerts, G.T.J Sieswerda, O. Kamp, C.A. Visser. *VU Medical Center, Cardiology, Amsterdam, Netherlands*

Background In two- and three-dimensional echocardiography, left ventricular (LV) volumes are measured by contour tracing of the innermost endocardial border. The ultrasound contrast agent Optison ® is used for improvement of LV endocardial definition. By filling up intertrabecular space it delineates the outermost endocardial border. This filling up and the "blooming" effect might increase LV volume measurements.
Aim To compare LV volume measurements with and without Optison infusion for LV opacification.
Methods Twenty coronary artery disease patients with a good apical acoustic window underwent transthoracic three-dimensional echocardiography using the TomTec Freehand ® method with and without continuous Optison infusion. Optison was given intravenously as a 0,2-0,3 ml bolus followed by 25 ml/hr continuous infusion. Infusion speed was adjusted to yield complete LV opacification, which could be maintained for 4-6 minutes. As a carrier liquid, 0,9% NaCl was used at an infusion speed of 200 ml/hr. Second harmonic gray-scale tissue imaging with normal (baseline) and low (Optison) mechanical index was used in all patients, and ultrasound machine settings were optimized for endocardial border delineation. LV volumes were measured off-line with TomTec Echo-Scan ® software.
Results For values of end-diastolic (EDV) and end-systolic (ESV) volumes, stroke volume (SV), and ejection fraction (EF) at baseline and during Optison infusion, see table (values expressed as mean ± 1SD, in ml or %).

	Baseline	Optison	p-value
EDV	109,2 ± 33,2	142,1 ± 53,4	0,001
ESV	65,8 ± 30,1	87,9 ± 44,6	0,002
SV	43,2 ± 11,5	54,2 ± 20,4	0,018
EF	41,8 ± 12,1	39,9 ± 14,7	0,499

Conclusions Optison causes a significant increase in LV volume, but not EF measurements compared to baseline. Intertrabecular space appears to be a substantial part of the LV cavity. Therefore, the "endocardial wall" concept should be redefined.

2729 Accelerated three-dimensional echocardiographic protocols for left ventricular volume quantification: comparison of quadriplane and octaplane mode

J.D. Kasprzak, M. Plewka, M. Krzeminska-Pakula, T. Jezewski, M. Borkowski, M. Ciesielczyk, P. Wejner-Mik, J. Drozdz. *Medical University, Cardiology IMW, Lodz, Poland*

Background: Long-axis based quantification (quadriplane and octaplane 3-dimensional echocardiography, Q3D, O3D) is feasible and accurate method of ejection fraction (EF) measurement in unselected routine patients, providing significantly better correlation with MUGA than 2-dimensional echocardiography. We aimed to assess the impact of different acquisition protocols upon Q3D/O3D quantification of LV volumes and EF using multiple gated radionuclide angiography (MUGA) as a reference.
Methods: 28 unselected patients referred for routine assessment of LV function (pts) were studied (5F,23M; age 56±9, BSA 1.93±.19m^2, no image quality criteria). Transthoracic two-dimensional echocardiography (2D) was performed using Toshiba Powervision 7000 and Tomtec Echoview was used for rotational acquisition of datasets for Q3D and O3D from the apical window at 3° and 10° interval. LV volumes were quantified by tracing in 4 (Q3D) or 8 (O3D) coaxial long axis cutplanes.
Results: Volumes could be calculated by 3D echocardiography (3DE) in 28/28 pts. Mean EF was 54±20% in MUGA and 48±17%, 49±17%, 49±18% and 49±18% in 3°O3D, 3°Q3D, 10°O3D, 10°Q3D, resp. (p<0.001 vs. MUGA). 3DE provided excellent correlation of WEF values with MUGA (r=0.92-0.93, similar for all modes). There were no differences between 4 modes of 3D regarding endsystolic and enddiastolic volumes (ANOVA p>0.05) as well as observer variability. The reproducibility of any 3DE method in unselected group was worse than that of MUGA and similar in the 4 approaches (Pearson's r 0.91-0.92 for EF and 0.98-0.99 for volumes). There was a twofold reduction of acquisition time between 3° vs 10° and, independently, analysis time between O3D and Q3D.
Conclusions: Quadriplane analysis of 3-dimensional echocardiography acquired at 10 degree interval provides optimal workload-to-accuracy relationship regarding the quantification of left ventricular volumes and ejection fraction using radionuclide values as a reference.

2730 Three-dimensional echocardiographic wall motion is related to haemodynamic improvement during invasive testing in resynchronization therapy

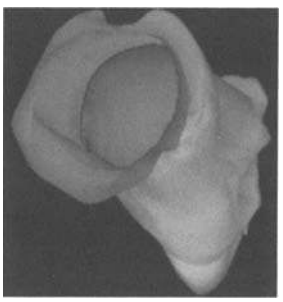
E. Wellnhofer[1], C. Butter[1], M. Seifert[1], M. Schlegl[1], W. Hoersch[2], A. Auricchio[3], C. Stellbrink[4]. [1]Deutsches Herzzentrum Berlin, Cardiology, Berlin, Germany; [2]CRM Guidant, Brussels, Belgium; [3]University Magdeburg, Cardiology, Magdeburg, Germany; [4]RWTH, Cardiology, Aachen, Germany

Background: Three-dimensional echocardiography (3-D-Echo) provides a quantitative assessment of left ventricular regional wall motion. Patients under resynchronization therapy demonstrate different patterns of regional wall motion in sinus rhythm and in the optimal pacing mode.
Methods: In 12 patients with chronic heart failure on resynchronization therapy differences of changes of partial volumes between sinus rhythm and optimized pacing mode were compared. 13-24 volumes per heart cycle were acquired by transoesophageal 3-D-Echo (HP-Sonos 5500/TOMTEC). Endocardial surfaces were generated by a validated automatical technique (thin plate spline model TOMTEC). Each volume was cut into 8 slices, each slice was subdivided into 6 segments resulting in a total of 48 regions. Cyclic changes of the partial volumes segments were evaluated quantitatively (MATLAB script). The number of dyskinetic segments and the regional ejection fraction in hypokinetic segments were evaluated. The changes of these parameters between sinus rhythm and optimized pacing mode were compared to respective changes in pulse pressure and dP/dt max at initial invasive testing.
Results: The number of dyskinetic segments decreased in 10/12 patients during optimized pacing as compared to sinus rhythm from a median value of 9 to a median value of 4-5. This decrease correlated significantly with percent increase of pulse pressure (r=0.64) and dP/dt max (r=0.48). There was a minor but significant increase of regional ejection fraction in hypokinetic segments in 6/12 patients without significant correlation with hemodynamic improvement.
Conclusion: The reduction of dyskinetic segments correlates with hemodynamic improvement and seems to be the major effect of resynchronisation therapy. Echocardiographic three-dimensional regional wall motion analysis provides a tool to study the effects of electrical therapy on the pattern of ventricular contraction.

2731 Experimental results and first human experiences with an interventional closing device of the left atrial apendage (PLAATO)

H. Omran, D. Hardung, H. Schmidt, G. von der Recke, C. Hammerstingl, T. Lewalter, S. Kuntz-Hehner, B. Lüderitz. *University of Bonn, Dept. of Cardiology, Bonn, Germany*

Background: Transesophageal echocardiography (TEE) is the method of choice for evaluating the left atrial appendage (LAA). However, complete morphological analysis of the LAA is often difficult due to its anatomical variability and trabeculation. This prospective study thought to determine experimentally, whether threedimensional (3D) TEE allows accurate determination of the volume and morphology of the LAA and hence may facilitate the human implantation of a LAA occlusion device in patients with atrial fibrillation.
Methods: The LAA was reconstructed in 17 pig hearts using 3D TEE (EchoPAC-3D®). Then, LAA casts were obtained (Technovit 7143®). The casts and 3D TEE results were compared with respect to volume, number of lobuli and main trabeculae (diameter > 5 mm). In addition, six 3D TEE reconstructions of the LAA were performed prior to and after interventional occlusion of the LAA with the PLAATOTM device.
Results: There was no difference in 3D-TEE reconstructed and cast determined volumes (R = 0,96; 95% KI 0,88 – 0,98). The quantity of lobuli was correctly determined by 3D TEE. The amount of main trabeculae was correctly obtained in 14 of 17 cases. 3D TEE allowed exact determination of the ostial diameter of the LAA in those patients who underwent interventional occlusion of the LAA. In addition, the complete occlusion of the LAA was demonstrated by 3D TEE in all cases.



Conclusions: 3D transesophageal echocardiographic reconstruction of the left atrial appendage allows accurate determination of the volume and morphology of the appendage and recognition of accessory lobuli and prominent trabeculae. In addition, the technique facilitates the implantation of a left atrial appendage occlusion device.

EUROPEAN SOCIETY OF CARDIOLOGY LECTURE ON POPULATION SCIENCES

2733 West of Scotland Coronary Prevention study (WOSCOPS): 5-year post-trial follow-up

I. Ford[1], S.M. Cobbe[2], A. Nears[1], J. Innes[1], H. Baillie[1] on behalf of The WOSCOPS group. [1]Glasgow University, Robertson Centre for Biostatistics, Glasgow, United Kingdom; [2]Glasgow Royal Infirmary, Dept of Medical Cardiology, Glasgow, United Kingdom

Background & Methods: WOSCOPS recruits were followed for 5 years after trial completion for assessment of the long-term benefits and safety of within-trial treatment with pravastatin. Subjects were withdrawn from study medication at trial closure, and returned to their general practitioners for lipid management. All deaths were recorded and adjudicated for cause.
Results: The Table shows the numbers of deaths in the 5-year post-trial follow-up and overall post-randomisation. P-values and hazard ratios (HR) for each mortality outcome were calculated from the log-rank test and Cox proportional hazards regression models comparing randomised treatment groups.

Cause of death	Pravastatin Post-trial	n=3302 Overall	Placebo Post-trial	n=3293 Overall	P (Log-rank)	HR (95% CI)
CV	92	142	113	186	0.010	0.75(0.60, 0.94)
Non-CV	130	186	134	196	0.505	0.93(0.76, 1.14)
All Cause	222	328	247	382	0.025	0.85(0.73,0.98)
Cancer	105	149	101	150	0.847	0.98(0.78,1.23)

WOSCOPS: 5 Year Post Study Mortality

Conclusions: Non-cardiovascular (CV) and cancer mortality were balanced between treatment groups throughout. The post-trial follow-up reinforces the benefits of pravastatin treatment on CV and all-cause mortality, with absolute risk reductions post-trial similar to those within-trial.

2734 Nutritional habits among subjects with cardiovascular risk factors

V. Bongard[1], J.B. Ruidavets[1], P. Amouyel[2], D. Arveiler[3], P. Ducimetière[4], J. Ferrières[1]. [1]INSERM U558, Department of Epidemiology, Toulouse, France; [2]INSERM U508, Lille, France; [3]Faculty of Medicine, Department of Epidemiology, Strasbourg, France; [4]INSERM U258, Paul Brousse Hospital, Paris, France

Background Diet is an underestimated therapeutic means for the management of cardiovascular risk factors particularly because of an insufficient knowledge concerning dietary habits of non insulin dependent diabetic (HG), hypercholesterolemic (HTC) and hypertensive (HBP) subjects. However, drug therapy effectiveness could be improved by the use of an appropriate diet. Dietary data were analysed for males participants in the cross-sectional nutritional survey carried out from 1995 to 1997 in three French regions Lille, Strasbourg and Toulouse.
Methods A sample of 1100 men aged 45-64 years was randomly drawn from electoral rolls. Subjects were screened for cardiovascular risk factors in a medical health centre and a 3-day food intake record was set up. HTC, HG and HBP subjects were defined as follows: total cholesterol >=6.2 mmol/l or drug therapy, glycemia >=7.8 mmol/l or drug therapy and systolic >=160 or diastolic blood pressure >=95 mmHg or drug therapy. Each risk factor was analysed separately and after taking into account these three risk factors together, a risk score was built and three groups were identified: 0 risk (group1), 1 risk (group2), and 2 or 3 risks (group3). Recorded energy intake was validated (EI) using the ratio between recorded energy intake and estimated basal metabolic rate (BMR). The statistical significance of the comparisons between groups for cardiovascular risk factors was assessed by ANOVA analysis with adjustment for confounders: age, educational level, centre, body mass index, tobacco consumption and physical activity.
Results Total energy intake and energy without alcohol were reduced by about 10% in the third group (2329/2074 kcal/d) when compared to group 1 (2577/2386 kcal/d) and the trend was significant. The proportion of energy supplied by carbohydrate was 42.6%, 42.2% and 40.7% in groups 1, 2 and 3 respectively ($p<0.05$). Globally, the proportion of energy supplied by carbohydrate was lower and energy coming from fat or protein was higher when one risk factor was prevalent whatever the type of risk factor. The proportion of calories from alcohol was 30% higher in group 3 vs group 1 ($p<0.001$). When subjects with EI/BMR ratio <1.05 were excluded from the analysis, the majority of the differences observed were not modified substantially.
Conclusion Among subjects with one or more cardiovascular risk factors nutritional habits were worse than among subjects with no risk factor and were not in agreement with classical dietary recommendations.

2735 Clinical and angiographic differences between smokers and non-smokers after successful thrombolysis: insights from the APRICOT trials

P.C. Kievit[1], M.A. Brouwer[1], G. Veen[2], W.R.M. Aengevaeren[1], P.J.P.C. van den Bergh[1], A. van Boven[3], D.P. Hertzberger[3], F.W.A. Verheugt[1]. [1]*University Medical Center, Heartcenter, Department of Cardiology, Nijmegen, Netherlands;* [2]*Free University Medical Center, Department of Cardiology, Amsterdam, Netherlands;* [3]*Interuniversity Cardiology Institute, Utrecht, Netherlands*

Background: In patients treated with thrombolysis for acute myocardial infarction (MI) a paradoxical beneficial outcome has been reported in smokers. This benefit was thought to be related to younger age, less severe coronary disease and a better response to thrombolytic therapy. In the subset of patients with successful thrombolysis clinical outcome is strongly related to reocclusion of the infarct related artery. The current analysis sought to identify clinical and angiographic baseline-characteristics in smokers, and tried to assess whether smoking status is associated with reocclusion.
Methods: In the Antithrombotics in the Prevention of Reocclusion In COronary Thrombolysis trials (APRICOT-1 and APRICOT-2) 335 consecutive patients < 71 years had thrombolysis for acute myocardial infarction within 4 hours of symptom onset and a patent infarct artery at angiography < 48 hours. In APRICOT- 1 (1987-1991) patients were randomized to aspirin 325 mg (n=87) or Coumadin (INR 2.8-4.0, n=72), in APRICOT-2 (1995-2000) to aspirin 80 mg (n=78) or aspirin 80 mg in combination with Coumadin (INR 2-3, n=98). Three-month follow-up angiography was performed to assess the patency status of the infarct artery.
Results: At baseline 68% (227/335) of patients were current smokers. Smokers were younger (53.3 9 versus 57.3 8, p< 0.01) and had less often a history of previous infarction (5% versus 17%, p< 0.01) than non-smokers. Enzymatic infarct size did not differ: maximum creatine kinase 1549 1657 versus 1239 1082, p=ns. At baseline angiography smokers had more often single vessel disease (62% versus 46%, p < 0.01) and smooth infarct lesions (68% versus 54%, p = 0.02). Reocclusion rates were 15% (34/227) in smokers as compared to 25% (27/108) in non-smokers (OR 0.53 (95% CI 0.29-0.97, p = 0.03). At multivariate analysis smoking was strongly associated with sustained patency of the infarct artery: OR 0.54 (0.28-1.03, p=.06).
Conclusions: Clinical and angiographic characteristics observed in smokers in the MI population at large also seem to apply to smokers after successful thrombolysis. However, in the APRICOT-patients smoking status appears to remain an important predictor of beneficial outcome, even after correction for baseline characteristics.

NEW ULTRASOUND TECHNIQUES TO UNDERSTAND CARDIOVASCULAR FUNCTION

2740 How useful is valve resistance for the distinction between true severe stenosis and "pseudostenosis" in low flow – Low gradient aortic stenosis

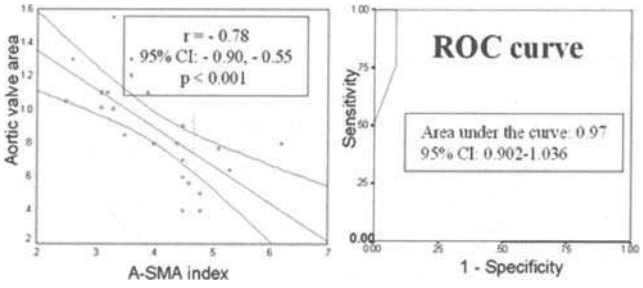
J. Mascherbauer[1], R. Rosenhek[1], H. Schima[2], G. Maurer[1], H. Baumgartner[1]. [1]*University of Vienna, Cardiology Dept., Vienna, Austria;* [2]*University of Vienna, LBI for Cardiosurgical Research, Vienna, Austria*

Background: Although we and others have shown that - in contrast to previous suggestions - aortic valve resistance (R) is flow dependent, the question whether R is of value for the distinction between true severe stenosis and "pseudostenosis" (functionally small aortic valve area [AVA]) in patients with aortic stenosis (AS) who present with small AVA but low flow and low gradient remains controversial.
Methods: To evaluate the value of R in this particular setting, models of stenotic aortic valves without doming (plates), models of doming valves (nozzles) and biological stenotic valves with various degrees of stenosis severity and extensible orifices were studied in a pulsatile in-vitro circuit using Doppler ultrasound and direct pressure and flow measurement. Anatomic AVA ranged from 0.5 to 1.25 cm^2 and cardiac output was varied from 2.0 to 8.9 l/min. R (dynes s cm^{-5}) was calculated as 1333 × mean transvalvular pressure gradient × ejection time/stroke volume. Effective orifice areas (EOA) were calculated with the continuity equation. Orifices of the biological stenotic valves were recorded with a high-speed video camera for AVA planimetry. Valves with EOA < 0.85cm^2 and mean gradients between 10 and 40 mmHg at low cardiac output (<3.5L/min) were divided into 2 groups. Group A = true severe stenosis: EOA remained < 0.85cm^2 at normal flow. Group B = pseudostenosis: increase of EOA beyond 0.85cm^2 at normal flow.
Results: R was significantly smaller in pseudostenosis as compared to true severe stenosis (129±28 vs 176±33 120 dynes s cm^{-5}; p< 0.001) even when baseline AVA did not significantly differ between groups. However, there was a wide overlap that did not allow the clear distinction between the two entities on the absis of an individual R value in the majority of settings. Nevertheless, R of < 120 dynes s cm^{-5} accurately identified nonsevere stenosis. When subgroups of A and B without significant difference in gradient were compared, R was no longer significantly different between group A and B (162±26 vs 141±22; p=.08).
Conclusions: Valve resistance is not only flow-dependent, it is also of limited value for the distinction between true severe stenosis and pseudostenosis in the setting of aortic stenosis with small AVA but low flow and low gradient. Only a very low R of < 120 dynes s cm^{-5} accurately identifies pseudostenosis. In most instances, procedures that attempt to normalize flow and repeat AVA calculations such as dobutamine echocardiography will be necessary for correct diagnosis.

2741 A new index based on an automated segmental motion analysis system in the evaluation of aortic stenosis severity

R. Moreno, J.L. Zamorano, C. Almería, J.L. Rodrigo, L. Alvarez, D. Herrera, L. Mataix, L. Sánchez-Harguindey. *Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain*

A slowered left ventricular contraction has been described in patients with aortic stenosis (AS). The aim of this study was to evaluate the possible role of a new Automated segmental motion analysis system in the assessment of AS severity.
Twenty-two patients with AS, sinus rhythm, and normal left ventricular ejection fraction were prospectively studied. All patients underwent two echocardiographic studies by two differente blinded investigators: 1) Conventional Doppler measurements: transaortic gradients, aortic valve area (continuity equation); 2) Automated Segmental Motion Analysis (ASMA, Aloka, Japan). This system automatically detect endocardial borders and quantitatively displays fractional area changes of left ventricular cavity in real time. An index (A-index) was calculated by dividing the time from the R wave of the ECG to the maximal area shortenning by the RR interval.
Results: (see figure) There was a significant strong negative correlation between the aortic valve area and A-index (r = -0.78; 95% confidence interval: -0.90, -0.55; p < 0.001). The area under the receiving operator characteristic curve in the diagnosis of severe AS was very high (0.97; 95% confidence interval: 0.90-1.0). An A-index of > 0.40 showed a sensitivity, specificity, positive predictive value, negative predictive value and overall accuracy for the diagnosis of severe AS of 100%, 91.7%, 92.3%, 100%, and 95.8%, respectively.



A-SMA index and aortic stenosis.

Conclusion: this new index based on an automated segmental motion analysis system is allows an easy evaluation of AS severity, showing a strong correlation with aortic valve area and a very high accuracy in the diagnosis of severe AS.

2742 Temporal changes in post systolic thickening during prolonged ischaemia quantified by ultrasound deformation imaging in a closed-chest pig model

O. Turschner, J. D'hooge, C. Dommke, P. Claus, I. DeScheerder, B. Bijnens, G. Sutherland. *UZ Gasthuisberg, Cardiology, Leuven, Belgium*

Study aim: To define the precise sequence of temporal changes in Post Systolic Thickening (PST) induced by a 90 minute total PTCA balloon coronary artery occlusion (CAO) as measured by ultrasonic deformation imaging.
Background: PST has been proposed as a clinical marker of viability in ischemic segments. Little information is available on the time course of changes in PST as total CAO progresses to acute transmural infarction.
Methods: In 6 pigs, basal posterior wall radial deformation data was acquired pre- and 1-, 5-, 30-, 60-, and 90 min after total circumflex CAO. High temporal and spatial resolution data sets were obtained at 5 MHz in M-mode RF-data format (Toshiba Powervision 6000). Customized software was used to extract strain rate and strain (S). Simultaneous LV pressures were recorded (Millar-catheter). Aortic valve closure (AVC) was defined to be 20 msec before peak negative dp/dt. End-systolic S, max S after AVC and their timings were measured. PST-Index (PSTI) was calculated from these measurements as the relation between max S and end-systolic S. Infarction was confirmed by TTC-staining.
Results: End-systolic S decreased significantly during CAO ($p<0.001$ vs baseline). Increased PSTI was found in all ischemic segments at all stages of CAO ($p<0.05$ vs baseline). The PSTI peaked at 5 min CAO then tended to decline. There was no increase in time to max S nor a change in the duration of systole. Moreover, EF based on Teichholz, remained constant after an initial small drop at 1 min CAO and thus did not bias regional S estimates.

	S End-Systole (%)	S max after AVC (%)	PST-Index (%)	EF (%)
Baseline	39 ± 12	39 ± 12	2 ± 4	59 ± 16
Occ. 1min	19 ± 10	31 ± 13	89 ± 41 *	42 ± 11 *
Occ. 5min	12 ± 5 *	21 ± 4 *	111 ± 93 *	39 ± 14
Occ. 30 min	12 ± 6 *	21 ± 4 *	79 ± 44 *	39 ± 8 *
Occ. 60 min	10 ± 7 *	19 ± 4 *	50 ± 41	42 ± 9
Occ. 90min	10 ± 7 *	19 ± 10 *	95 ± 15 *	40 ± 17

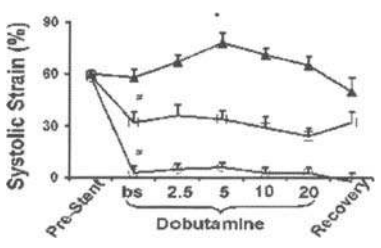
*$p<0.05$ vs baseline

Conclusion: An increase in PSTI occurs instantly in ischemic segments following CAO. PSTI then decreases with duration of ischemia. Time to max S is not affected by ischemia duration. To use PST as a marker of viability it is essential to integrate PSTI data with that of changes in end-systolic S.

2743 The non-invasive differentiation of chronic nontransmural versus transmural myocardial infarction by ultrasonic strain rate imaging

F. Weidemann[1], C. Dommke[2], B. Bijnens[2], P. Claus[2], P. Mertens[2], E. Verbeken[2], I. De Scheerder[2], G. Sutherland[2]. [1]*University Hospital Wuerzburg, Cardiology, Wuerzburg, Germany;* [2]*University Hospital Gasthuisberg, Cardiology Dept., Leuven, Belgium*

Background: In a correlative functional/histopathological study we sought to investigate whether the measurement of induced changes in regional ultrasonic strain profiles could reliably differentiate chronic nontransmural from transmural myocardial infarction.
Methods and Results: After implantation of a stenosing copper-coated stent to produce marked endothelial proliferation in the circumflex artery, a series of pigs were followed over a 5-week period. Post-sacrifice histology studies showed 10 to have developed a nontransmural and 8 a transmural myocardial infarction. Eight additional animals, without stent implantation, were enrolled to serve as a control group. Changes in regional radial function were monitored by measuring systolic strain pre-stent implantation and at 5 weeks, at baseline (bs) and during an incremental dobutamine infusion. In the control group, the dobutamine infusion induced an initial increase of strain at low dose dobutamine (bs=58±5%, at 5 μg/kg/min=78±6%; $p<0.05$) but a subsequent decrease during higher infusion rates with a return at peak infusion to bs values. In the nontransmural infarct group, baseline strain were significantly lower compared to pre-stent values (32±6%, $p<0.05$). During the dobutamine infusion, strain showed no change but postsystolic thickening increased significantly. The transmural myocardial infarction group showed almost no measurable strain in the posterior wall at dobutamine bs (3±4%; $p<0.0001$ vs pre-stent) and there was no further change during the incremental dobutamine infusion (at 20 μg/kg/min:3±3%; p=NS vs bs).
Conclusions: In the experimental setting, the regional ultrasonic strain response to a dobutamine infusion can clearly differentiate chronic nontransmural from transmural myocardial infarction.



Non-transmural vs transmural infarction.

2744 Can the ultrasonic comets announce the presence of extravascular lung water?

Z. Jambrik, R. Siracusa, S. Monti, E. Agricola, F. Serafini, B. Tarabella, M. Miniati, E. Picano. *Institute of Clinical Physiology, PISA, Italy*

Background: The "comet-tail" is an ultrasound sign detectable with cardiac ultrasound instrument on the chest, and consisting of multiple comet-tails fanning out from the lung surface. It originates from water-thickened interlobular septa. Portable echocardiographic systems would be ideal for non-radiological bedside assessment of extravascular lung water.
Aim: to assess the feasibility and value of ultrasonic comet sign.
Methods: We studied 38 consecutive in-hospital patients (11 females, age 61±14 years) admitted in cardiological intensive care unit, with a portable cardiac echo system (Optigo, Agilent Technologies, 2.5 MHz transducer). In each patient, we scanned by echo the chest (right and left hemithorax, from second to fourth intercostal space,from parasternal to midaxillary line) and the presence of comet-sign was noted by observers blinded to clinical diagnosis. An individual patient comet echo score was obtained by summing the number of comets (from 0 to 4) in each of the scanning spaces. On the same day, the patients underwent a chest X ray, with specific assessment of extravascular lung water by two pneumologist-radiologists blinded to clinical and echo findings. Radiological lung water score ranged from 0 (no interstitial water) to 50 (marked increase in water); this previously validated score incorporated assessment of hilar vessels (dimension, density, blurring), Kerley lines (A, B and C), micronoduli, widening of interlobar fissures, peribronchial and perivascular cuffs, subpleural effusion, and diffuse increase in density.
Results: The chest ultrasound scan was obtained in all patients (feasibility= 100%). The imaging time per examination was always <3 minutes. The Comet sign was found in 8/28 patients without and 10/10 patients with radiological signs of extravascular lung water (interstitial in 5, alveolar in 5). The Comet echo score was higher in the 5 patients with alveolar when compared to the 5 with only interstitial lung water (39±20 vs 17±8, $p< 0.06$). There was a linear correlation between echo comet score and radiological lung water score ($r=0.69$, $p<0.001$).
Conclusion: The Comet-tail is a simple, non time-consuming and reasonably accurate chest ultrasound sign of extravascular lung water which can be obtained at bedside with portable echo equipment and is not restricted by cardiac acoustic window limitations.

COMPUTER DEMONSTRATION

2746 G8 cardio-ANMCO: a common, national computerized program for echocardiogram archiving and reporting

L. P. Badano[1], A. Pizzuti[2], A. Mantero[2], D. Cianflone[2], M. Tubaro[2], E. Neri[2], S. Carerj[2], G. Gullace[2]. [1]*A.O.S Maria della Misericordia, Cardiovascular Science Dpt., Udine, Italy;* [2]*G8-Cardio Echo Task Force, Florence, Italy*

Availability of a common computerized program for echo archiving and reporting at national and/or international level could make possible to standardize the echo report between different echo-labs, and to use the wealth of data obtainable with echocardiography, and to exploit its capillary territorial distribution to collect echo data in a standard format for epidemiologic, scientific and administrative purposes. Therefore, an ad hoc joint Italian Society of Cardiology, and Italian Society of Echocardiography task force worked in conjunction with Italian branch of Agilent Technology to standardize the phraseology of accepted echo terms and of the quantitative parameters derived from transthoracic and transesophageal echo examination at rest as well as during exercise and pharmacological stress, and to develop an ad hoc software. This echo archiving and reporting program is part of the whole G8-CARDIO-ANMCO software project addressed to standardize and computerize the whole cardiological chart. The software was developed by Agilent Technology to provide a fast, easy-access, easy to use report generator for the non-computer specialist using Oracle 7.0 database and Power Builder 5.0 to develop a user-friendly interface. Between July and September 2001, the program was tested by 22 echo-labs throughout Italy selected for not being involved in the software analysis and development. Test was carried out using predefined standardized forms and qualitative evaluation of 4 software characteristics. The number of reports databased was 2464 for resting echo (reporting time= 8±3 min), and 273 for stress echo (reporting time= 10±5 min). Resting echo software characteristics analysis results were: thoroughness (complete 40%, rather complete 60%, incomplete 0%, inadequate 0%), user-friendliness (very easy 13%, easy 67%, difficult 20%, unusable 0%), graphic-look (very nice 7%, nice 80%, misleading 13%, difficult 0%), final report (adequate 67%, too long 7%, difficult-to-read 13%, inadequate 13%). Stress echo software characteristics analysis results were: thoroughness (complete 45%, rather complete 36%, incomplete 18%, inadequate 0%), user-friendliness (very easy 18%, easy 73%, difficult 9%, unusable 0%), graphic-look (very nice 18%, nice 73%, misleading 9%, difficult 0%), final report (adequate 73%, too long 18%, difficult-to-read 0%, inadequate 9%).

To our knowledge this software represents the first experience of a common computerized programme for echo archiving and reporting carried out at national level.

2747 EchoAnalyzer: software for the analysis of three- and four- dimensional echocardiographic data

I. Wolf[1], S. Mottl-Link[2], M. Hastenteufel[1], R. De Simone[2], H.P. Meinzer[1]. [1]*DKFZ, MBI/H0100, Heidelberg, Germany;* [2]*University Heidelberg, Cardiac Surgery, Heidelberg, Germany*

Purpose: For improved visualization of 3- and 4-dimensional (3D/4D) echocardiographic data sets a major issue is the capability of performing interactive measurements. Some of the techniques already described are not yet available for clinical routine due to the lack of appropriate, integrated software. Our purpose was to develop a new system that can provide visualization and quantification of 3D/4D echocardiographic data sets.

Methods: We have developed an echocardiographic analysis system - called EchoAnalyzer - integrating many up-to-date visualization and quantification methods. The EchoAnalyzer analysis software is developed in C++ using the GUI library Qt (Trolltech, Oslo, Norway) and runs on all 32-bit Windows systems and on all major Unix derivatives including Linux. The performance of an up-to-date low-cost PC is sufficient for all visualization and quantification methods described in the following.

Results: The EchoAnalyzer system provides color-coded, interactive 3D/4D volume visualization, measurements of cavity volumes, ejection fraction and cardiac output, regurgitation quantification and display of flow profiles.

The visualized volume can be interactively rotated and clipping planes can be used to mask the parts of the volume that obstruct the view on the structures of interest.

The difficult task of the segmentation for the determination of the ejection fraction was solved by the integration of a nearly automatic segmentation algorithm. This reduces the user time and enables the user to correct segmentation results if necessary.

Cardiac output measurements can be performed with EchoAnalyzer either by segmentation of the left ventricle or by spherical surface integration of velocity vectors (SIVV).

To quantify regurgitation, a method was implemented which yields reliable volumetric measurements also for asymmetrical, wall-impinging regurgitation jets. Velocity landscapes have been developed for visualization and quantification of blood flow. After definition of the primary direction of flow by the user an angle correction of the velocity component is performed and the result is displayed as a 3D profile plot, which can be rotated interactively.

Conclusion: The presented EchoAnalyzer software enables visualization and quantification of three-/four-dimensional echocardiographic data sets. It integrates several recently developed methods into a user-friendly environment, making them available for routine clinical medicine.

MODERATED POSTER SESSION V

P2748 Tissue Doppler echocardiography: the new method of right ventricle preload assessment in patients with atrial septal defect

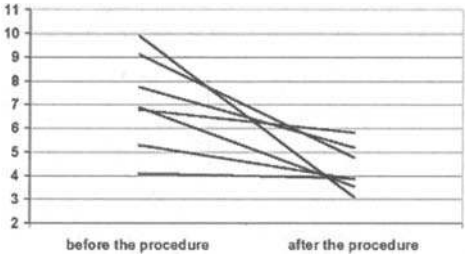
W. Plazak, E. Suchon, L. Tomkiewicz, P. Podolec, T. Przewlocki, W. Tracz. *John Paul II Hospital, Cardiac and Vascular Department, Krakow, Poland*

Introduction: Recently the new method of left ventricle preload assessment based on tissue doppler echocardiography was described. The maximal early diastolic mitral inflow velocity (E) depends on diastolic compliance of left ventricle and left ventricle preload. The maximal early diastolic velocity of mitral annulus assessed by tissue doppler (Ea) depends only on diastolic compliance of left ventricle. Thus, E/Ea ratio represents left ventricle preload. To assess right ventricle preload by E/Ea ratio, E should represent maximal early diastolic tricuspid inflow velocity and Ea should represent maximal early diastolic velocity of tricuspid annulus.

Aim of the study: To assess right ventricle preload in patients with atrial septal defect (ASD) by E/Ea ratio before and after closure of the defect.

Material and methods: In 7 patients (5 females, 2 males) aged 19-60 years (mean age 42.6) ASD was diagnosed by transesophageal echocardiography. The diameters of the defects were 9-14mm (mean diameter 12.4mm). In all the patients maximal early diastolic tricuspid inflow velocity (E) and maximal eary diastolic velocity of tricuspid annulus (Ea) were calculated. The measurements were done before and after the percutaneous closure of the defects by Amplatzer devices.

Results: Significant decrease of E/Ea ratio after the procedure was observed. The E/Ea ratio decreased from 6.65±2.25 to 4.27±0.93 ($p<0.01$).



Conclusion: Significant decrease of E/Ea ratio was observed after the closure of ASD. E/Ea ratio seems to be useful noninvasive method for right ventricle preload assessment.

P2749 The C825T-polymorphism of GNB3 gene is associated with reduced expression of IK,ACh mRNA in patients with coronary artery disease

D. Dobrev, E.M. Graf, U. Ravens. *University of Technology Dresden, Institute of Pharmacology, Dresden, Germany*

Stimulation of muscarinic receptors activates the G-protein-regulated inward rectifying potassium current (IK,ACh), the major effector of cholinergic stimulation in atrial myocytes. We recently showed that homozygous 825T-allele carriers of the GNB3 gene exhibit larger density of the background inward rectifier current IK1 but reduced activation of IK,ACh. Here we studied whether the observed current changes are due to alterations mRNA levels of the main IK1 transcript Kir2.1 and those of the IK,ACh transcripts GIRK1 (Kir3.1) and GIRK4 (Kir3.4). Differences in mRNA levels of respective channel subunits were evaluated by competitive RT-PCR in right atrial biopsies from patients with coronary artery disease but without rhythm disturbances. To quantify the target mRNA concentrations, internal RNA competitors (mimics) containing the respective specific primers flanking a part of the coding sequence for cardiac alpha-actin were used to quantify the mRNA levels of respective channel subunit. The GNB3 genotype of the patients was determined in peripheral blood by PCR and restriction analysis. The mRNA concentrations of the IK1 transcript Kir2.1 was not different between the three genotype groups (23.6±3.7 fmol/μg RNA, n=8, TT-genotype vs. 19.2±2.4 fmol/μg RNA, n=5, CC-genotype and 21.1±2.2 fmol/μg RNA, n=7, CT-genotype, respectively (mean±SEM; n.s.). On the other hand, the mRNA concentration of GIRK4 was significantly smaller in homozygous 825T-allele carriers when compared to the two other genotype groups: 5.4±0.6 fmol/μg RNA, n=12, TT-genotype vs. 11.9±0.9 fmol/μg RNA, n=15, CC-genotype and 12.2±0.4 fmol/μg RNA, n=9, CT-genotype, respectively ($P<0.05$). Similar significant differences were detected for the mRNA levels of GIRK1. Our data point to a genetically fixed transcriptional down-regulation of IK,ACh in homozygous 825T-allele carriers. The reduced channel expression may be interpreted as an adaptation mechanism to the enhanced G-protein-mediated signal transduction in these subjects.

P2750 Role of endothelin in metabolic regulation of coronary blood flow

D. Merkus, P.D. Verdouw, D.J. Duncker. *Erasmus University Rotterdam, Thoraxcenter, Rotterdam, Netherlands*

Coronary metabolic dilation is likely mediated by the production of a myriad of vasodilators. However, withdrawal of vasoconstrictors may also play a role in this process, because the titration of production of constrictors and dilators may confer finer and quicker regulation of myocardial perfusion. Because endothelin-1 (ET) is a potent vasoconstrictor and is produced in the heart, we hypothesized that ET-induced constriction decreases during augmented metabolic demands. To test this hypothesis instrumented swine (n=7) were studied while running on a treadmill (0-5 km/h) before and after ETA antagonism (ETA) and non-specific ET receptor antagonism (ETAB). ETA and ETAB decreased myocardial oxygen extraction at rest and to a lesser extent during exercise, thereby shifting the relation between myocardial oxygen supply and demand upward. The effect of ETA was significantly larger than that of ETAB. In conclusion, ET has a tonic constrictor influence through the ETA receptor at rest, but its constrictor influence is decreased during increased myocardial metabolism. Stimulation of the ETB receptor exerts a tonic vasodilator influence that partially counteracts the effect of ET on the ETA receptor.

P2751 Correlation of pacing "stress" NOGA mapping with SPECT for diagnosis of myocardial ischaemia

E.C. Perin[1], H.F. Dohmann[2], G. silva[1], R.S. Leite[1], C.T. Mesquita[2], W.K. Vaughn[1], N. Mattos[2], H.J. Dohmann[2]. *[1]texas heart institute, cardiology, houston, United States of America; [2]Hospital Pro-Cardiaco, Cardiology, Rio de Janeiro, Brazil*

Background: Biosense NOGA Electromechanical mapping (EMM) has been shown to identify viable myocardium but not to reliably distinguish between normal and ischemic regions of the Left Ventricle. Since Linear Local Shortening (LLS) is a validated measurement of myocardial mechanical function we postulated that the findings of LLS obtained during active stress would reflect a worsening in mechanical function that could identify areas of ischemic myocardium. In the present study EMM was performed at rest and with atrial pacing (stress) and subsequently compared to rest/stress SPECT.

Methods: EMM at rest and during atrial pacing at 85% of MPHR was performed in 16 patients (pts) (256 segments) and matched to SPECT imaging (99Tc-sestamibi).Both methods were displayed in a 16-segment bull's eye. A T-test was used to compare means and SD of rest and paced LLS values within each perfusion group and a comparative analysis between the four perfusion groups regarding LLS values was performed by ANOVA in both rest and paced states. A $P< 0.05$ was considered significant.

Results: The table shows values for LLS at rest and with atrial pacing according to the results of the perfusion studies. The differences between normal and reversible segments and normal and non-reversible segments with little residual activity (scar) were significant ($p<0.05$).

SPECT(No. Segments)	Rest LLS%	Paced LLS %
Normal (n=151)	15.0±8.7(a)	11.3±8.7(e)
Reversible(n=49)	12.3±6.5(b)	7.3±5.9(f)
Non-reversible viable(n=26)	11.9±5.2(c)	8.6±5.0(g)
Non-reversible scar (n=30)	10.9±6.9(d)	5.4±6.5(h)

$p<0.05$- T-test: a vs. e, b vs f, c vs g, d vs h. ANOVA: e vs. f, e vs.h

Discussion: This study describes the first pacing stress model for EMM. A uniform response to atrial pacing characterized by a drop in LLS is noted but is significantly greater in ischemic myocardium compared to normal myocardium. Areas of non-reversible scar type perfusion defects demonstrate even greater deterioration in LLS. Thus, this is the first evidence that Pacing "Stress" EMM allows for the characterization of ischemic myocardial segments. Further studies with larger sample sizes need to be performed to confirm the present findings.

P2752 Pacing "stress" electromechanical mapping: detecting myocardial viability in SPECT non-reversible perfusion defects

E.C. Perin[1], H.F. Dohmann[2], G. silva[1], R.S. Leite[1], C.T. Mesquita[2], A.L.S. Souza[1], A.L. Feijo[2], H.J. Dohmann[2]. *[1]texas heart institute, cardiology, houston, United States of America; [2]hospital pro-cardiaco, cardiology, Rio de Janeiro, Brazil*

Background: Upcoming studies using stem cells incorporate electromechanical mapping (EMM) to guide local myocardial treatment. Therefore, EMM has to accurately identify viable myocardium.Prior studies have shown good correlation between EMM and SPECT perfusion imaging in identifying reversible vs. non-reversible defects according to Unipolar Voltage (UniV) values. Non-reversible defects however may retain significant residual tracer activity after resting injection (viable) as opposed to very little residual activity (scar). Given the above, we postulated that "stress" EMM technique could be useful to identify areas of viability with more precision than could previously be achieved with resting maps.

Methods: EMM at rest and during atrial pacing at 85% of MPHR was performed in 16 patients (pts) (256 segments) and matched to SPECT imaging (99Tc-sestamibi).Both methods were displayed in a 16-segment bull's eye. A T-test was used to compare means and SD of rest and paced UniV values within each perfusion group and a comparative analysis between the four perfusion groups regarding UniV values was performed by ANOVA in both rest and paced states. A $P< 0.05$ was considered significant.

Results: The table shows values for UniV at rest and with atrial pacing according to the results of the perfusion studies.

SPECT(No.Segments)	Rest UniV (mV)	Paced UniV (mV)
Normal(n=151)	17.9±5.1(a)	24.8±7.6(e)
Reversible(n=49)	16.3±4.5(b)	23.3±8.0(f)
Non-reversible Viable(n=26)	13.0±5.0(c)	22.1±9.0(g)
Non-reversible Scar(n=30)	10.5±3.0(d)	14.4±5.4(h)

$P<0.05$- T-test: a vs. e, b vs f, c vs. g, d vs h.ANOVA: a vs. c, a vs. d, b vs. d, h vs. e, h vs. f, h vs. g.

Discussion: Pacing "stress" EMM describes a generalized increase in UniV associated with atrial pacing. However, voltage values during stress cannot be utilized to diagnose myocardial ischemia. Moreover, "stress" electromechanical map is able to further identify viable myocardium in areas where a non-reversible perfusion defect is present by SPECT imaging, which cannot be accomplished by resting maps. "Stress" EMM may play a role in the precise guidance of direct myocardial injection therapies though future studies with larger sample sizes need to be performed to confirm the present results.

P2753 Does microbubble destruction influence the assessment of contrast replenishment kinetics using power pulse inversion imaging?

C. Veltmann[1], S. Lohmaier[1], T. Schlosser[1], A. Ehlgen[1], J. Schrickel[1], J.O. Schwab[1], H. Becher[2], K. Tiemann[1]. [1]*University of Bonn, Cardiology, Bonn, Germany;* [2]*University of Oxford, Cardiology, Oxford, United Kingdom*

In contrast echocardiography microbubble replenishment kinetics (RKs) allow the assessment of blood volume (parameter A) and mean microbubble velocity (parameter β) using the exponential function f(t)=A*(1-exp(-β*t)). The new imaging technique Power Pulse Inversion (PPI) allows real-time imaging of echocontrast agents, however, bubble destruction might occur even at lowest emission power. We therefore assessed the impact of the emission power on bubble destruction and on the fitting parameters using a hard- and a soft shell echo-contrast agent. Methods: In a capillary flow phantom mimicking microcirculation, blood flow was varied from 10-45 ml/min which corresponded to flow velocities between 2 and 9 mm/s. During constant infusion of Definity (BMS Medical Imaging) and AF0150 (Alliance Pharmaceutical Corp.), real-time PPI imaging (20Hz) was performed at variable emission power (MI = 0.09-0.39) using an HDI 5000 (ATL). For both agents, bubble destruction was calculated at all emission power levels. RKs following ultrasound-induced destruction of microbubbles were assessed at the same emission powers. The parameters A and β were calculated using the fitting function described above. Results: 1) No significant bubble destruction was observed using Definity at MIs < 0.13 and AF0150 at MIs < 0.11. At higher emission powers, the PPI signal intensity dropped significantly indicating the presence of bubble destruction ($p < 0.001$). Higher degrees of bubble destruction were observed at lower flow velocities. 2) Using Definity at MIs < 0.13 and AF0150 at MIs < 0.11 no significant differences were found for the slopes of the β/flow and A*β/flow regression curves. However, higher emission power levels caused a significant decrease of absolute β values and of the slopes of the β/flow and A*β/flow regression curves ($p < 0.001$). Conclusion: At low emission powers, PPI allows non-destructive real-time imaging of Definity and AF0150 microbubbles. Bubble destruction at higher emission power levels could cause 1) a decrease of PPI intensity resulting in an underestimation of regional blood volume and 2) changes in the β/flow relationship resulting in underestimation of regional flow velocity. Thus, to adequately assess absolute or relative changes in regional blood volume and mean microbubble velocity, non-destructive real-time imaging might be a prerequisite.

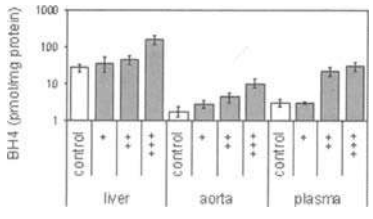
P2754 Systemic adenovirus-mediated gene transfer of human GTP cyclohydrolase-1 increases liver, plasma and aortic tetrahydrobiopterin levels in mice

N. Alp[1], S. Cai[1], I. Smith[2], K. Channon[1]. [1]*Dept of Cardiovascular Medicine, Oxford, United Kingdom;* [2]*John Radcliffe Hospital, Department of Biochemistry, Oxford, United Kingdom*

Background Reduced NO bioavailability due to endothelial nitric oxide synthase (eNOS) dysfunction is a feature of vascular disease. Tetrahydrobiopterin (BH4) is a required co-factor for NO production by eNOS, but the relationship between plasma and intracellular endothelial BH4 levels in the regulation of eNOS function remains unclear. To investigate the utility of gene transfer to increase BH4 levels in vivo, we aimed to augment plasma and vascular BH4 levels in mice by systemic gene transfer of human GTP cyclohydrolase-1 (GTPCH), the rate-limiting enzyme in BH4 biosynthesis.

Methods We constructed a recombinant adenovirus (Ad.GTPCH) encoding human GTPCH cDNA linked to the HA epitope. 5×10^8 (+) 5×10^9 (++) or 5×10^{10} (+++) virus particles of Ad.GTPCH or Ad.GFP (control) were injected into tail veins of 24 week old C57Bl6 mice (n=3 per group). Organs were harvested for analysis after 5 days. Expression of recombinant GTPCH protein was assessed by immunohistochemistry and Western blotting. BH4 levels were measured using differential iodine oxidation and HPLC.

Results We observed high level recombinant GTPCH expression in liver 5 days after gene transfer. GTPCH gene transfer markedly increased BH4 levels in liver, plasma and aorta compared to controls, in a dose-dependent fashion (Figure).



Conclusion Systemic adenovirus-mediated gene transfer of GTPCH in mice is a promising in vivo model to investigate modulation of eNOS dysfunction by systemically increased BH4 in vascular disease.

P2755 Assessment of circumferential-radial shear strains in normal and ischaemic myocardium based on ultrasonic strain/strain rate imaging

J. Separovic Hanzevacki, P. Claus, L. Herbots, J. D'Hooge, F. Rademakers, M.C. Herregods, B. Bijnens, G.R. Sutherland. *University Hospital Gasthuisberg, Cardiology Department, Leuven, Belgium*

Background: Until now ultrasonic strain(S) and strain rate(SR) estimates have measured one-dimensional strain (either radial or longitudinal) to quantify regional myocardial deformation. However, to quantify three-dimensional deformation one needs to resolve the complete strain tensor, including shear strains, as the latter describe torsion and local twisting/untwisting. Shear deformation develops gradually during systole but is a dominant and very fast event in the opposite direction during isovolumic relaxation (IVR). In magnetic resonance tagging (MR) studies circumferential-radial shear strain has already been shown to be of clinical relevance in patients with aortic stenosis.

Study Aims: To determine if circumferential-radial shear strain (CRSS) could be measured during the isovolumic relaxation period by a modification of the ultrasonic SR/S technique.

Methods: High frame rate (>200 f.p.s)/Color Doppler Myocardial velocity data sets (parasternal short axis view at a midpapillary muscle level) were acquired in 11 young normals and in 6 patients with regional ischemic septal hypokinesia. CRSS rates (CRS SR) were extracted off-line using custom-made software and were estimated as the lateral gradient of the axial velocity. CRSS was obtained as a temporal integral of the CRS SR. The CRSS describes the epi- to endocardial torsion. For statistical analysis the non-parametric Mann-Whitney test was used.

Results: From 34 acquired segments, 3 (8%) were rejected from analysis due to low signal-to-noise ratio. In normals during IVR the maximal CRS SR value for the septum was 0.553±0.20 1/s and for lateral wall was -0.723±0.45 1/s. CRSS in IVR was -2.79±1.0% in the lateral wall and 2.98±1.7% in the septum. These values corelate well with the normal CRSS values previously obtained by MR. In patients all measured values were significantly lower both in septum (maximal CRSSR: 0.148±0.11/s**; CRSS: 0.7±0.1%*) and in the lateral wall (maximal CRSSR: -0.307±0.28 1/s**; CRSS: 1.15±1.02*) compare to normals, *p<0.02,**p<0.01.

Conclusions: In conclusion, CRSS can be calculated from a high temporal resolution CDMI velocity data set. Initial clinical findings have shown this technique can identify and quantify normal segmental values and can quantify abnormal regional CRSS related to segmental disease.

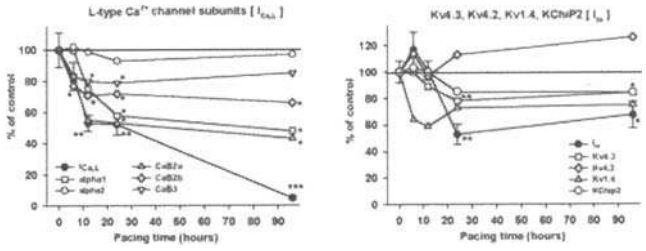
P2756 Molecular mechanisms of short-term electrical remodelling in a rabbit model of rapid atrial pacing

R.F. Bosch[1], C. Scherer[2], S. Woehrl[1], N. Rueb[1], R. Laszlo[1], L. Seipel[1], K. Steinmeyer[2], V. Kuehlkamp[1]. [1]*University of Tuebingen, Department of Cardiology, Tuebingen, Germany;* [2]*Aventis Pharma Germany GmbH, DG Cardiovascular, Frankfurt, Germany*

Studies in experimental models have demonstrated that electrical remodeling in chronic rapid atrial pacing reduces L-type Ca^{2+} currents (ICa,L) and transient outward K^+ currents (Ito) by transcriptional downregulation of the underlying ionic channels. Similar observations were made in patients with chronic atrial fibrillation. However, electrical remodeling starts early after the onset of rapid atrial rates. We have previously shown that ICa,L and Ito are decreased within the first hours after the onset of rapid atrial rates. In this study, we present the molecular mechanisms underlying early current changes.

Methods: Rapid (600ppm) right atrial pacing was performed via a transvenously implanted right atrial lead in female New Zealand rabbits. The animals were divided into 5 groups (sham(P0), 6h(P6), 12h(P12), 24h(P24), and 96h(P96) pacing, n=5 for each. mRNA measurements of L-type Ca^{2+} channel alpha1,alpha2delta, CaB2a,CaB2b, CaB2c and of Kv4.3, Kv4.2, Kv1.4 and KChiP2 mRNA were done by one step RT-PCR in right atrial specimen.

Results: The reduction in ICa,L was paralleled by a downregulation of mRNA expression of the alpha1 subunit of the L-type Ca^{2+} channel and of the auxillary subunits CaB2a, CaB2b and CaB3, respectively. alpha2delta mRNA expression was unchanged. Ito changes were also paralleled by a decrease in Kv4.3 mRNA expression. KChiP2 expression was only mildly reduced at 24 and 96h. Kv4.2 and Kv1.4 mRNAs were not affected by rapid atrial pacing.



Rapid ion channel remodeling.

Conclusions: The early changes of ICa,L and of Ito are paralleled by a reduced mRNA expression of the underlying channel alpha and beta-subunits. The mechanism of reduced currents appears to be a transcriptional downregulation of underlying ion channels even in early stages of electrical remodeling.

PULMONARY VEIN ABLATION IN ATRIAL FIBRILLATION

P2757 Collateral damage from circumferential laser energy ablation of pulmonary veins

W.W. Su, S.B. Johnson, D.L. Packer on behalf of Mayo Clinic. *Rochester, United States of America*

Background: Laser energy applied circumferentially at the pulmonary vein ostium is an effective technique for isolation of pulmonary vein from the left atrium. However, the collateral damage profile is unclear.

Method: To determine the collateral damages associated with circumferential laser energy application at the pulmonary vein ostium, 24 pulmonary veins were ablated in 9 dogs. Laser energy was delivered at 3.5 watt/cm to 5.4 watt/cm (average= 4.3) for 120 to 600 seconds (average= 225 seconds). Pulmonary vein and neighboring tissue were examined for acute lung burns, collateral vascular burns, and other tissue injury.

Results: Lung burns were noted in 4 (17%) of 24 pulmonary vein ablation: 8 energy deliveries at left superior pulmonary vein resulted in no left upper lobe lung burn. 6 energy deliveries at left inferior pulmonary vein resulted in 1 left lower lobe hilar lung burn. 9 deliveries at right superior pulmonary vein resulted in 3 right upper lobe hilar lung burns, and 1 delivery at right inferior pulmonary vein resulted in 1 right lower lobe hilar lung burn. No evidence of pulmonary artery, aorta, pericardial, or superior vena cava injury was seen.

Conclusion: Minimal collateral damages were observed with laser energy application at the pulmonary vein ostium. This may support the safety profile for the use of circumferential laser energy ablation in pulmonary vein ablation.

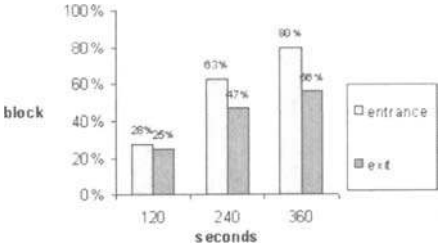
P2758 First experience with circumferential pulmonary vein ablation using a laser energy balloon catheter

W.W. Su, S.B. Johnson, D.L. Packer on behalf of Mayo Clinic. *Rochester, United States of America*

Background: Electrical isolation of pulmonary veins (PV) is crucial to treating atrial fibrillation. Creating bi-directional block of the PV with circumferential lesions at the ostium has been difficult to achieve with radiofrequency energy. Laser energy ablation has been shown to be effective in creating atrial lesions, but the duration of energy application with laser ablation is not clear.

Methods: To determine the time-dependence of laser balloon catheter ablation in creating conduction block at the PV ostium, 32 PVs were ablated in 20 dogs under intracardiac ultrasound and fluoroscopy guidance. 3.1 to 5.4 watts/cm of laser energy were delivered for 120-600 seconds. Efficacy was established acutely as the presence of entrance and exit block in the PV during mapping with a multi-polar catheter positioned across the PV sleeve.

Results: Average laser energy of 4.0 watts/cm at 3.8 ± 2.0 minutes (range from 2 to 10 minutes) was delivered. Entrance block was achieved in 28% (n=9) of lesions after the first energy delivery, in 63% (n=20) after 240 seconds, and 80% (n=26) after 360 seconds. Exit block was achieved in 25% (n=8) of PVs after one energy delivery of 120 seconds, 47% (n=15) after two, and 56% (n=18) after three.



Block time table.

Conclusions: Laser energy is an effective energy source to produce conduction block in PVs. However, energy deliveries of two to three minutes may be required.

P2759 Complications and pulmonary vein anglograms after pulmonary vein ablation

C. Mewis, B. Eigenberger, R.F. Bosch, K. Kettering, L. Seipel, V. Kühlkamp. *Medizinische Klinik III, Cardiology Dept., Tübingen, Germany*

Pulmonary vein ablation is a new method to treat atrial fibrillation. Therefore its complications in the acute setting are not fully known. We analysed all complications which occurred during the initial hospital stay and one week later after pulmonary vein ablation. In addition we analysed all pulmonary vein angiograms, which were performed before and after ablation of each pulmonary vein. In 76 patients 84 PV-ablations were performed (age 58±8 years). In 174 PVs it was performed either a focal ablation (n=32) or a complete PV-isolation using a circumferential mapping catheter (n=132). Results: In patients with focal PV-ablations we found 7 severe PV-stenosis, and 14 non-severe (<50%) PV-stensosis. In the patient group with PV-isolations one total PV-occlusion occurred, which was dilated successfully during the same procedure. 62% of all ablated PVs showed non-severe stenosis (20-30%). The occurrence of PV-stenosis was dependent on the number of radiofrequency applications (p=0.002) and independent of the PV-localization (p=0.3). 6 patients complained during the following days of severe chest pain lasting from 2 hours to 3 days. None of these patients showed PV-stenosis in the angiograms. One patients suffered from severe singultus, which was refractory to any therapy for weeks. None patient reported about PV-stenosis related symptoms. Conclusion: PV-ablation is correlated with significant morphological changes of the pulmonary vein. Focal ablations within the vein are high risk ablations for severe PV-stenosis. In the majority of the patients PV-isolations led to non-severe PV-stenosis. Hence ostial PV-isolation without ablating within the vein is not feasible in 62% of the patients. Long term effects of such complications might occur in these patients. Therefore a meticulous follow-up is warranted in all patients with PV-ablations in order to detect late PV-stenosis.

P2760 Reasons for relapse of atrial fibrillation after successful pulmonary vein isolation

S. Ernst, F. Ouyang, M. Goya, K. Menke, M. Hoffmann-Riem, T. Vogtmann, M. Antz, K.H. Kuck. *AK St. Georg, II. Med. Abteilung, Hamburg, Germany*

Trigger elimination by pulmonary vein (PV) isolation has been proposed to cure drug-refractory atrial fibrillation (AF) with varying success. Reasons for arrhythmia recurrence might include re-conduction or new atrial triggers.

Methods: A total of 158 pts (36 f, mean age 56 ± 10 years) underwent pulmonary vein isolation (125 pts with intermittent AF) for the treatment of atrial fibrillation (mean duration 7.8 ± 6.5 years) after drug-refractoriness to a median of 3 antiarrhythmic medications. After double transseptal puncture, PV isolation was performed in each PV that exhibited a typical spike potential by focal interruption of the conducting myocardial fibres using radiofrequency application (max. 30 W, 50° C over max 180 sec). Loss of the PV spike was demonstrated as endpoint of catheter ablation in each pt at the procedure end.

Results: A mean number of 22.6 ± 10.9 RF applications were used to achieve PV isolation (right upper PV (RUPV) 7.4 ± 5.2, left upper PV (LUPV) 7.9 ± 5.5, left inferior PV (LIPV) 5.7 ± 3.8, right inferior PV(RIPV) 4.8 ± 3.9), which took in mean 306 ± 98 min (42 ± 17.8 min of fluoroscopy). In all pts the LUPV and the RUPV were targeted, in 85% the LIPV and in 42% the RIPV. During follow-up after the initial procedure, 54% (86/158 pts) had a recurrence of AF. A total of 34 of these pts underwent a second ablation procedure. In all pts, re-conduction of at least one previously isolated PV was demonstrated, either inside the PV or by persisting spike potentials at the PV ostium, that were then subsequently ablated (mean number of RF 17.7 ± 9.9, mean duration 303 ± 87,4 min, mean fluoroscopy 38.7 ± 15.9 min.). Subsequently, follow-up resulted in 65% (22/34) of these pts in stable SR.

Conclusion: In all our patients, who previously underwent a successful pulmonary vein isolation procedure, at least one spike potential inside or in close proximity to the pulmonary vein ostium could be demonstrated during the repeat procedure. This underlines the importance of permanent interruption of myocardial fibres and a truly ostial placement of lesions.

P2761 Does the number of disconnected pulmonary veins affect long-term outcome after catheter ablation of atrial fibrillation?

M. Casella[1], N. Trevisi[2], P. Della Bella[1], C. Tondo[1], M. Berti[1]. [1]*Centro Cardiologico, Laboratory of Electrophysiology, Milan, Italy;* [2]*Centro Cardiologico Monzino, Institute of Cardiology, Milan, Italy*

Backgrounds. The pulmonary veins (PVs) are frequent sources of ectopic beats triggering atrial fibrillation (AF) and therefore electrical disconnection is regarded as the procedure of choice for AF catheter ablation (RFCA). Whether the number of disconnected PVs affects long-term outcome is unknown.

Methods: 70 patients (pts)(57% males, mean age 49 ± 7 years) with idiopathic AF resistant to at least 2 antiarrhythmic drugs (AADs) (including amiodarone and class Ic drugs), were evaluated.56 pts (80%) had paroxysmal AF (pAF)(at least 1 episode/week), and 14 pts (20%) had persistent AF. In all pts PVdisconnection guided by PV angiogram and PV ostium mapping by means of circumferential catheter was performed during sinus rhythm or distal coronary sinus pacing.After procedure pAF pts were discharged without AADs if complete PV disconnection was achieved, or with flecainide if one or more PVs could not be disconnected; amiodarone was maintained in all pts with previuos persistent AF. The furhter follow-up consisted of monthly clinical evaluation and 24 hours Holter recording at 1,3,6 and 12 months (mts).

Results: Complete disconnection of all PVs was achieved in 44 (63%) pts and in a greater proportion of pAF pts (38, 67.9%) than persistent AF pts (6, 42.9%; p: 0.08). One ore more PVs could not be disconnected in 26 pts (37%). Actuarial arrhythmia free cumulative survival was significantly better in pts after disconnection pf all PVs than in those with incomplete disconnection of some PVs (3-, 6-, 12-mts cumulative arrhythmia free survival: 89%, 85%, 75% versus 40%, 35%, 35%; Logrank: $P<0.0001$). Arrhythmia pattern (paroxysmal versus persistent) did not affect long term outcome after complete PV disconnection.

Conclusions: Short and long term outcome is significanly better in pts with complete disconnection of all PVs. In view of this results, complete disconnection of all PVs should be regarded as the endpoint of AF RFCA. Failure to obtain this endpoint should call for a repeat procedure within the same hospitalization

P2762 Comparison of long-term outcome of focal ablation versus pulmonary veins disconnection

N. Trevisi[1], M. Casella[2], P. Della Bella[1], C. Tondo[2], S. Riva[2], G. De Martino[3], G. Fassini[2], F. Giraldi[2]. [1]*Centro Cardiologico Monzino, Institute of Cardiology, Milan, Italy;* [2]*Centro Cardiologico, Laboratory of Electrophysiology, Milan, Italy;* [3]*Policlinico A. Gemelli, Department of Cardiology, Rome, Italy*

Pulmonary veins (PVs) ostium electrical disconnection have been introduced as an alternative approach to ablation of atrial fibrillation (AF) trigger foci in PVs. Aim of this study was to compare the efficacy of these approaches in preventing AF recurrences.

Methods.110 patients (pts) (61% males, mean age 51±8 years)with lone AF refractory to antiarrhythmic drugs (AADs) were retrospectively evaluated. 93 pts (84.5%)had paroxysmal AF and 17 pts (15.5%) persistent AF.

40 pts (36.4%)underwent focal ablation. Frequent spontaneous ectopies were present during the procedure in 22/40 pts (55%); in the remaining 18 pts without spontaneous ectopies, ablation was perfomed by abolition of the electrogram of the "presumably guilty" PV. Multiple foci were localized in 22/40 pts (55%). Mean number of procedure/pt was 1.8±0.6 (range 1-4)and 36 pts (90%) required at least 2 procedure to prevent AF recurrences.

Electrical disconnection of all PVs was attempted in 70 pts. Complete disconnection of all PVs was achieved in 44 pts (63%), while 1 or more PV were not disconnected in 26 pts (37%). Actuarial arrhythmia free survival analysis revealed better outcome in pts in whom successful disconnection of all PV was achieved (cumulative 3-, 6-, 12 months arrhythmia free survival: 89%, 85%, 75%) than in those that underwent focal ablation either guided by spontaneous ectopies (cumulative 3-, 6-, 12 months arrhythmia free survival: 55%, 52%, 44%)or guided by PV potential abolition (cumulative 3-, 6-, 12 months arrhythmia free survival: 62%, 42%, 20%)(Logrank $p<0.0003$).There was no significant difference in AF recurrence rate among failed PV disconnection pts (cumulative 3-, 6-, 12 months arrhythmia free survival: 40%, 35%, 35%) and PV focal ablation patients.

Conclusions: Due to the frequent presence of multiple foci in more PVs and the inconsistance of spontaneous ectopies in many istances, long term results are significanly better after PV disconnection -provided that all PVs are successfully disconnected- than after focal ablation.

P2763 Electrical pulmonary vein disconnection with multipolar mapping technique: differences of left and right superior pulmonary vein

T. Korte, M. Niehaus, M. de Sousa, J. Tebbenjohanns. *Medical School Hannover, Cardiology Dpt., Hannover, Germany*

Background: Most of the triggers initiating focal AF are located in the left and right superior pulmonary vein (LSPV, RSPV). The extent of ostial ablation necessary to electrically disconnect the pulmonary-vein-left-atrial (PV-LA)- extension, which is limited by the variable anatomy and the risk of PV stenosis, has not been analyzed comparing LSPV and RSPV.

Methods: 20 Pt (age: 55±2 years, 9f) with focal AF, no structural heart disease and an LA < 40mm were included in the study. RF ablation (max. 50°C, 30 Watts) of the arrhythmogenic PVs was performed as proximal as possible, targeting the PV perimeter on the basis of bipoles from a circular mapping catheter (Lasso) showing the earliest activation during SR or pacing from the CS. The ablation catheter was positioned correspondingly on fluoroscopy. Endpoint was the elimination of all PV-LA-extensions.

Results: In the LSPV, PV-spikes were found in 20/20 patients with 1 PV-LA-extension in 12 Pt, 2 in 4 Pt and 3 in 4 Pt. Complete isolation was performed in 18/20 Pt (90%) with 9.6±4.1 RF applications and a cumulative RF duration of 7.2±3.2 min. In the RSPV, PV-spikes were found in 17/20 Pt with 1 PV-LA-extension in 16 Pt and 2 in 1 Pt. Complete isolation was performed in 17/17 Pt (100%) with 5.9±3.7 RF applications ($p<.05$ vs LSPV) and a cumulative RF duration of 5.2±3 min. In 1/20 Pt (5%) a 30% stenosis of both the LSPV and RSPV ostium was found after ablation.

Conclusions: RF ablation for electrical disconnection of the LSPV is more complex compared to the RSPV due to more PV-LA-extensions and needs a significantly higher number RF applications. In this study this did not result in an increase of acute stenosis of the LSPV.

P2764 Long-term follow-up in patients with refractory atrial fibrillation after pulmonary vein ablation using radiofrequency energy

T. Arentz[1], N. Jander[2], J. von Rosenthal[1], T. Blum[1], G. Bürkle[1], R. Fürmaier[3], D. Kalusche[1]. [1]*Herzzentrum, Abt. Interventionelle Kardiologie 2, Bad Krozingen, Germany;* [2]*Herzzentrum, Echokardiographie, Bad Krozingen, Germany;* [3]*Institut für diagnostische Radiologie, Freiburg, Germany*

Pulmonary vein (PV) ablation offers the potential for cure in selected patients (Pts) with paroxysmal atrial fibrillation (AF). However, results of long-term follow up are currently scarce.

Methods: Between 1996 and 1999, 55 patients (mean age 54 ± 10 years, 38 male) underwent radiofrequency energy catheter (max. 50°C, 30-35 W) ablation of PV foci, or ostial isolation of arrhythmogenic PVs. All Pts had refractory and highly symptomatic AF (paroxysmal n = 44, persistent n = 11). 47 Pts underwent a follow up exam with Holter, transesophageal echo-doppler and angio MRI.

Results: 12 of the 47 Pts underwent a focal PV trigger ablation (18 PVs), 37 Pts underwent ostial PV isolation procedure (70 PVs). Mean number of procedures per Pts was 1.6. Early recurrence of AF was noted in 48%. Acute complication: pericardial tamponade in 3, acute PV stenosis in 4. Mean follow up was 24 ± 10 months (range 12-55), 50% of Pts are in sinus rhythm without antiarrhythmic drugs, 31% of Pts are taking antiarrhythmic drugs and experience a clinically important improvement. 19% of Pts are without change in symptoms. 16 of 47 Pts studied in f/u (11 with ostial pulmonary vein isolation procedure) showed a significant pulmonary vein stenosis: 3 pts had a complete occlusion of one PV, 13 pts 18 PV stenosis, of which 3 progressed to complete occlusions. Procedure characteristics (distal or ostial ablation site, No of RF pulses, max. and total power, max. temperature) did not predict PV stenosis. 4 of the 16 patients with a PV stenosis had complained of dyspnea at moderate exertion.

Conclusion: In our patient group, the risk of potential significant pulmonary vein stenosis is 34%, a significant progression of a PV Stenosis to a complete occlusion was noted 3 times. These results need to be considered when recommending pulmonary vein ablation therapy for atrial fibrillation.

P2765 Pulmonary vein stenoses after ostial radiofrequency catheter ablation. Incidence and time course

T. Dill[1], T. Neumann[1], O. Ekinci[1], J. Sperzel[1], G. Bachmann[2], H.-F. Pitschner[1]. [1]*Kerckhoff-Clinic, Department of Cardiology, Bad Nauheim, Germany;* [2]*Kerckhoff-Clinic, Department of Radiology, Bad Nauheim, Germany*

Introduction: The segmental radiofrequency catheter ablation (RFCA) for electric isolation of atrial myofibrils crossing into the pulmonary veins (PV) in patients with paroxysmal atrial fibrillation is promising. However, the temporal course of the development of potential PV-stenoses and occlusions is not investigated in consecutive patients undergoing ablation. Methods: Fifty-four patients were treated at 175 PV by RFCA. The minimal PV diameter (DR) was measured ostially and 2 cm post ostially 1 day prior to-, 1 day after- and 3 months after RFCA by magnetic resonance imaging with contrast-enhanced 3D angiography (MRA).

Results: The correlation of diameters of 44 untreated PV by using a standard X-ray angiography resulted in r=0.93 compared to MRA. One day after RFCA, 26/175 PV (15%) had a reduction of DR, 10 of them >30% DR compared to baseline. After 3 months another 12 PV with normal diameters at day 1 showed a DR, and 6 PV with a DR on day 1 demonstrated a progression. Maximum DR observed was 75%. A regression of initial DR was seen in 8 PV - all in PV with an initial DR < 30%. All measured DR of >30% were characterized by a cumulative radiofrequency current delivery at one ostium of > 25000 joules. All patients showing DR were clinically free of symptoms, e.g. pulmonary hypertension.

Conclusion: Observed DR of >30% correlates to the amount of applied radiofrequency energy. Initial DR that disappears after 3 months could be caused by acute edema or intramural bleeding. The results indicate that the induction of a chronic progressive inflammatory process with the development of higher graded PV stenoses and the risk of total occlusion is possible. A long-term non-invasive follow up in this group of patients appears to be imperatively indicated.

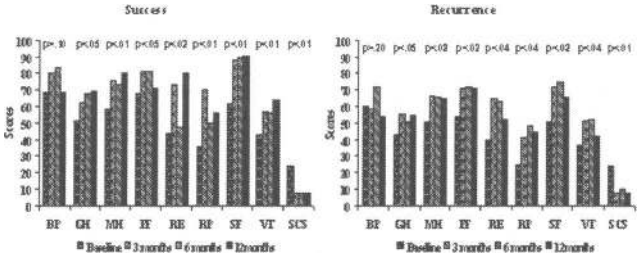
P2766 Quality of life in patients with paroxysmal atrial fibrillation after pulmonary vein isolation

A. Berkowitsch, T. Neumann, K. Kurzidim, G. Siemon, J. Sperzel, H-F. Pitschner. *Kerckhoff-Clinic, Cardiology Dept., Bad Nauheim, Germany*

Previous studies have shown that pulmonary vein isolation or segmental ablation (PRFA) in patients with paroxysmal atrial fibrillation (PAF) improved success rate compared to right atrial procedures. However there is no information on quality of life (QoL) after PRFA. The aim of the study was to evaluate QoL of in these patients before and after PRFA.

Fifty six consecutive patients with symptomatic PAF (37 male, mean age: 58 ±10 years) refractory to > 3 antiarrhythmic drugs were enrolled in the prospective study at our institution. The QoL was measured using generic SF-36 scale(BP-Bodily Pain; GH-General Health; MH-Mental Health; PF-Physical functioning; RE-Role-Emotional; RP-Role-Physical; SF-Social Functioning; VT-Vitality) and Symptom Checklist Severity (SCS) scale. The questionnaires were administered before the procedure and during follow- up at 3,6 and 12 months. The scores for patients with clinical success and with PAF recurrence were separately analyzed using ANOVA to discern QoL over time. The differences were considered as significant by error probability $p<.05$.

With the exception of BP scores, all subscales of the SF-36 and SCS were significantly improved after PRFA in 35 pts. without PAF recurrence (see figure, the graphs represent means of scores). In 21 pts. with PAF recurrence an improvement was also found in 7 SF-36 subscales and in SCS. Only in BP scores no significant improvement could be detected.



QoL at baseline and follow-up.

We conclude that PRFA significantly improved QoL in our patients with PAF by reducing arrhythmia related symptoms. Patients with recurrence of PAF also had a benefit in QoL and a significant reduction of SCS although to a lesser extend.

P2767 Analysis of farfield atrial components in left inferior pulmonary vein electrograms

D. Shah[1], M. Haissaguerre[2], P. Jais[2], M. Hocini[2], L. Macle[2], K.J. Choi[2], H. Sunthorn[1]. [1]*Cantonal Hospital, Cardiology, Geneva, Switzerland;* [2]*Hopital Haut Leveque, Electrophysiologie, Pessac, France*

Pulmonary vein (PV) disconnection requires distinction of extravenous electrogram components from pulmonary venous myocardial potentials. Farfield extravenous components recorded in the left inferior PV (LIPV) have not been studied though their recognition is essential to avoid unnecessary ablation.

Methods: 20 patients (19M, 53±12yrs) undergoing catheter ablation for AF were studied. LIPV recordings were obtained with a circular decapolar catheter before and after ablation and during sinus rhythm as well as coronary sinus (proximal and distal) and left atrial appendage pacing. Selective LAA angiography was performed in 2 views with the circular catheter in the LIPV. RF ablation was performed at PV ostia guided by earliest circumferential activation to eliminate PV arrhythmias and abolish or dissociate all distal PV potentials.

Results: Single potentials or closely separated double potentials (29±8 ms in 6 patients) were recorded in sinus rhythm while during pacing, double potentials were recorded in 17. The larger, sharper second potential was activated radially from the input into the vein where it fused with the first potential. LAA pacing captured the first potential with a longer activation time (47±22ms vs 21±10ms, $p<0.05$) compared to distal CS pacing. Distal and proximal CS pacing did not differ significantly (27±11 vs 21±10 ms). Larger amplitude and sharper activation of the anterior LA below the LAA or close to the bottom of the LIPV ostium coincided with the first potential. Stimulation from this site made the first potential disappear by incorporating it within the artifact. No atrial activation was found coinciding with the second potential which was selectively eliminated by ablation. Angiography showed that the LAA was more than 15mm away from the LIPV in both views in 19/20, as a result, the low LA below the LAA was closest to the electrodes of the decapolar catheter.

Conclusions: Electrical activity originating from the low LA below the LAA and surrounding the ostium can be recorded in 92% of LIPVs. PV potentials can be reliably distinguished by pacing manoeuvers.

P2768 Atrial electrogram components recorded in the right superior pulmonary vein

D. Shah[1], P. Jais[2], M. Haissaguerre[2], M. Hocini[2], K.J. Choi[2], L. Macle[2], H. Sunthorn[2]. [1]*Cantonal Hospital, Cardiology, Geneva, Switzerland;* [2]*Hopital Haut Leveque, Electrophysiologie, Pessac, France*

Pulmonary vein (PV) isolation is probably the most effective curative treatment for paroxysmal atrial fibrillation. Successful catheter ablation is dependent on recognising venous myocardial components within complex electrograms which include both right and left atrial contributions.
Methods: 20 patients (12M, 30±13yrs) without structural heart disease undergoing catheter ablation were studied. Right superior PV (RSPV), superior vena cava (SVC), complete left and limited right atrial (LA, RA) 3-D activation mapping (Biosense) was performed during sinus rhythm and right atrial pacing, and local activation assigned to the maximum negative dv/dt of simultaneous bipolar and unipolar electrograms.
Results: In sinus rhythm, both the RSPV and SVC were activated from proximal to distal. Double or triple component electrograms were recorded from the anterior RSPV in 18/20 patients, with their separation increasing distally within the PV (from 12±5 proximally to 51±23ms). The initial component of double or triple component electrograms coincided with the surface ECG P wave onset and preceded earliest left atrial septal activation. Its origin was confirmed by recording higher amplitude and sharper electrograms with identical timing from the adjacent SVC. Later sharper components coincided with activation of the high interatrial septum, with progressive delay distally within the vein accentuated by local slow conduction (CV <0.5m/s) observed in 13 patients inside or at the PV os. No significant change was observed in the configuration of complex RSPV potentials during pacing from the low lateral right atrium.
Conclusion: Sequential activation of the SVC, high septal LA, and the RSPV combine to produce complex multicomponent electrograms in the RSPV The initial component represents far field SVC activation, while later components represent activation at the RSPV - LA junction and within the RSPV. Low RA pacing does not change RSPV activation significantly.

P2769 Voltage atrial map analysis to predict atrial fibrillation recurrence in patients undergoing circumferential pulmonary vein ablation

C. Pappone, S. Rosanio, G. Augello, A. Pappone, C. De Asmundis, S. Gulletta, S. Nardi, G. Vicedomini. *San Raffaele University Hospital, Cardiology/Arrhythmology, Milan, Italy*

Background: The safety and efficacy of circumferential radiofrequency (RF) ablation around pulmonary vein (PV) ostia to treat atrial fibrillation (AF) has recently been demonstrated. Identifying factors affecting its success could give insight into the mechanism and aid patient selection. Methods: Between June 1999 and July 2001, 648 patients with resistant paroxysmal (n=419) or permanent (n=229) AF (79% M, age 59±9 years, AF duration 7±2.5 years; 59% with structural heart disease) underwent circumferential PV ablation using CARTO. Patients were followed-up with serial visits, Holter recordings, transthoracic and transesophageal echocardiography. Results: After 18±6 months, 356 patients with paroxysmal AF (85%) and 172 with permanent AF (75%) were AF-free without antiarrhythmic drugs. Among clinical, procedural, echocardiographic and electrophysiological variables examined, significant univariate predictors associated with AF recurrence comprised either pre-RF variables (ie, age>65, left atrial diameter >45mm and bipolar signal amplitude around PV ostia <0.5mV) or post-RF ones (ie, low-voltage [<0.1mV] PV encircled area <15% of left atrial map surface). By multivariate analysis, independent predictors of a higher likelihood of sinus rhythm restoration were post-RF amount of low-voltage encircled area (odds ratio [OR] adjusted for other variables in model, 3.08; 95% confidence interval [CI], 1.66 to 5.72) and pre-RF low-amplitude electrical activity surrounding PV ostia (adjusted OR, 2.86; 95%CI, 1.92 to 4.27). Conclusion: Quantitative voltage map analysis is useful to stratify the risk of AF recurrence after circumferential PV ablation. Measurement of PV ostial electrograms amplitude provides incremental information, as a low "electrical power" in this region appears to identify individuals at risk of recurrence before ablation is performed. These results are clinically relevant as they should be considered in selecting patients for ablation and planning post-procedural management.

P2770 Atrial electroanatomic remodelling time course after circumferential pulmonary vein ablation for atrial fibrillation: is it related to recurrence?

C. Pappone, S. Rosanio, G. Augello, C. Dicandia, A. Pappone, E. Ficarra, A. Pisani, G. Vicedomini. *San Raffaele University Hospital, Cardiology/Arrhythmology, Milan, Italy*

Background: Circumferential radiofrequency (RF) ablation of pulmonary vein (PV) ostia has evolved as a potential curative therapy for atrial fibrillation (AF). However, few follow-up data are available on left atrial (LA) electroanatomical remodeling induced by this technique. This prospective study investigated the relation between AF recurrence and serial LA electroanatomical changes after ablation, using LA voltage map analysis (VMA) and transthoracic echocardiography (TTE). Methods: 135 consecutive pts with resistant paroxysmal (n=81) or permanent (n=54) AF (67% M; age 60±19 yrs; AF duration 6±2 yrs; 49% with structural heart disease) underwent circumferential PV ablation guided by CARTO. Pts were followed-up with serial visits and Holter recordings. LA VMA and TTE were performed at 3, 6, and 12 months. Results: After 13±2 months, 108 pts (80%) were AF-free without antiarrhythmics. Pts with and without recurrence did not differ in age, AF duration, prevalence of heart disease, and proportion of PVs with complete lesions (bipolar voltage <0.1mV inside the encircled area). Pts without recurrence showed a larger early post-RF low-voltage area, in % of total LA map surface (31±11% vs 21±9%, P<0.001), predominantly due to a greater extent of low-amplitude (<0.1mV) area outside the lesions (P<0.01). During follow-up, in all pts without recurrence the extent of low-voltage area either inside or outside the lesions didn't vary whereas a significant LA size reduction and improvement in its transport function was detected. In contrast, pts with recurrent AF showed a significant and progressive decrease in the extent of low-voltage area involving only the region outside the lesion with not significant changes in LA size and contraction versus pre-RF. Conclusion: Ablation, when effective, results in a profound LA electroanatomical remodeling involving, to some extent, the LA posterior wall to the point that the substrate for AF is no longer present. The phenomenon of voltage amplitude recovery outside the circular line appears to be a key factor for recurrence. Why and how it occurs remains to be clarified.

P2771 Pulmonary vein fibrillation and dissociated activity inside disconnected pulmonary veins

T. Risius, C. Weiss, R. Ventura, T. Rostock, T. Meinertz, S. Willems. *University Hospital Hamburg-Eppendorf, Dept. of Cardiology, Hamburg, Germany*

Paroxysmal atrial fibrillation (PAF) is predominantly triggered by focal ectopies located within the pulmonary veins (PV). Although isolation of arrhythmogenic PV has been introduced as a curative treatment the exact underlying mechanism of PAF initiation has not been completely elucidated. The present study sought to investigate the electrophysiological properties of isolated PV following successful radiofrequency (RFC) catheter ablation.
Methods: Thirty consecutive patients (55±9 years) with recurrent PAF refractory to antiarrhythmic drug treatment were prospectively included. RFC ablation supported by the electroanatomical mapping CARTO (n=21) or conventional approach (n=9) targeted a total number of 52 PV. RFC was applied at the ostial region (max. power 30 W, 50°C). Complete abolition of specific PV potentials were considered as successful ablation. Following functional isolation (FI) the incidence of dissociated pulmonary vein activity and its response to Orciprenalin (Orc, 5mg in 500 ml NaCl) was analyzed.
Results: PV conduction was abolished with a mean of 10.6±6.4 RFC applications in 49 out of 52 potentially arrhythmogenic PVs (94%). After ablation slow dissociated autonomic activity with a baseline rate of 20±7/min was found in 6 PVs of 6 patients (RSPV:n=2, LSPV:n=1, LIPV:n=1, common left PV:n=2). PV-activity increased to 26±9/min during infusion of Orc. After FI sustained or non sustained local fibrillation was recorded within two common left sided PV with preceding autonomic activity. In one patient PV fibrillation occurred during Orc-infusion following a repetetive response to a dissociated automatic rhythm with increasing destabilization and duration. The second patient showed PV fibrillation immediately after the occurrence of PV automaticity. After successful ablation PV-pacing showed no evidence for local capture in all but both patients with common PV and local PV fibrillation.
Conclusions: Slow dissociated automatic rhythms within disconnected pulmonary veins are a phenomenon occurring in about 12% of isolated PV. The unique anatomic substrate of common left PVs seems to predispose to the occurrence of local fibrillation. The initiation pattern of fibrillation within isolated PV demonstrates a possible contribution of multiple factors to the onset and sustenance of PAF.

P2772 Surface electrocardiogram-based T-wave subtraction combined with PV pacemapping for the prediction of pulmonary vein ectopy source

D. Shah[1], K.J. Choi[2], L. Macle[2], P. Jais[2], M. Hocini[2], M. Haissaguerre[2], S. Yang[3], D. Macadam[3]. [1]*Cantonal Hospital, Cardiology, Geneva, Switzerland;* [2]*Hopital Haut Leveque, Electrophysiologie, Pessac, France;* [3]*Bard Electrophysiology, Boston, United States of America*

Background: The surface ECG P wave morphology of ectopics initiating atrial fibrillation (AF) could allow localization and facilitate mapping and ablation of paroxysmal AF. However, because of their coupling interval, most ectopics are concealed by the T-wave and analysis of the P wave morphology is difficult.
Methods: T wave subtraction was performed to unmask ectopic P-wave morphology buried in the T-wave in patients with AF initiation during EP study. The pulmonary vein (PV) source was predicted based on a previously proposed algorithm using the subtracted P wave. PV pacemapping was also performed to compare with subtracted P-waves in order to improve prediction accuracy. The origin of ectopic foci was confirmed by intracardiac mapping and elimination by specific PV disconnection.
Results: Thirty-eight ectopic P-wave morphologies in 34 PAF patients with ectopics or mappable AF initiations were prospectively analyzed. Four foci originating from atrial foci were excluded. Correct prediction of PV ectopy origin was achieved using the P-wave algorithm alone in 28/34 ectopics (82%, 11/11 in RSPV, 12/18 in LSPV, 2/2 in LIPV and 3/3 in RIPV). In 6 patients, ectopics from the LSPV were erroneously ascribed to the RSPV (n=3) because of an unusually high amplitude positive P-wave in lead I; or to the LIPV (n=3) because of an unusually low amplitude P-wave in lead II and III. PV pacemapping with 11-12/12 leads match increased correct prediction to 32/34 (94%).
Conclusions: Accurate unmasking of the ectopic P-wave morphology concealed within the preceding T-wave in conjunction with pacemapping from the PVs allows quick and accurate localization of 94% of PV ectopic foci to facilitate rapid targeting of arrhythmogenic PV. This technique may also allow non-invasive recognition of multiple ectopics from different sources.

P2773 Intraoperative evaluation of bilateral pulmonary veins isolation: unipolar versus bipolar radiofrequency energy application

P. Adragão[1], J. Melo[2], J. Neves[2], C. Aguiar[1], D. Cavaco[1], T. Santiago[3], D. Bonhorst[1], R. Seabra-Gomes[1]. [1]*Hospital Santa Cruz, Department of Cardiology, Carnaxide, Portugal;* [2]*Hospital de Santa Cruz, Department of Cardiothoracic Surgery, Carnaxide, Portugal;* [3]*Instituto do Coração, Carnaxide, Portugal*

Eight patients (pts) (2 female, 58±12 yrs) with paroxysmal atrial fibrillation (AF) (duration 39±20 months) were submitted to AF surgery, concomitant with myocardial revascularization in 2 pts and myomectomy in 1 (HOCM). AF was idiopathic in the remaining 5 pts. AF surgery consisted of bilateral isolation of pulmonary veins (PV) using radiofrequency (RF) energy applied epicardially by a heptapolar catheter (Thermaline) - 5 pts - or a novel system (AtriCure) - 3 pts. For the first, each set of <= 7 simultaneous applications aimed at a maximal duration of 2+2 min, preset temperature <= 80°C and output <= 150 Watts. With the novel system, we performed bipolar applications; energy delivery was controlled by impedance monitoring and applications were ended after abrupt, sustained elevation of impedance (peak temperature achieved was 49 ± 7 °C and applications took 8.3 ± 3.1 sec). Epicardial bipolar voltage mapping (CARTO) was performed before and after the RF procedure. Using the navigator catheter, points were recorded at the insertion of each PV and at the non-isolated left atrial posterior wall (average 10 points/map). The amplitude of the local electrograms (LE) was measured before and after RF applications. If LE amplitude inside the isolated zone was not < 0.1 mV and not reduced by >80%, a second application was performed. A maximum of 2 epicardial applications was allowed in each pt and if the final result was unsatisfactory, further endocardial applications were performed.
Results: Baseline LE amplitudes were invariably > 1.0 mV. Successful isolation of right PV was achieved in 7 pts: after 1 set of applications in 5 pts (2 treated with AtriCure) and a second set in 2. Left PV isolation required 2 sets of epicardial applications in all pts, being successful in only 2 (both treated with AtriCure); 4 pts received endocardial applications, successful in 3. Overall, bilateral PV isolation was achieved in 5 pts.
Conclusions: CARTO bipolar voltage mapping is a fast, simple means for evaluation of PV isolation. Epicardial PV isolation is achieved easier in the right PV. Bipolar RF isolation is a faster procedure than conventional unipolar ablation and seems to be at least as effective.

P2774 Temporal course of relapses after radiofrequency catheter ablation of the pulmonary vein ostia in patients with paroxysmal atrial fibrillation

T. Neumann, K. Kurzidim, C. Reiner, G. Siemon, J. Sperzel, H.-F. Pitschner. *Kerckhoff-Clinic, Department of Cardiology, Bad Nauheim, Germany*

Introduction: Focal radiofrequency catheter ablation (RFCA) of the trigger substrates in the pulmonary veins (PV) or complete isolation of the ostia cannot modify the substrate in a way that prevents atrial fibrillation (AF) in the atria as the MAZE-III-surgery. We tested the hypothesis whether early relapses may be counteracted by inverse electric remodelling due to a reduction of AF burden. In such a case a long term success of RFCA, although early relapses are observed, could be possible.
Methods: In 48 patients (mean age 51±10years, male=31) with frequent drug-refractory episodes of AF (> 10/month) an 48-hours Holter ECG (HECG) was performed 24 hours after RFCA of atrial fibrillation. Twenty-six patients had lone atrial fibrillation and 22 patients had a mild heart disease, including hypertensive cardiomyopathy and CAD with normal ejection fraction and normal atrial dimensions. During the follow-up (FU) all patients received at discharge and x = 5.9 months ordinary two eventrecordings (ER) with evaluated automatic arrhythmia detection for 3 weeks each.
Results: At HECG after ablation, 20/43 (47%) patients showed relapses of AF. AF-relapses occurred in 21/43 (49%) patients during ER. Fourteen (33%) patients had early and late relapses observed during the HECG and ER after ablation. However, 6/43 (14%) patients showed AF relapses during the initial HECG, proved to be free of relapses in the FU. 51% of the patients did not show any documented AF during the whole FU. Antiarrhythmic drugs were continued in 4 patients with observation of AF-relapses at HECG and in 5 patients with observation of sinus rhythm. The antiarrhythmic drugs were continued in 7 patients with observation of AF during ER and in 4 patients with sinus rhythm.
Discussion: Comparable with the results after Mini-MAZE-surgery (reduced number of lessions compared to MAZE III) 14% of our observed patients showed early relapses without further ones. This observation can be explained with the hypothesis given above.

P2775 Analysis of P-wave morphology during pulmonary vein ectopic activity

D. O'Donnell, S. Furniss, J.P. Bourke. *Freeman Hospital, Department of Academic Cardiology, Newcastle Upon Tyne, United Kingdom*

Background Ablation of focal activity, most commonly from the pulmonary veins, can reduce the occurrence of atrial fibrillation (AF). Because of the infrequent, unpredictable nature of this focal activity, algorithms have been derived to allow prediction of the arrhythmogenic pulmonary veins, by analyzing the P wave morphology from a standard 12 lead ECG. This report investigates P wave morphology during pulmonary vein ectopic activity in patients with AF and in normal controls.
Methods The study enrolled 55 patients, 40 consecutive patients with symptomatic, drug refractory AF scheduled for focal ablation and 15 controls undergoing ablation of supra-ventricular tachycardia. AF patients were subdivided into those with paroxysmal or persistent AF at the time of the study; and those with electrically and structurally 'normal' (defined as maximum LA size < 4.5 cm, total P wave duration < 100 msec and P wave dispersion < 60 msec.) or 'abnormal' atria.
P wave morphology on 12 lead ECG was analyzed during spontaneous ectopy and published algorithms were used to predict the culprit PV. Further analysis of P wave morphology was undertaken during decremental cycle length pacing from the PVs.
Results The various algorithms designed to predict the PV generating ectopic activity have similar predictive accuracy. Accuracy is highest in patients with paroxysmal AF and normal atria (93%), but much less in patients with abnormal atria (64%) or persistent AF (51%).
P wave morphology during pacing from the pulmonary veins is similar to spontaneous ectopy, if performed at similar coupling intervals. P wave morphology can vary with cycle length. In patients with abnormal atria or persistent AF, a significant change in P wave morphology was observed in 25% as cycle length shortened.
Conclusion P wave morphology during ectopic activity from the pulmonary veins is affected by cycle length and the presence of underlying atrial electrical and structural abnormalities. This reduces the accuracy of non invasive methods in localizing arrhythmogenic veins.

P2776 Early recurrences of atrial fibrillation are not predictive for the long-term success of pulmonary vein ablations

C. Mewis, K. Kettering, B. Eigenberger, R.F. Bosch, L. Seipel, V. Kühlkamp. *Medizinische Klinik III, Cardiology Dept., Tübingen, Germany*

The recurrence rate of atrial fibrillation after pulmonary vein ablation ranges from 30% to 50%. The significance of early or late recurrences of AF are unknown. Therefore we did a close detailled follow-up of all patients who were treated by PV-ablations. All patients received Holter-Monitorings and event-recorder immediately after the ablation procedure. All antiarrhythmic drugs had to be discontinued and were not initiated if the patient had AF recurrences during the first month after PV-ablation. Results: 52 patients (52±9 years) were followed up 10±5 months after PV-ablation. 19 patients were free of any AF recurrences during this period. In 34 patients one AF recurrence was at least detected. In 8 patients of this group a early AF recurrence was found (14±12 hours after PV-ablation). The remaining first recurrences occurred 28±20 days after the procedure. While 6 patients with early AF recurrences did not report any further recurrences during the following 5±6 months, all patients with late recurrences did report further AF episodes. Cardiac disease, atrial diameters or characteristics of AF were not predictive für early recurrences ($p>0.05$). Conclusion: Early AF recurrences did not mean failure of the PV-ablation, because these episodes were not predictive for the long-term success of the ablation. Prophylactic antiarrhythmic therapy after early AF recurrences are not justified. A second early intervention does not seem appropriate.

P2777 The significance of early atrial fibrillation recurrence post pulmonary veins isolation

N. Marrouche[1], W. Saliba[1], E. Saad[1], T. Dresing[1], J. Guenther[2], J. Brachmann[2], A. Natale[1]. [1]*Cleveland Clinic Foundation, Department of Cardiology, Cleveland, United States of America;* [2]*Klinikum Coburg, Department of Cardiology, Coburg, Germany*

Background: The majority of atrial fibrillation recurrences post pulmonary veins (PV) isolation occurs within the first 4 weeks. The significance of this early recurrence of AF remains unclear. We compare long-term follow-up in patients with early versus late recurrence of AF post PVs isolation.
Methods and Results: Two hundred and forty patients underwent circular mapping guided PVs isolation (190men; mean age 54±11 years) for treatment of symptomatic AF. All patients underwent ostial isolation of all PVs. Eighty-nine patients (37%) experienced recurrence of AF within the first 2 weeks post PVs isolation. All patients with recurrence of AF underwent pharmacological or DC cardioversion and were started on a limited 6 weeks antiarrhythmic drug (AAD) trail. After a mean follow-up of 8±4 months 62% (56/89) remained in SR (group 1), and 37% (33/89) continued to have AF > 6 weeks post PVs isolation. The table shows demographics and follow-up results of the 2 groups.

	Group 1	Group 2	P value
Patients	56	33	ns
Age (years)	53 ± 8	55 ± 9	ns
Ejection fraction %	52 ± 8	51 ± 9	ns
Left atrial size (cm)	4.1±0.3	4.3±0.5	ns
Duration of AF	6.1 ± 3.4	6.4 ± 3.5	ns
Follow-up (months)	8±3	7.5 ± 3	ns
In AF after AAD	none	100% (33/33)	p<0.05
2nd ablation	none	42% (14/33)	p<0.05
Chronic cure (no AAD)	100%	42% (14/33)	p<0.05
Chronic cure (on AAD)	none	51% (17/33)	p<0.05

AAD=antiarrhythmic drugs

Conclusion: Early recurrence of AF post circular mapping guided isolation of all PVs does not seem to reflect true procedural failure. From our preliminary data short term AAD trail prior to 2nd ablation procedure seems to be an appropriate approach in this group of patients.

P2778 Is complete pulmonary veins isolation necessary to reduce the recurrence rate after RF ablation of atrial fibrillation?

M. Scanavacca, R. Sartini, F. Tondato, A. d Ávila, D. Hachul, S. Lara, F. Darrieux, E. Sosa. *Heart Institute(Incor) of Sao Paulo, Arrhythmias Dept., Sao Paulo, Brazil*

Localizing and ablating the focal triggers of atrial fibrillation (AF) has been proven an effective approach for radiofrequency (RF) AF ablation, but this strategy is time consuming and often requires multiple procedures. So, empirical electrical isolation of all pulmonary veins has been suggested as the best method to treat these patients. The purpose of this study was to assess the relationship between the number of pulmonary veins empirically isolated during the first RF ablation for paroxysmal AF and recurrence.
Patients and Methods: The study included 35 consecutive patients (24 male; mean age 51 years old) who had frequent symptomatic paroxysmal AF refractory to at least three antiarrhythmic drugs. Using the lasso decapolar catheter (J&J) for mapping and a 4-mm distal tip catheter, two to four pulmonary veins were ablated at the venoatrial junction (30 W and 500 C), aiming to achieve electrical isolation of the veins. The patients were periodically followed with loop recorder monitoring.
Results: Ninety-three veins were ablated (LSPV: 34; RSPV: 31; RIPV: 16; LIPV: 12). True electrical isolation could be achieved only in 61(65%) veins (LSPV: 68%; RSPV: 71%; RIPV: 50%; LIPV: 67%). After ablation 23 (66%) of 35 patients presented recurrence (< 48 h: 12; < 30 days: 10; > 30 days: 1). Six patients had not any vein isolated, all presented recurrence; 18 patients had one or two veins isolated, 15 (83%) presented recurrence and 11 patients had three or four veins isolated, 4 (36%) presented recurrence ($p < 0,05$).
Conclusion: Empirical isolation of pulmonary veins appears to be an effective approach to avoid recurrences in patients with paroxysmal AF when three or four true electrical isolations are achieved.

BIVENTRICULAR PACING AND HEART FAILURE

P2779 Biventricular pacing has both arrhythmogenic and antiarrhythmic effects: results from the MUSTIC study

C. Alonso[1], C. Leclercq[1], S. Cazeau[2], P. Mabo[1], C. Daubert[1] on behalf of MUSTIC study group. [1]*University Hospital, Cardiology, Rennes, France;* [2]*St Cloud, France*

Atrial and ventricular arrhythmias are frequent in patients with severe heart failure due to chronic left ventricular systolic dysfunction and may influence prognosis. The aim of this study was to assess the incidence of arrhythmias and the influence of biventricular pacing in the MUSTIC study patients.
The MUSTIC study was a randomized, crossover, single blinded study including patients with chronic severe heart failure,stable sinus rhythm, and intra ventricular conduction delay (QRS > 150ms). Patients were implanted with a DDD BiV pacemaker and entered a 6-month crossover phase with the pacemaker programmed active (BiV) or inactive (VVI 40 bpm) during 2 periods of 3 months each. At the end of the crossover phase the pacemaker was programmed BiV and patients were re-assessed 6 months (FU) later. 24-hours ECG recording was performed at baseline, randomisation time (Rando), at the end of each 3-month crossover period, and at FU. 28 patients had complete data. The median number of premature atrial contractions (PAC), premature ventricular contractions (PVC), ventricular tachycardia (VT) and atrial fibrillation (AF) episodes are summarized in the table.
Results:

	Baseline	Active	Inactive	FU
PAC	26.5	17	88.5	47
PVC	122.5	158.5*	301**	57
VT	0	0	1	0
AF	0	1	0	0

* p<0.05 vs baseline, ** p<0.05 vs active

Conclusion: Implanting a biventricular pacing system is associated with a significant increase in the incidence of PVC's, and at a lesser degree of PAC's. This "arrhythmogenic" effect could be of mechanical origin (intracardiac leads). However it was principally observed with the device programmed inactive, and decreased over time during active biventricular pacing.

P2780 Resynchronisation therapy in patients with and without sinus rhythm

B. Lamp[1], J. Heintze[1], J. Vogt[1], L. Faber[1], F. Warzok[1], B. Hansky[2], U. Schulz[2], D. Horstkotte[2]. [1]Heart Center North Rhine-Westphalia, Department of Cardiology, Bad Oeynhausen, Germany; [2]Heart Center North Rhine-Westphalia, Dept. of Thoracic Cardiovasc Surgery, Bad Oeynhausen, Germany

Resynchronisation therapy (RT) in patients (pts) with severe heart failure (CHF) and left bundle branch block (LBBB) improves clinical symptoms and myocardial function. However, conflicting data exist for pts. with atrial fibrillation (AF) or preexisting DDD-pacemaker (PM).
We analysed 196 pts. (mean age 61 years (y), 109 with DCM, 71 with CAD, 17 with other underlying diseases, mean FU 12 ± 9 m) who received RT with respect to the underlying rhythm at baseline. Analysis of baseline characteristics in the different groups shows no statistical differences between the SR-pts. and the non-SR-pts. (11xAF, 4xVVI-SM, 8x intermittent AF, 15x DDD-PM) concerning age, NYHA class, peak oxygen consumption (VO2peak), oxygen consumption at anaerobic threshold (VO2AT), workload, 6-min walking distance, LVedD, LVEF). QRS is wider due to PM stimulation in the non-SR group (199 ms versus 186 ms) and the proportion of pts. with valvular disease is larger (15.7% versus 5.1% in SR). After 3, 6 and 9 m however, the clinical course in the non-SR group seems less favorable (table), suggesting a more advanced disease in these pts. The number of Subanalyses for pts. with chronic AF, intermittent AF, any AF and DDD-PM show, that the main cause for deterioration is any kind of AF at baseline.

	SR			NonSR		
	pre (n=158)	6 m (n=111)	9 m (n=90)	pre (n=38)	6m (n=27)	9 m (n=23)
NYHA	3.1±0.3	2.2±0.5*	2.3±0.6*	3.1±0.3	2.5±0.8*#	2.4±0.7*
VO2peak	13.0±2.9	15.1±3.3*	16.0±4.2*	11.8±1.9	12.6±5.3#	12.2±2.3#
VO2AT	10.8±2.5	12.6±3.9*	13.1±3.1*	10.3±1.7	12.1±5.4	9.6±1.0#
LVedD (mm)	82±11	73.8±13.8*	75.3±12.5*	78.0±10.4	73.8±12.4	73.6±15.8

Our data show a favourable outcome after RT for pts. with normal SR. However in pts. with preexisting AF or AV-block III with DDD-PM the clinical benefit seems to be less sustained. These results are comparable to those of the AF-arm in MUSTIC.

P2781 Continuous improvement in heart rate variability with biventricular pacing in patients with severe heart failure: the MUSTIC study

C. Alonso[1], C. Leclercq[1], P. Ritter[2], P. Mabo[1], C. Daubert[1] on behalf of MUSTIC study group. [1]University Hospital, Cardiology, Rennes, France; [2]St Cloud, France

Heart rate variability (HRV) is frequently impaired in patients with severe heart failure and is an independent prognosis factor. The aim of this study was to assess the effects of biventricular pacing (BiV) in a subgroup of the MUSTIC study patients. This randomized, crossover, single blinded study included patients with chronic severe heart failure, intra ventricular conduction delay (QRS > 150ms) and stable sinus rhythm. Patients were implanted with a DDD BiV pacemaker and entered a 6-months crossover phase with the pacemaker programmed active (BiV) or inactive (VVI 40 bpm) during 2 periods of 3 months each. After the crossover period the pace maker was programmed on a BiV mode and patients were followed for 24 months more. 24-hours Holter recording was performed at baseline, randomization time (rando), at the end of each crossover period and then after 3 (FU I) and 6 months (FU II). Patients who didn't complete the 2 crossover periods (n=18), or with > 20% atrial paced cycles (n=5) or poor data (n=3), were excluded from the analysis. No modification in drug treatment was allowed from the time of inclusion until the end of the crossover phase. Heart rate variability analysis (time domain measurements) was performed in the 22 eligible patients. Main results are summarized in the table.

	Baseline	Rando	Active	Inactive	FU I	FU II
pNN50 (%)	5.2±5	3±3	15.3±9	9±8*	17±9**	13±8**
RMSSD (ms)	27±11	23±7	41±12	38±22	49±14**	48±24**
ASDNN (ms)	35±10	33±10	40±9	36±12	45±8**	39±16**
SD (ms)	85±31	87±24	98±31	82±16*	94±34	103±46**

* p<0.05 vs BiV, ** p<0.05 vs baseline

Conclusion: HRV was significantly higher with biventricular pacing as compared to no pacing during the crossover phase. Improvement of HRV with biventricular pacing was preserved over time until at least one year.

P2782 Spontaneous conversion of chronic atrial fibrillation as potential benefit of biventricular pacing in patients with congestive heart failure

M. Mende[1], N. Klein[1], R. Surber[2], P. Pohl[2], G. Oltmanns[3], A. Neugebauer[1], D. Pfeiffer[1]. [1]Universitity of Leipzig, Department of Cardiology, Leipzig, Germany; [2]University Hospital of Jena, Cardiology, Jena, Germany; [3]DRK Hospital, Cardiology, Sömmerda, Germany

Atrial fibrillation (AF) is a common problem in patients (pts) with congestive heart failure (CHF). It has been shown in former studies that biventricular pacing may lead to hemodynamic improvement in selected pts with CHF. The impact of chronic biventricular pacing on recurrence and stabilization of sinus rhythm (SR) in pts with CHF and permanent AF remains unclear.
Patients/ Method: In 14 pts with CHF NYHA class III-IV (6 pts with chronic refractory AF, 8 pts with SR) biventricular devices (Pacesetter Frontier™ 5200, St. Jude Medical; Contak TR™ or Contak CD™ CHFD™, Guidant) were implanted. Electrocardiogram (ECG), Holter-ECG and echocardiography were performed before implantation and during follow up (time between 2 and 19 months). Left ventricular ejection fraction (LVEF), left atrial diameter (LAD), left ventricular enddiastolic diameter (LVEDD) and mitral valve insufficiency (MI) were used as parameters for hemodynamic assessment.
Results: All pts showed an improvement of LVEF, NYHA class, LAD and LVEDD. In 67% of pts with chronic refractory AF at time of implantation spontaneous conversion into SR occurred 1, 3, 10 and 19 months after implantation due to a significant (p<0.05) improvement of LVEF, reduction of LAD/LVEDD and a decrease of MI (table), 33% of pts. remaining in AF showed no significant improvement in hemodynamics.

Hemodynamic parameters

N=4	AF	SR
LVEF (%)	17 ± 5 (p<0.05)	37 ± 11 (p<0.05)
LAD (mm)	53 ± 7	46 ± 7
LVEDD (mm)	68 ± 6	63 ± 8
MI	II-III	I-II

AF: atrial fibrillation; SR: sinus rhythm; LVEF: left ventricular ejection fraction; LAD: left atrial diameter; LVEDD: left ventricular enddiastolic diameter; MI: mitral valve insufficiency

Conclusion: The potential benefit of biventricular pacing due to hemodynamic improvement may result in obtaining sinus rhythm in pts with CHF and chronic AF. Further studies are necessary to answer the question, if the prophylactic implantation of an atrial lead during AF is useful.

P2783 Resynchronization therapy significantly reduces mitral regurgitation in congestive heart failure patients

F. Zanon, S. Aggio, C. Bilato, E. Baracca, K. D'Elia, A. Nascimben, P. Zonzin. General Hospital, Division of Cardiology, Rovigo, Italy

Mitral regurgitation (MR) plays an important role in the pathophysiology of congestive heart failure (CHF). Its contribution in long term prognosis, however, is still unclear. Biventricular pacing (BiV) improves clinical status and functional class in CHF patients, but the underlying mechanisms are not completely understood. We analyzed the beneficial effects of resynchronization therapy in term of reduction of MR. 33 pts (25 man, 72±6 y.o.) with cardiomyopathy of any etiology underwent BiV implantation in our institution. All pts were in NYHA class III/IV despite optimal medical treatment, with a mean ejection fraction (EF) of 23±5% and a QRS duration of 196±25 ms. In all pts v-wave was invasively measured with Swan-Ganz catheter at baseline and after 15 min of BiV. Before and one week after implantation all the subjects underwent complete echocardiography examination in order to determine EF, systolic mitral annulus diameter (SMAD), mitral regurgitation area (MR area), MR area percentage of left atrium area (%MR area), mitral regurgitation score (MR score). Pre and post BiV data are summarized in the following table.

Data pre and post BiV

	PRE	POST	p
EF %	23,24 ± 5,43	33,39 ± 6,91	<.001
SMAD (mm)	39,69 ± 3.06	36,25 ± 4,37	<.001
MR area (cm^2)	7,47 ± 4,9	4,4 ± 3,81	<.001
% MR area	24,54 ± 13,76	5,62 ± 13	<.001
MR score (1-4)	2,14 ± 0,83	1,47 ± 0,59	<.001
v-wave (mmHg)	26 ± 11	17,4 ± 9,7	<.05

These observations confirm the important role of MR in the pathophysiology of CHF and suggest that the beneficial effects of resynchronization therapy may also be related to the partial correction of MR.

P2784 Cardiac resynchronization therapy in advanced congestive heart failure: mid-term clinical and haemodynamic results

F. Oliva, M. Lunati, M. Frigerio, G. Bruschi, G. Cattafi, G. Foti, G. Masciocco, M. Paolucci. *Niguarda-Ca' Granda Hospital, De Gasperis Cardiac Dept., Milan, Italy*

Background: Cardiac resynchronization therapy (CRT) by biventricular pacing (BIV P) has been recently proposed as a means to improve hemodynamics and symptoms in patients (pts) with advanced congestive heart failure (CHF) and interventricular conduction delay (IVCD).
Objective: The aim of this report was to analyze the mid term clinical and hemodynamic results of CRT.
Methods: Between March 1999 and January 2002, CRT was attempted in 117 pts (age 62±9 years; 98 male; n=63 idiopathic, n=39 ischemic, n=15 valvular etiology) with advanced CHF despite optimal medical therapy and IVCD. At baseline NYHA class was 3.0±0.5, QRS duration 180±34 msec, echo LVEF 25±7%, LVEDV 276±88 ml, LVEDD 71±8 mm, MR grade 2.2±1.1, VO2 max 12.9±3.0 ml/min/Kg. Cardiac index (CI) and wedge pressure measured by right heart catheterization were 1.9±0.4 l/min/m^2 and 15±9 mmHg respectively. 12% of pts were in chronic atrial fibrillation; 16% had a pacemaker already implanted and 7% an implantable cardioverter defibrillator. The mean number of hospitalizations/pt for worsening heart failure in the 12 months before enrollment was 1.2±1.3.
Results: CRT was not feasible in 14 pts (10%). After the implantation, the QRS duration shortened to 156±20 msec. After a mean follow up of 9.6+5.0 months, NYHA class was 2.2±0.5 ($p<0.01$), LVEF 28.7±8.% ($p< 0.01$), LVEDV 231±85 ml ($p< 0.01$), LVEDD 68±9 mm ($p<0.01$), MR grade 1.7±0.9 ($p<0.01$), VO2 max 14.5±3.7 ml/Kg/min ($p< 0.01$), CI 2±0.4 (p: n.s.), wedge pressure 11±7,6 mmHg ($p<0.05$). There were 21 cardiovascular hospitalizations in 13 pts. Seven pts died (6%; 4 refractory CHF, 1 ventricular fibrillation, 1 sudden cardiac death, 1 sepsis complicating the replacement of a dislodged left ventricular lead). Concerning HTx candidates: one pt died while awaiting, 2 pts were excluded from the waiting list because of clinical improvement, 2 pts were succesfully transplanted and 7 pts are alive awaiting for HTx.
Conclusions: Our preliminary experience shows that CRT is feasible in the majority of pts. Symptoms, echocardiographic parameters, exercise capacity and hemodynamics significantly improved after implantation with reduced need for hospitalization. In some pts CRT may prevent or postpone the need for HTx or provide a bridge to HTx. These results need to be validated from ongoing randomized controlled trials.

P2785 Magnitude of systolic improvement with resynchronization therapy predicts magnitude of clinical benefit for heart failure

C. Stellbrink[1], A. Auricchio[2], C. Butter[3], H. Kirkels[4], M. Kloss[2], J. Vogt[5], A. Kramer[6], F. Cuesta[6] on behalf of the PATH-CHF II Investigators. [1]*Univ Hosp RWTH, Cardiology, Aachen, Germany;* [2]*Univ Hosp, Cardiology, Magdeburg, Germany;* [3]*German Heart Institute, Cardiology, Berlin, Germany;* [4]*Univ Hosp, Cardiology, Utrecht, Netherlands;* [5]*Heart Center, Bad Oeynhausen, Germany;* [6]*Guidant Corporation, CRM Dept., St. Paul, United States of America*

Cardiac resynchronization therapy (CRT) with left ventricular (LV) or biventricular pacing has been shown to improve LV systolic function and to increase exercise capacity, quality of life, and functional status of heart failure (HF) patients with intraventricular conduction delay. We analyzed results of the completed PATH-CHF II CRT study to test the hypothesis that the magnitude of hemodynamic improvement with CRT predicts the magnitude of clinical benefit with CRT.
Methods: Patients were randomized to 3 months LV pacing followed by 3 months no-pacing or vice versa. Patients were prospectively stratified into equal groups with QRS between 120-150 msec and QRS greater than 150 msec. Changes in peak VO2 measurements from adjacent no-pacing and pacing periods were available from 71 randomized HF patients (NYHA class II&III, EF<30%). The LV max dP/dt and aortic pulse pressure (PP) with pacing at the programmed device settings were measured acutely from LV and aortic pressure recordings. Comparisons were made by unpaired t-test.
Results: The median hemodynamic change with CRT was 13.8% for max dP/dt and 5.1% for PP. Patients with QRS>150 msec or above-median increase in max dP/dt (but not PP) had significantly larger increase in peak VO2 (table). A max dP/dt increase greater than 5% predicted a positive VO2 change with 75% accuracy and had a 80% positive predictive value and a 63% negative predictive value. QRS had a maximum predictive accuracy of 69%.

Predictor	Peak VO2 Change Predictor > Median	Peak VO2 Change Predictor < Median	P Value
QRS	2.31 ± 2.7	0.32 ± 2.3	0.001
max dP/dt	2.24 ± 2.7	0.35 ± 2.4	0.004
PP	1.78 ± 2.7	0.84 ± 2.7	0.153

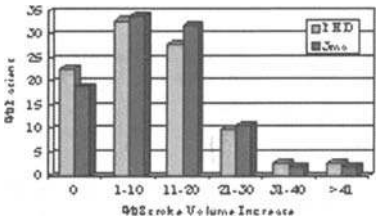
Peak VO2 Change (ml/min/kg) with CRT (mean ± SD)

Conclusion: Long QRS with HF is known to predict increased contractile function with CRT. Our results indicate that acute increase in contractile function also predicts improved exercise capacity after three months of treatment. This relationship may explain why patients with longer QRS have larger clinical benefit with CRT.

P2786 Interventricular delay increases stroke volume in cardiac resynchronization patients

A.R. Leon[1], S. Brozena[2], C.S. Liang[3], W.T. Abraham[4], E. Chinchoy[5], M.R.S. Hill[5] on behalf of US InSync III Investigators and Coordinators. [1]*CrawfordLong/Emory University Hospital, Atlanta, United States of America;* [2]*University of Pennsylvania, Philadelphia, United States of America;* [3]*Univ. of Rochester Med. Ctr., Rochester, United States of America;* [4]*Univ. of KY College of Med., Lexington, United States of America;* [5]*Medtronic, Inc., Heart Failure Management, Minneapolis, United States of America*

Cardiac resynchronization therapy (CRT) has been demonstrated in prospective, randomized, controlled trials to improve patient functional status and exercise capacity. CRT is currently delivered with simultaneous RV and LV pacing. Enhancement to CRT may be provided by adjusting the relative timing of the RV and LV activation (sequential biventricular pacing). The objective of this study was to compare the optimal sequential biventricular pacing interval to simultaneous biventricular pacing.
Methods: Heart failure patients with dilated cardiomyopathy and interventricular conduction delay were implanted with the InSync III CRT device. Pulsed-wave Doppler echocardiography was used to optimize each supine resting patient's A-V delay by maximizing LV filling, and then V-V timing by maximizing the velocity time integral measure of LV stroke volume at the aortic valve annulus. V-V timing was measured at both baseline and at 3 months at simultaneous (0), 20, 40, and 80 ms with either LV or RV first.
Results: In 300 pts (59% male, age = 66±11 yrs, QRS duration = 164±22 ms) included in this study, stroke volume was optimal at simultaneous biventricular pacing in 23% pts. and at sequential biventricular pacing with LV first in 54% pts. and with RV first in 23% pts. In 16% pts., sequential biventricular pacing provided a greater than 20% incremental improvement in stroke volume. Similar results were observed at 3 months (Figure).



Conclusions: This study demonstrated that in 77% of CRT pts., sequential biventricular pacing consistently provides an improvement in stroke volume compared to simultaneous biventricular pacing. These results suggest that independent pacing ability between the RV and LV provides an incremental hemodynamic benefit during cardiac resynchronization.

P2787 Optimized left ventricular systolic function through asynchronous biventricular pacing

K. Kurzidim[1], H. Reinke[2], T. Neumann[3], N. Guettler[3], A. Berkowitsch[3], J. Sperzel[3], C.W. Hamm[3], H.F. Pitschner[3]. *[1]Kerckhoff-Clinic, Cardiology, Bad Nauheim, Germany; [2]BIOTRONIK GmbH, Erlangen, Germany; [3]Kerckhoff-Clinic, Cardiology, Bad Nauheim, Germany*

Biventricular pacing (BiP) can improve left ventricular (LV) function in congestive heart failure (CHF) and left bundle branch block. Acute hemodynamic studies have shown that despite broad QRS isolated LV pacing (LVP) is often superior or equal to BiP. We investigated the impact of asynchronous BiP (asyBiP) on acute LV systolic function.

Methods: 13 pts (3 female, 6 ischemic CHF, 7 non-ischemic CHF), ejection-fraction 24± 8%, NYHA>3) were included. LV hemodynamic response was evaluated by the first derivative of LV pressure (+dP/dt) recorded by a catheter with micromanometer (Millar®). During atriobiventricular-pacing the AV intervall was optimized along the LV pressure curve and kept constant. For asyBiP 8 interventricular delays were tested (20 ms steps, ±80 ms).

Results: To ensure 100% pacing at an intrinsic intervall of 911±242 ms an average intervall of 744±113 ms was necessary. Compared to baseline +dP/dt (801±179 mmHg/s) the maximum hemodynamic response was obtained by asyBiP in 9 pts, BiP or LVP in 3 pts and RVP in 1 pt. In 2 pts neither pacing mode could increase LV+dP/dt. The optimized RV/LV -delay was highly variable ranging from -20 ms (RV stimulated first) to + 80 ms (LV stimulated first). In 8/9 pts with positive response by asyBiP the LV had to be stimulated ahead of the RV.

LV-systolic function and QRS duration

	RVP	LVP	BiP	AsyBiP
dP/dt (mmHtg/s)	865 (±221)	1054 (±261)*	1074 (± 287)*	1126 (±292)**
QRS (ms)	195 (±33)	208 (±37)	151 (±19)*	152 (±24)*

mean values (± standard deviation)*p<0.01 vs. RVP, **p<0.01 vs. BiP and LVP

Discussion: Asynchronous biventricular pacing may compensate differences in excitation propagation due to stimulation site. Synchronized LV contraction may therfore be achieved by asynchronous stimulation. Invasive testing prior to implantation allows resynchronization therapy to be adjusted to individual needs.

P2788 Left ventricular versus biventricular pacing in chronic heart failure: a stress-echocardiographic study

P. Fridl, J. Kautzner, P. Peichl, M. Buncova Jr, M. Vitovec, T. Marek, J. Bytesnik. *Institute Clin & Experimental Medicine, Department of Cardiology, Prague, Czech Republic*

Acute left ventricular (LV) pacing has been shown to improve hemodynamics in patients with chronic heart failure (CHF) and left bundle branch block to the same extent as biventricular (BI) pacing. However, less information is available on hemodynamic effect of LV pacing during exercise. To address this issue, LV vs BI pacing modes were compared during stress-testing echocardiography.

Methods: Study population consisted of 12 patients with CHF (3 women, age 65.3±8.8 years) due ischemic (n=4) or idiopathic dilated cardiomyopathy (n=7) and/or corrected aortic valve disease (n=1). At baseline, all patients presented with significant left ventricular dysfunction (LVEF 23.8±2.3%) and dilatation (LVEDD 74.4±7.3mm), and intraventricular conduction delay (QRS > 150 ms). They underwent BI pacing system implant (InSync III, Medtronic Inc) that allows separate pacing of the LV, and were evaluated more than 3 months later. Stroke volume (SV) was measured by echocardiography using VTI formula with a sample volume placed in the LV outflow tract (System V, GE-Vingmed) before and during each 3 min period of bicycle exercise with stepwise workload increase of 25 W (Marquette). Both blood pressure and heart rate were measured along with SV. Stress-test was performed in the morning on two consecutive days. Patients were randomly allocated to either BI pacing or to LV pacing mode with a cross-over on the next day.

Hemodynamic changes on exercise

Exercise step	No of pts	SV-BI (l/min)	SV-LV (l/min)	p<
Rest	12	3.01±0.62	3.39±0.57	0.01
25 W	12	4.22±0.89	4.79±1.05	0.01
50 W	11	5.36±1.14	5.64±1.11	n.s.
75 W	8	5.70±1.19	6.50±1.64	n.s.
100 W	3	5,96±0.92	6.73±1.44	n.s.

Results: Exercise tolerance was similar for both pacing modes and all patients terminated test for dyspnea. There were no significant differences in blood pressure during exercise in each pacing mode. Major study results are summarized in the table.

Conclusions: LV pacing results in better hemodynamic response as compared with BI pacing in patients with CHF, both at rest and during dynamic physical exercise. This finding provides support for controlled clinical studies comparing efficacy of LV and BI pacing modes.

P2789 Activation time difference between right and left ventricle – A potential new discrimination algorithm for biventricular ICDs

C. Stellbrink, A.M. Sinha, B. Diem, K. Mischke, P. Hanrath. *RWTH Aachen, Medizinische Klinik I, Aachen, Germany*

Cardiac resynchronization therapy (CRT) by biventricular (BV) pacing improves hemodynamics and functional capacity in patients (pts) with heart failure (HF) and left bundle branch block (LBBB). Many HF pts are at risk of developing sustained ventricular tachyarrhythmias (VT) and are thus in the need for implantable cardioverter-defibrillator (ICD) backup. Inadequate therapies due to supraventricular tachycardia (SVT) are still a limitation in modern ICDs and may be prevented by VT/SVT discrimination algorithms. We investigated whether the activation time difference (ATD) between right (RV) and left (LV) ventricular electrode may be used for VT/SVT discrimination in a BV-ICD. In 16 HF pts (15 males, 63±13 yrs., 7 ischemic, 9 non-ischemic HF, PR 229±63 ms, QRS 176±27 ms, all LBBB) an invasive electrophysiological (EP) study was performed placing EP catheters in the anterior interventricular (AIV), the posterior or lateral (PLV) vein, in the RV apex (RVA), then outflow tract (RVOT) and the high right atrium (HRA). Pacing was performed at cycle lengths (CL) of 500, 400 and 300 ms from proximal and distal AIV/PLV, RVA, RVOT and HRA; ATD between RVA/RVOT and the latest activated PLV site was measured at each pacing site/CL and during induced VT.

Results: 6 VTs were induced in 5 pts (mean CL 325±36 ms). For an ATD difference (Delta-ATD, sinus rhythm (SR) vs. paced/VT) cut-off of 20 ms specificity for VT detection was 100%, sensitivity 86.7% for all pacing sites and RVA or RVOT sensing. For RVA sensing and only LV pacing sensitivity increased to 96.1%, with addition of a V>A criterion to 100%. All induced VTs were correctly classified.

Conclusion: Measurement of RV-LV-ATD may be a new efficient VT/SVT discrimination algorithm for the use in BV-ICDs.

Abstract P2789 – Table: ATD results

Rhythm/pacing site	SR	RA	VA	VOT	IVprox	IVdist	LVprox	LVdist	T
ATD[RVA-PLV] (ms)	112±34	111±33	168±65	99±27	46±40	60±76	-169±40	-159±76	75±101
Delta-ATD[RVA-PLV] (ms)	—	4±5	66±59	28±25	81±44	72±57	278±51	263±87	101±63

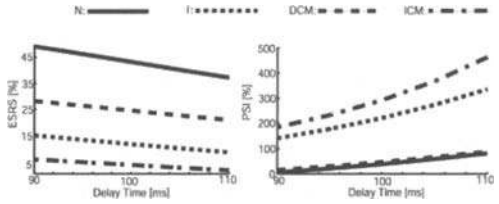
Delta-ATD[RVOT-PLV] (ms)	—	5±4	80±110	56±57	55±46	57±46	256±72	234±78	126±73

P2790 A simulation study to evaluate mechanisms underlying cardiac resynchronization therapy – Influence of delayed activation on regional deformation

P. Claus, B. Bijnens, L. Herbots, O. Breithardt, G.R. Sutherland. *University Hospital Gasthuisberg, Department of Cardiology, Leuven, Belgium*

Background: The mechanisms underlying cardiac resynchronisation therapy(CRT) for ischaemic and non-ischaemic dilated myopathies is poorly understood. Both segmental ischaemia and delayed activation result in deteriorating regional stroke volume.
Study Aim: To study the influence of regional delayed activation times(DAT) on deformation in normal(N) and ischaemic(I) non-dilated hearts and in dilated(DCM) and ischaemic dilated(ICM) cardiomyopathies.
Model description: A mathematical model of a left ventricular midlevel short-axis slice was established to enable the description of radial deformation in interacting segments with heterogeneous (a)elasticity and (b)onset, magnitude and duration of active contraction. Ischaemia can be simulated by a reduced and prolonged active force. The active force always subsided before aortic valve closure(AVC). End-Systolic Radial Strain(ESRS) and a Post-Systolic Index(PSI), i.e. the thickening after AVC versus ESRS, were calculated. Typical end-diastolic diameters (N,I: 5 cm; DCM,ICM: 10 cm) and a range of delay times (90-110 ms) were extracted from patient data.
Findings: Both dilation and ischaemia reduced the ESRS, with a greater reduction in ischaemia, while PSI increased with ischaemia, but depended less on dilation (Fig. 1). ESRS decreased and PSI increased with increasing DAT. For dilated hearts ESRS is less influenced by DAT, with a further decrease for ischaemia. PSI depended significantly less on DAT for N/DCM than for I/ICM.



Conclusions: These findings suggest that segments with DAT and I/ICM would benefit less significantly from CRT to increase their stroke work. The same conclusion does not hold for DCM since for large ventricles a small increase in ESRS results in a significant increase in stroke volume.

P2791 Cardiac resynchronisation therapy tailored by echocardiographic evaluation of ventricular asynchrony

G. Luzzi[1], M. Iacoviello[1], R. Romito[2], P. Guida[1], A. Andriani[1], B. Rizzon[1], P. Rizzon[1], M.V. Pitzalis[1]. [1]*University of Bari, Institute of Cardiology, Bari, Italy;* [2]*S. Maugeri Foundation, Cardiology Dept., Cassano M, Italy*

Cardiac resynchronisation therapy (CRT) is a promising strategy in patients with severe heart failure (HF) and left bundle branch block (LBBB). However, no criteria are yet available to predict which patients will gain. The aim of this study was to investigate the value of inter- and intra-ventricular echocardiographic asynchrony parameters in predicting reverse remodelling after CRT.
We studied 20 patients (63±10 years, 8 male) with advanced HF (4 with ischemic and 16 with non-ischemic cardiomyopathy) and LBBB (QRS duration =>140 ms). Before pacemaker implantation, left ventricular asynchrony was assessed using echo-Doppler by calculating septal-to-posterior wall motion delay (SPWMD, i.e the shortest interval between the maximum posterior displacement of the septum and the maximum displacement of the left posterior wall during systole) and left ventricular electromechanical delay (LVEMD, i.e. the time between the onset of QRS and aortic flow). Inter-ventricular asynchrony (inter-ventricular delay, IVD) was evaluated by measuring the difference between the LVEMD and the right electromechanical delay (i.e. the time between the onset of QRS and pulmonary flow). Left ventricular end-diastolic (LVEDVI) and end-systolic (LVESVI) volume indexed for body surface area were calculated before and one month after implantation. The patients with a reduction in LVESVI >15% were considered responders.
CRT significantly improved LVEDVI (from 150±53 to 119±37 ml/m^2, p<0.001) and LVESVI (from 116±43 to 85±29 ml/m^2, p<0.0001). The responders showed a SPWMD significantly longer than non-responders (246±68 ms vs 110±55 ms, p<0.001). No differences were found between responders and non-responders in terms of QRS duration (173±18 ms vs 164±12 ms, p=NS), LVEMD (126±40 ms vs 163±55 ms, p=NS) and IVD (59±19 ms vs 73±21 ms, p=NS). All responders had a SPWMD > 130 ms. At this cut-off the specificity in predicting reverse remodelling was 63%, with a positive predictive value of 80% and an accuracy of 85%.
In conclusion, in patients with advanced HF and LBBB, baseline SPWMD is a strong predictor of the occurrence of reverse remodelling after CRT, thus suggesting its usefulness in identifying patients likely to benefit from biventricular pacing.

P2792 Improvement of cardiac efficiency by resynchronization therapy in dilated cardiomyopathy studied noninvasively with positron emission tomography

D. Baller[1], J. Vogt[1], B. Lamp[1], O. Lindner[2], J. Holzinger[2], A. Kammeier[2], W. Burchert[2], D. Horstkotte[1]. [1]*Heart Center North Rhine-Westphalia, Department of Cardiology, Bad Oeynhausen, Germany;* [2]*Heart Center North Rhine-Westphalia, Inst Mol Biophys, Radiopharm, Nucl Med, Bad Oeynhausen, Germany*

Experimental investigations of our group had indicated adverse effects of both left bundle branch block (LBBB) and right ventricular pacing on cardiac efficiency that could be reversed by resynchronization (RT). Clinically, we examined the effects of RT by use of positron emission tomography (PET).
Patient characteristics and methods: 28 patients (pts) (11 females; age 63±7 y; EF 23±7%, NYHA class III; QRS duration 190±19 msec) with advanced DCM were studied before and 3-4 months after RT. PET data analysis: C-11 acetate clearance (k2-value; ~370 MBq C-11 acetate) was determined in a 1-compartment model as an index of myocardial oxygen consumption (MVO2). K2 (1/min) was related to individual rate-pressure product (RPP). In addition, myocardial blood flow (MBF) was measured quantitatively from C-11 acetate kinetics in a 20-segment model (polar maps) for parametric description.
Results: After RT mean K2-values of the left ventricle significantly decreased from 0.082±0.02 to 0.072±0.02 (p<0.001). Cardiac efficiency, estimated from pressure work related K2-ratio, increased by about 11.4%. Concomitantly, MBF related to RPP (7281±1709 vs. 8441±1985 after RT), decreased from 54±0.2 to 47±0.13 ml/min x 100 g (p<0.001) after RT. Regional MVO2 analysis of mainly involved regions (septal/lateral ratio) showed a normalization (1.0 vs. 0.83; p<0.01) after RT.
Conclusions: 1. RT improves cardiac efficiency in pts with DCM and LBBB estimated from noninvasive indices of pressure work and MVO2. 2. RT reversed inhomogeneity of regional MVO2 due to asynchronous contraction.

SIGNAL AVERAGED ELECTROCARDIOGRAM

P2793 P-wave signal-averaged electrocardiogram after successful cardioversion of acute and persistent atrial fibrillation

M. Buncova, J. Bytesník. *IKEM, Cardiology department, Prague, Czech Republic*

A prolonged P wave in signal averaged high resolution ECG (P-SAECG) may indicate the presence of an impaired intra- and interatrial conduction, which could be a predisposing factor for atrial fibrillation (AF). The aim of the study was to evaluate the changes of P-SAECG in sinus rhythm restored in patients with different duration of AF.
Methods and Results: We evaluated 37 patients (29 males, age 62 ±12 y) after successful cardioversion (CV) of AF persistent more than one month (group A) and 20 patients (15 males, age 63±15 y) after CV of acute AF with duration less than 48 hours (group B). The control group consisted of 21 healthy subjects(11 males, 62±11 y) without history of AF and/or organic cardiac disease. We measured the filtred P wave duration and the root mean square voltage in terminal 20 ms of P wave (RMS 20), using the analysis of three orthogonal ECG leads (MAC 5000, Marquette). Left atrial diameter (LAD) and left ventricular ejection fraction (LVEF) were evaluated by 2D-echocardiography.
Results: Comparison of filtered P wave duration and LAD parameters for both AF patient groups is shown in the Table. Although filtered P wave duration was significantly longer and LAD significantly greater in group A as compared with control subjects, no such a difference was found between group B and controls.

Characteristics of group A and B

	Group A (n=37)	Group B (n=20)	P value
Age	62.2 ±12.1	63.0 ± 14.6	NS
LVEF (%)	57.4 ± 12.1	63.2 ± 5.9	NS
LAD (mm)	44.8 ± 6.2	37.5 ± 4.9	< 0.001
Mitral valve disease	10.8%	10.0%	NS
Amiodarone	27%	25%	NS
Propafenone	14%	20%	NS
P wave duration (ms)	173.0 ± 47.9	132.5 ± 21.1	< 0.001
RMS 20 (ms)	3.2 ± 1.8	4.2 ± 3.0	NS
Noise level (uV)	0.49 ± 0.20	0.44 ± 0.14	NS

Conclusion: Significant prolongation of the P wave duration in high resolution ECG after longer period of atrial fibrillation could reflect atrial electrophysiological remodeling caused by this tachyarrhythmia.

P2794 P-wave signal-averaged time domain parameters in interatrial septum pacing and dual site right atrial pacing

D. Szczesniak, A. Kutarski, T. Widomska-Czekajska. *University Medical Academy of Lublin, Department of Cardiology, Lublin, Poland*

Interatrial conduction disturbances (IACD) are the known substrate of re-entrant atrial arrhythmias and atrial pacing modes providing more symmetrical activation both of atria consist promising chance for this pts. The time domain of the signal-averaged (SA) P wave is considered as an easy and valuable method to investigate the electrophysiological properties of atrial myocardium. Promising results obtained previously by Padeletti and by us using only single site CS ostium region pacing inspired us for this study. Its aim was the comparison of influence of low-posterior interatrial septum pacing (IAS) and dual site (RAA+IAS) of right atrium pacing (DuRA) on SA P wave parameters.

Patients & methods: We examined 19 patients with dual site right atrial pacing system. Examinations were performed during IAS (SSI UP pacing program – cathode was connected to IAS lead) and DuRA pacing (SSI BP pacing program) 80 bpm. We analyzed the time domain of the signal averaged (SA) P wave from three orthogonal bipolar leads (XYZ) during pacing using both pacing modes. We considered three parameters: SA P wave duration, the root mean square voltage of the last 20 ms of SA P wave (RMS20) and the duration of oscillations lower than 5mV of the final part of the P vector magnitude (LAS5) as well as the presence of atrial late potentials (LP) criteria.

Results:

Parameters/average (SD)	IAS pacing	DuRA pacing	p
SA P wave duration	133.1(19.6)	131.2(15.8)	0.59
SA P wave RMS 20	3.2(1.21)	2.7(0.66)	0.06
SA P wave LAS 5	5.88(3.64)	6.13(4.3)	0.8
Atrial LP criteria*	4	5	-

*Atrial LP criteria–P wave duration > 125ms, RMS20<2,4mV, statistically significant p<0,05

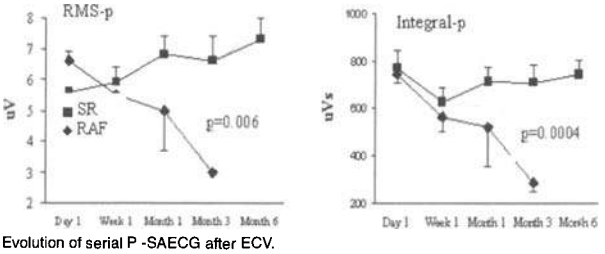
The SA P wave time domain parameters analysis indicates, that there is no statistically significant differences between IAS pacing and DuRA pacing in the examined group of patients.

Conclusion: Low-posterior IAS pacing shows similar effects to DuRA pacing; it can to confirm utility this simple pacing mode for pts. with atrial arrhythmias.

P2795 Prognostic significance of serial P-wave signal-averaged electrocardiogram following electrical cardioversion of atrial fibrillation: a prospective study

X. Guo, M.M Gallagher, J. Polonieki, Y. Gang, M. Malik, A.J Camm. *St George's Hospital Medical School, Cardiological Sciences, London, United Kingdom*

We hypothesise that the persistence of delayed atrial conduction detected by serial P-wave SAECG (P-SAECG) can identify pts who may recur atrial fibrillation (R-AF) after external electrical cardioversion (ECV). P-SAECGs were recorded on 60 pts after ECV for persistent AF(53 men, 66 ± 10 yrs) and repeated on pts maintained sinus rhythm (SR) 1-week (w), 1-month (m), 3 and 6m later. Filtered P wave duration (PD), RMS of the terminal 40, 30, 20 ms (RMS-40, 30, 20) of the filtered P wave, RMS of the entire filtered P wave (RMS-P) and the integral of voltages in entire P wave (integral-p) were obtained from each recording. Of 60 pts, 31(52%) returned to AF within 1w, 11(18%) between 1w and 1m, 2(3.3%) between 1 and 3m and 2(3.3%) returned to AF between 3 and 6m. There were no significant differences between pts with(n=46) and without R-AF(n=14) in clinical variables except AF duration. The pts with R-AF had longer PD (157±24 vs. 143±17ms, p<0.0001) and lower RMS-40, RMS-30, RMS-20 (5.3±2 vs. 6.1±3.4 μV; 4.3±1.5 vs. 5.7±3.2 μV; 3.6±1.4 vs. 5.2±3 μV, all p<0.007, respectively) than pts with SR. Above 4 indices did not change significantly over time, however the RMS-p was increased in SR pts (p=0.009) whilst a reduction was noted in R-AF group(p=0.032), integral-p was only decreased in R-AF group (p=0.0028). In RMS-P and integral-p (Fig) the difference between SR and R-AF slopes were significant.



Evolution of serial P -SAECG after ECV.

The inclusion of dynamic changes in PD and RMS-p in the 1w recording in the definition of an abnormal P-SAECG provided improved predictive power compared to analysis of the P-SAECG at day 1 alone. Sensitivity for detecting R-AF between 8-30 days was increased from 72.7 to 100% and positive predictive accuracy from 72.7 to 84.6%.

Conclusion: Serial P-SAECG following ECV can be used to predict AF recurrence.

P2796 Late potentials in patients with acute myocardial infarction treated with thrombolytic therapy-are they predict the long-term prognosis?

B. Stefanovic, P. Mitrovic, Z. Vasiljevic, G. Matic, A. Milosevic, M. Grujic. *Belgrade, Yugoslavia*

Background: Signal averaged ECG is useful non-invasive tool for detecting patients at risk for sudden cardiac death after acute myocardial infarction. The aim of the study was to estimate prognostic significance of ventricular late potentials in pts with AMI treated with thrombolytic therapy during the long-term follow-up.

Method: The 281 pts with AMI treated with intravenous streptokinase and discharged alive were followed-up to 10 years. There were 85% male, mean age 55 ± 9 years (range 32-77). Signal-averaged ECG was performed within 1 month after AMI. Late potentials were considered positive if 2 of 3 criteria were found. Positive LPs had 52 (18.5%)-group I, and negative LPs 229 (81.5%) pts-group II. There were no significant differences between groups in gender, age, history of diabetes, previous infarct, QRS score, Killip class, peak CPK level, left ventricular end-systolic volume and ejection fraction.(p=NS). Patients with positive LPs had a higher mean end-diastolic volume (p<0.02), as well as more occluded IRA (p<0.03) than those with negative LPs.

Results: During 10-year follow-up 67 (23.8%) pts died: 22 in group I and 45 in group II, (42.3% vs. 19.7%, p<0.0005). A half of all deaths were sudden cardiac deaths (SCD), 34/67 (51%). SCD was recorded in 11 pts with positive and 23 pts with negative LPs (21.1% vs.10.0%, p<0.05). Actuarial curves comparing all cause death-free survival in those groups were estimated. There was significant difference between groups I and II after 16, 32, 48, 64, 80, 96 and 108 months, respectively: 88.5% vs. 96.5%; 78.8% vs. 93.9%; 76.9% vs. 91.7%; 66.8% vs. 88.5%; 64.5% vs. 83.8%; 61.6% vs. 78.8%; 54.8% vs. 77.2%. (p<0.000). Likewise, actuarial curves comparing SCD-free survival differed significantly between groups I and II after 16, 32, 48, 64, 80, 96 and 108 months, consecutively: 94.0% vs. 98.2%; 87.8% vs. 96.4%; 85.6% vs. 95.9%; 83.3% vs. 94.6%; 80.3% vs. 91.2%; 80.3% vs. 89.1%; 75.8% vs.87.3%.(p<0.02)

Conclusion: Presence of positive LPs in patients with acute myocardial infarction treated with thrombolytic therapy is a significant predictor of sudden cardiac death and overall mortality during long-term follow-up. Patients with positive LPs had more occluded IRA and higher mean EDV.

P2797 Late potentials in arrhythmogenic right ventricular cardiomyopathy: long-term follow-up

A.F. Folino[1], B. Bauce[2], G. Frigo[2], P. Michieli[1], A. Nava[2]. [1]*University of Padua, Department of Cardiology, Padova, Italy;* [2]*University of Padua, Department of Cardiology, Padua, Italy*

The aim of our study was to evaluate the modifications of late potentials during a long-term follow-up in patients with arrhythmogenic right ventricular cardiomyopathy, and to compare these results with the echocardiographic findings during the same period. We studied 20 consecutive patients (12 males, 8 females) with a mean age of 27±14yrs. After the baseline visit, all of them were followed by outpatients controls every 2 years until 8 years. At each visit they underwent signal averaging ECG and echocardiography with measurements of left and right ventricle volumes and ejection fractions. The two filter settings considered showed a similar behaviour, with a progressive increase of late potentials through alternate phases of increment and reduction (table). Echocardiographic indexes did not show significant modifications during follow-up.

Signal-averaging ECG parameters

	Visit 1	Visit 2	Visit 3	Visit 4	Visit 5
5O-250Hz					
QRS	127±12	133±11	127±13	128±13	135±19
HFLA	26±10	26±11	27±12	28±10	31±14
RMS	59±57	38±20	51±50	43±35	40±31
40-250Hz					
QRS	119±15	127±16	122±16	121±12	128±19
HFLA	38±13	43±18	42±14	44±12	48±21
RMS	27±16	21±16	22±16	21±16	19±12

Values are expressed as mean ± standard deviation. QRS: filtered QRS duration; HFLA: high frequency low amplitude signals duration in the terminal portion of QRS; RMS: root mean square voltage in the last 40ms of the filtered QRS.

In conclusion, signal averaged ECG puts in evidence a progressive extension of zones with delayed conduction, that is not related with noticeable modifications detectable by echocardiography. Transient reductions of late potentials could reflect the formation of compact fibrotic/fatty tissue, with a complete substitution of myocardial fibres with delayed conduction.

P2798 Prognostic value of the signal-averaged P-wave for the recurrence of atrial fibrillation after successful cardioversion

M. Hofmann, L. Goedel-Meinen, K. Koppitz. *Deutsches Herzzentrum, München, Germany*

The aim of this prospective study was to assess the prognostic value of the signal-averaged p wave for the recurrence of atrial fibrillation (AF) after successful electrical cardioversion (CV). In 57 patients (11 women, 46 men; mean age 61 years) who had had sinus rhythm(SR) restored the day before, a signal-averaged ECG of the p wave was recorded and analysed using unidirectional, bidirectional and FIR filters. Four weeks and 12 months later, all patients were evaluated for the recurrence of AF.

Results: After cardioversion, 10 pts (18%) had a normal p wave <138.5 ms in the signal averaged ECG. Four weeks later, 22 pts (39%) had atrial fibrillation; their mean p wave duration in the first signal-averaged ECG had been 157 ms. The 34 pts who still remained in SR had had a mean p wave duration of 148 ms (P=0.07). Kaplan Meyer graphs of the AF recurrence-free periods over the entire 12-month-interval show overlapping curves of the two groups with normal and prolonged p wave durations (log rank test: P=0.62). Results were comparable when bidirectional and FIR filters were used, including parameters like root mean square voltage.

Conclusion: In spite of a tendency towards longer p waves in the AF recurrence group, the signal averaged ECG of the p wave is not a useful method to predict the recurrence of atrial fibrillation in patients after successful electrical cardioversion. Only a small proportion of signal averaged p waves qualifies as "normal" after a period of atrial fibrillation and consequent electrical cardioversion.

P2799 Transcoronary ablation of septal hypertrophy for HOCM. No evidence for the induction of an arrhythmogenic substrate

F.H. Gietzen, M. Bartelsmeier, T.H. Lawrenz, L. Obergassel, C. Strunk-Mueller, C.H.J. Leuner, H. Kuhn. *Staedtische Kliniken Bielefeld, Medizinische Klinik II, Bielefeld, Germany*

Transcoronary ablation of septal hypertrophy (TASH) is a catheter interventional therapy for HOCM. However, for reduction of septal thickness, elimination of outflow obstruction and improvement of symptoms, the injection of 96% ethanol (2.6±1.6 ml) into a septal branch as well as the induction of a septal necrosis (~3% of the left ventricular mass) had to be accepted. Consideration had to be given predominantly to the possibility of the induction of an arrhythmogenic substrate with subsequently enhanced risk of sudden cardiac death.

To evaluate the influence of TASH on the signal-averaged ECG (SAECG) a time domain analysis was performed in 30 consecutive pts. (17 men, 51±16 y., prior syncope in 11) with sinus rhythm and normal intraventicular conduction before and after intervention. The results were correlated to haemodynamic and electrophysiologic parameters including programmed ventricular stimulation (PVS) at 2 right ventricular sides with up to 3 extrastimuli. Clinical information is obtained with a max. of 68 months after TASH (average 37±16 months).

Two weeks and six months after septal infarction the QRS duration (from 102±12 to 101±20 to 100±10 ms), the amplitude in the last 40 ms of the filtered QRS-complex (RMS) (from 69±44 to 61±41 to 63±42 μV) and the duration of late potentials (LAS) (from 26±9 to 26±10 to 25±8 ms) remained unchanged despite a peak CK-activity of 453±227 U/L induced. Furthermore, with regard to the Simson rules 25 out of 27 initially "late potential negative" pts. remained without evidence for a newly developed abnormal SAECG. This was accompanied by a lack of inducebility at PVS in all pts. investigated. During follow up non of the 30 pts. enrolled suffered an arrhythmogenic event like sustained ventricular arrhythmia or death.

Conclusion: With regard to time domain analysis of the signal-averaged ECG a TASH induced septal necrosis remained without evidence for the induction of an arrhythmogenic substrate. However, further investigations and a longer follow up in a larger number of pts. are needed.

SUDDEN DEATH – RESUSCITATION

P2800 Dispatch delay of first responders in out-of-hospital cardiac arrest limits its benefit

A.P. Van Alem, R. Vrenken, R.W. Koster. *Academic Medical Center, Cardiology, Amsterdam, Netherlands*

Objective: Early defibrillation by first responders can significantly improve survival of out-of-hospital cardiac arrest. For early defibrillation travel-time of the first responder but also the rapid dispatch is crucial. We analyzed the functioning of the dispatch system in the Netherlands.

Methods: Medical calls to the central alarmnumber 112 are directed to the emergency medical system (EMS) dispatch center (DC). When the EMS DC receives a call concerning a cardiac arrest, 2 ambulances are sent and the police or fire DC, depending on the region, is alarmed. The police or fire DC directs a police patrol or fire engine with AED to the scene. All relevant time points and time intervals, corrected to a standard clock, were obtained from interviewing of witnesses at the scene, the system information of the DCs and the time registration of the defibrillators.

Results: 479 bystander-witnessed cardiac arrest were analyzed. In 138 calls a fire engine and in 341 calls a police patrol was dispatched as first responder. In the table the time intervals of dispatching the EMS and first responder are shown.

	EMS	Police	Fire fighters
Collapse to call EMS	120 (60-224)	120 (60-210)	120 (60-240)
Call EMS to call first responder DC	N/A	120 (60-189)	154 (81-271)
Call first responder DC to dispatch first responder	N/A	60 (0-60)	60 (60-127)
Call EMS to dispatch	120 (90-180)	184 (120-274)	259 (183-360)
Driving time	300 (240-435)	180 (120-300)	180 (120-261)
Collapse to arrival	607 (480-818)	540 (411-720)	632 (519-855)
Arrival at the scene to shock (in case of VF)	144 (86-225)	125 (77-186)	130 (74-180)

Time interval in seconds, median (25%-75%)

Conclusion: Driving time of first responders is very short, but much time is lost in decisions in EMS dispatch centers and in communication between dispatch centers. To optimize a first responder project separate dispatch centers must integrate and speed up dispatch decisions.

P2801 Sudden death in children and young adults: still cases of unknown cause

E. Karvouni[1], A. Anastasakis[1], C. Spiliopoulou[2], N. Protonotarios[1], A. Theopistou[1], A. Rigopoulos[1], M. Agapitos[3], P. Toutouzas[1]. *[1]University of Athens, Cardiology Department, Athens, Greece; [2]University of Athens, Department of Forensic Medicine, Athens, Greece; [3]University of Athens, Department of Pathology, Athens, Greece*

Aim: Aim of the study was to investigate the causes of sudden death (SD) in the young in a representative Greek population.

Methods: We recorded consecutive cases of SD in children and young adults(1-35 years) in the region of Attica and Cyclades during a 4-year period and identified the cause of death according to pathological examination.

Results: We recorded 130 consecutive cases of SD. Eighty-nine (69%) were males (mean age 27.0±8.6 yrs) and 41 (31%) females (mean age 24.3±10.0 yrs) (p=0.11). SD was of cardiovascular origin in 96 (74%) cases. In 29 (22%) cases, the cause of SD remained unknown despite detailed pathological investigation. In 37(28%) cases, SD occurred at age range 1-20, while in 93(72%) cases in age between 21-35 years. In age group 1-20, the most frequent cardiac cause of SD was hypertrophic cardiomyopathy (HCM) (9 cases, 24%). In age group 21-35, atherosclerotic coronary artery disease (CAD) was the leading cause of SD (26 cases, 28%). In males, atherosclerotic CAD was the most frequent cause of SD (25 cases, 28%). In females, the majority of SD cases was of unknown cause (12 cases, 29%).

Causes of sudden death

Causes of SD	SD cases (%)
Cardiac causes	80 (62%)
– Atherosclerotic CAD	27(34%)
– HCM	16(20%)
– Congenital heart disease	12(15%)
– Myocarditis	4(5%)
– Dilated cardiomyopathy	4(5%)
– Unclassified cardiomyopathy	3(4%)
– Naxos disease	2(2%)
– Arrhythmogenic right ventricular cardiomyopathy	1(1%)
– Myocardial ischemia	1(1%)
Vascular causes	16(12%)
Non-cardiovascular causes	5(4%)
Unknown cause	29(22%)

Conclusions: SD in children and young adults is of cardiovascular origin in the majority of cases. A considerable number of SD cases in the young remain of unknown cause despite detailed investigation, especially in females. There is a preponderance of male gender in the SD young population.

P2802 Prolonged cardiopulmonary resuscitation should be not a contraindication for the thrombolytic therapy in acute myocardial infarction

G. Tatu-Chitoiu, C. Teodorescu, M. Dan, M. Guran, P. Capraru, O. Istratescu-Wolkowski, M. Dorobantu. *Spitalul de Urgenta, Card. Dept., Bucharest, Romania*

Background: Taking into consideration a potential risk for internal bleeding, the ACC/AHA and the ESC guidelines consider prolonged or traumatic cardiopulmonary resuscitation (CPR) as a relative contraindication for thrombolysis in acute myocardial infarction (AMI).
Objective: Safety and efficacy of thrombolysis in a group of patients (pts.) with AMI and prolonged CPR have been studied.
Methods: In a group of 946 consecutive pts. with ST segment elevation AMI treated with thrombolysis (Streptokinase 1.5 MU/20-60 min.) within the first 6 hours after the onset of the chest pain we identified 51 pts. (18 females, 33 males, age 62±12) who underwent more than 10 min. of CPR. CPR was performed by a trained personnel according to the European Resuscitation Council,s (ERC) Guidelines for basic and advanced life support.In 18 pts. CPR was performed before, in 20 pts. during and in 13 pts. immediately after thrombolysis. Sixteen pts. (39%) were in Killip class I, 10 pts (24.4%) in class II, 7 pts (17.3%) in class III and 8 (18.5%) in class IV. All pts. who survived received aspirin and heparin 1000 i.u./hour, 48-72 hours. Autopsy was performed in all pts. who died. The incidence of the minor and major haemorrhagic events have been evaluated.
Results: The average time of CPR was 26 ±15 min. (limits: 10-60 min.). Seventeen pts. (33.3%) survived. Major bleeding was registered in 4 pts. (9.2%) (hemathemesis in all 4) but this complication was not a cause of death. Minor bleedings were registered in 8 pts. (18.5%). No stroke was registered in this group. Autopsy performed in the 34 pts. who died did not show any sign of serious intra thoracic or intra abdominal bleeding.
Conclusions: Prolonged CPR performed in pts. thrombolised for AMI according to the ERC Guidelines does not increase the risk for serious internal bleedings. Our data suggest that prolonged CPR should be not considered as a contraindication for the thrombolytic therapy.

P2803 Epidemiological pattern and prediction of sudden cardiac death after myocardial infarction in patients with optimized beta-blocking therapy

H.V. Huikuri[1], J.M. Tapanainen[2], K. Lindgren[2], P. Raatikainen[2], T.H. Mäkikallio[2], R.J. Myerburg[3]. *[1]University of Oulu, Dept. of Int. Med., Div. of Cardiology, Oulu, Finland; [2]University of Oulu, Dept. of Int. Med., Div. of Cardiology, Oulu, Finland; [3]Miami University Medical Center, Florida, United States of America*

Background: Data from various sources have shown that one half of cardiac deaths are sudden occurring mostly within the first year after an acute myocardial infarction (AMI), and that some arrhythmia risk variables are able to predict the occurrence of sudden cardiac death (SCD). We studied whether the prediction and epidemiological pattern of SCD will change, if the medical therapy of the patients is optimized according to contemporary guidelines after the AMI.
Methods and Results: A consecutive series of 700 patients (mean age 62± 10years, 182 females and 518 males) with an AMI was included in this single-center, prospective follow-up study. The end-points were non-SCD, SCD, and arrhythmia events. Arrhythmia risk variables, such as non-sustained ventricular tachycardia (VT), heart rate variability, baroreflex sensitivity, signal averaged electrocardiogram (SAECG) and QT dispersion were analyzed among the patients who were discharged alive from the hospital (n=675). Cardiac medication was optimized according to contemporary guidelines with special emphasis on the implementation of long-term beta-blocking therapy, which was used by 97% of the patients at the time of discharge from hospital and by
95% at one year after the AMI, respectively. During the mean follow-up of 40±14 months, 34 non-sudden (5.0%), and 19 sudden (2.8%) cardiac deaths occurred, and 15 patients had an arrhythmia event (2.2%). Only few SCDs (3/19, 16%) and arrhythmia events (3/15, 20%) occurred during the first 12 months after the AMI compared to non-SCDs (18/34, 53%) ($p<0.01$ for both). Most of the arrhythmia risk variables, e.g. non-sustained VT, QT dispersion, baroreflex sensitivity and SAECG predicted the occurrence of non-SCD ($p<0.05$ for all) but not the SCD (NS for all).
Conclusions: The epidemiological pattern of SCD is different from that reported earlier among the post-AMI patients in whom the beta-blocking medication has been optimized. The common arrhythmia risk variables seem to lose their power as predictors of SCD among these patients.

P2804 Death due to pulmonary embolism: a post mortem study

M D. Stewart[1], H H. Gray[2], P. Gallagher[3]. *[1]Southampton General Hospital, Wessex Cardiac Unit, Southampton, United Kingdom; [2]Southampton General Hospital, Wessex Cardiac Unit, Southampton, United Kingdom; [3]University of Southampton, Department of Pathology, Southampton, United Kingdom*

Pulmonary embolism (PE) is reported to be the third commonest cardiovascular cause of death. Despite an increased awareness of the need for thromboprohylaxis, a significant number of deaths due to PE still occur without the condition being considered or recognised. We present the results of a post mortem review carried out as part of an epidemiological study into the incidence of PE in Southampton, UK (population of 430,408).
Over a one-year period from June 2000 to May 2001 all post mortem examinations performed in Southampton University Trust hospitals were reviewed for evidence of PE. 1164 post mortem examinations were performed during the study period, with evidence of pulmonary thromboembolism being identified in 87 cases, giving an overall post mortem incidence of 7.5% [95%CI, 5.96% - 8.98%]. Of the 1164 deaths, 668 were sudden or unexplained (57.4%), 514 of these occurring in the community (76.9%) and 154 in hospitalised patients (23.1%). PE was identified as the main or significant contributor to the cause of these sudden/unexpected deaths in 42 community and 20 hospital cases (8.2% and 13.0% of cases respectively).
PE remains a significant cause of death in the UK, both in community and hospital settings, despite an increased awareness and recommendations for the use of thromboprophylactic precautions. At post mortem, PE can be identified as the cause of almost 1 in 10 sudden or unexpected deaths.

P2805 Revascularisation after aborted sudden death: the most important treatment option for secondary prevention? Substudy from the LOHCAT trial

A.E. Borger van der Burg, L. van Erven, M. Bootsma, E.E. van der Wall, M.J. Schalij. *Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Introduction: Life-threatening ventricular arrhythmias (VA) occur frequently in pts with coronary artery disease. The risk of recurrence of VA is according to the literature over 30% per year, so carefull evaluation is mandatory to determine the optimum treatment strategy for these pts. We prospectively evaluated the effects of revascularisation of survivors of sudden cardiac death. The Leiden Out of Hospital Cardiac Arrest Trial (LOHCAT) applies a standardized screening protocol in pts with VA.
Methods: The LOHCAT screening protocol includes: echocardiography, nuclear imaging, coronary angiography and an EP study. Pts with primary VF due to acute myocardial infarction (<48 hours) were excluded.
Results: From 1994 until 2001, 444 consecutive survivors of sudden cardiac death are included (350 male, 59±13 yrs, VF:235, VT:209). After evaluation coronary revascularisation was performed in 90 (20%) pts (45 pts CABG, 40 pts PTCA, 5 pts both CABG and PTCA). LV ejection fraction was 42±21%. Four pts died post operatively. All pts were inducible before revascularisation. The effects of revascularisation on inducibility of VT/VF were evaluated after the procedures with an EP study (37 pts were not inducible anymore). Before discharge, an ICD implantation was performed in 48 pts (56%) (3 underwent catheter ablation of VT as well) and one pt underwent catheter ablation of VT. Anti arrhythmic drugs were used by 36 pts. During follow-up (32±29 mos) 4 pts died (none of them due to VA). Recurrences were observed in 10 (12%) pts (9 with ICD back up, 5 shocks/pt, and one patient with AAD).
Conclusion: Revascularisation after aborted sudden death due to VA is a successful approach. The risk for recurrence decreases significantly to 12% in our study population during a follow-up of nearly three years. No patient died due to recurrent VA.

P2806 Age-dependency of various causes of sudden cardiac death in the young

C. Basso, D. Corrado, G. Thiene. *University of Padua, Pathology, Padova, Italy*

Objective: The aim of the present study was the establish the age-distribution of various causes of sudden cardiac death (SCD) in a series of young people (aged 1-35 yrs) who suffered cardiac arrest.
Design and Results. In the time interval 1980-2001, 317 (91 female and 226 male) consecutive cases of SCD in the young in Northeast of Italy have been prospectively studied according to a detailed pathology protocol as well as clinico-pathologic correlation. Cardiac arrest was mechanical in 21 (7%) due to aortic rupture (14), pulmonary embolism (5) or haemorrhagic shock (2). In the remaining 296 (93%) SCD was arrhythmic and major causes included atherosclerotic coronary artery disease (CAD 61,19%), arrhythmogenic right ventricular cardiomyopathy (ARVC 42, 13%), myocarditis (36, 11%), valve disease (31, 10%), conduction system disease (27, 8%), hypertrophic cardiomyopathy (28, 9%), congenital CAD (21, 7%), dilated cardiomyopathy (13, 4%), acquired non-atherosclerotic CAD (9, 3%) and postoperative congenital heart disease (5, 2%). In 23 cases (7%) no evidence of structural heart disease was found ("mors sine materia").
By ANOVA test a statistically significant difference in terms of mean age was found between subgroups of patients with different causes of SCD. In particular, mean age of patients who died suddenly due to atherosclerotic CAD was higher than that of patients with other cardiovascular substrates (29.8 vs 23.2 yrs, $p<0.0001$). We then subdivided the study population in four age-groups, ie group I <10 yrs(5%), group II 10-19 (19.5%), group III 20-29 (43.5%), and group IV 30-35 (32%), to analyze the distribution of various causes of SCD in the different age-intervals. In group I hypertrophic cardiomyopathy was the leading cause (25%) followed by congenital CAD (19%). In group II the leading cause was ARVC (18%) followed by congenital CAD (13%) and myocarditis (13%). In group III major causes of SCD were atherosclerotic CAD and ARVC (16% both). Atherosclerotic CAD was the leading cause in group IV accounting for 35% of all SCDs (vs 16% group III and none in group I and II).
Conclusions: The disorders responsible for SCD in children and adolescents are different from those in people older than 30 yrs. In the last segment of population, atherosclerotic CAD is by far the most common cause accounting for more than one-third of all SCDs. On the other hand children and adolescents die more often due to congenital abnormalities or myocarditis.

P2807 Sudden unexpected death in children with a previously diagnosed heart defect

F.N. Polderman[1], J. Cohen[1], N. Blom[2], T. Delhaas[3], W.A. Helbing[4], J. Lam[5], M. Sobotka-Plojhar[6], N. Sreeram[1]. *[1]Wilhelmina Children's Hospital, Dept of Cardiology, utrecht, Netherlands; [2]Academic Hospital Leiden, Dept of cardiology, Leiden, Netherlands; [3]Academic Hospital Maastricht, Dept of cardiology, Maastricht, Netherlands; [4]Sophia Children's Hospital, Dept of Cardiology, Rotterdam, Netherlands; [5]Academic Medical Center, Dept of cardiology, Amsterdam, Netherlands; [6]Vrije Universiteit, Dept of cardiology, Amsterdam, Netherlands*

Objectives: the aim of the study was to identify all infants and children within the Netherlands with previously diagnosed heart disease who had a sudden and unexpected death (SUD), and to identify the possible cause of death.
Background: It is known that children with previously diagnosed heart defects die suddenly. The causes of death are often unknown.
Methods: All children (<19 years) with a previously diagnosed heart defect and SUD between January 1990 and June 2001 presenting to 7 of 8 tertiary centers in the Netherlands were identified using hospital databases. We excluded patients receiving compassionate care. Diagnoses, clinical status and circumstances of death were sought from casenotes and postmortem reports. Deaths were classified as of cardiac or non-cardiac origin.
Results: We identified 150 cases of SUD (89 male) at a median age of 2.3years (18 days - 18.9 years); 49/150 patients (33%) were <1 year. Diagnostic categories included left to right shunts (N=34, 14 <1 year), cyanotic lesions (N=38, 13 <1 year), cardiomyopathy (N=11, 2 <1 year), univentricular heart (N=24, 10 <1 year), obstructive lesions (N=11, 3 <1 year), primary arrhythmia (N=8, 0 <1 year), and miscellaneous defects (N=18, 5 <1 year). 108 of 150 patients (72%) had been operated of whom 61 (57%) had had corrective surgery. Of the infants with SUD, 32/49 (65%) had undergone surgery (11 corrective); 76/101 older children had undergone previous surgery (50 corrective). 114 of 150 children (76%) died of a cardiac cause. Causes of death were arrhythmia (59), heart failure (25), shunt occlusion (10), pulmonary hypertensive crisis (8) and acute myocardial infarction (4). 30 of 49 infants died of a cardiac cause; causes of death included arrhythmia (10), heart failure (8), shunt occlusion (7), acute myocardial infarction (2).
Conclusions: The incidence of SUD in children with previously recognised heart defects is low. The majority of deaths were of cardiac origin. Pump failure and arrhythmias were terminal events in a significant number of patients in the entire population.

P2808 Advanced cardiac life support training does make a difference

M.A. Moretti, L.A.M. Cesar, J.F.M. Ferreira, J.A.F. Ramires. *University of São Paulo Medical School, Heart Institute (InCor), São Paulo, Brazil*

Many factors influence the success of in-hospital cardiopulmonary resuscitation (CPR). This multicenter, prospective study examined how Advanced Cardiac Life Support (ACLS) training influenced CPR outcomes in 156 patients who experienced 172 in-hospital cardiorespiratory arrest (CRA) events from 01/98 to 03/01. Rates of return of spontaneous circulation (ROSC), short-term survival (alive at hospital discharge), and long-term survival (30 days and 12 months) were compared between two patient groups: "With ACLS" (at least one team member had ACLS training) and "Without ACLS" (no team member had ACLS training). The ROSC rate was 37.8% (65/172) for all events and 39.7% (62/156) for all patients. This rate was 43.4% (49/113) versus 27.1% (16/59) in the "With ACLS" and "Without ACLS" groups, respectively ($p=0.037$). Hospital discharge rates were 22.1% (21/95) and 1.2% (5/49), respectively ($p=0.08$). After one year, 9.6% (15/156) of patients, all from the "With ACLS" group, were alive. Other factors related to survival included the event site, immediate cause, initial rhythm, duration of care, prior presence of oral-tracheal intubation, and need for a transcutaneous pacemaker. In conclusion, we found that the presence of at least one ACLS-trained team member doubles the chances of ROSC, thus, increasing the chances of survival until discharge.

P2809 Psychological stress in lay defibrillation: cognitive and emotional aspects

R. Gaillet[1], C. Morger[2], M. von Planta[3], H. Saner[4]. *[1]Prevention and Rehabilitation, Swiss Cardiovascular Center, Bern, Switzerland; [2]Cantonal Hospital, Dept. of Medicine, Olten, Switzerland; [3]Basel, Switzerland; [4]Prevention and Rehabilitation, Swiss Cardiovascular Center, Bern, Switzerland*

Objective: The emotional and cognitive effects on persons in defibrillation teams and the opinion of the patients treated by these first responders were analysed for the first time in a prospective study.
Methods: After training in CPR and semiautomatic defibrillation, members of 36 different fire-brigades in the region of Olten (Switzerland) act in AED-teams as first responders in cardiac emergencies. At the beginning of the study relevant psychological and social aspects were analysed; after interventions, the participants were questioned on the emotional situation regarding coping, causal attribution and stress. Furthermore, in a parallel case-control study, survivors of cardiac emergencies were interviewed immediately upon hospitalisation and questioned in a semi-structured way on the emotional strain caused by intervention of the AED-team in comparison with the intervention of the regular ambulance team.
Results: 369 members of AED-teams participated in this study (78% of all members; mean age 36 years, 86% men). Duration of observation was 8±6.5 months. On average, 6±3.5 interventions/ defibrillations were made by the team members. At the beginning of the study, 32% expressed fear to make a mistake during the intervention/defibrillation; after there interventions the percentage was down to 9% ($p<0.01$). 79% considered a persisting fear to be confronted with friends/family during an intervention as the main subjective stress factor. After an intervention, the AED-team-members were often preoccupied with the fate of the relatives of the patient (86%). 14% of the men and 34% of the women ($p<0.01$) were preoccupied with the intervention/ defibrillation for at least 30 minutes and up to <24h; 7% of them were preoccupied for more than one day. 36% of the women and 16% of the men ($p<0.01$) considered discussing the case within the team to be the most effective coping strategy. Women expressed significantly more fear to fail (16% vs. 34%; $p<0.01$).
64 patients were questioned after intervention of the AED-team (control group n=61) and noticed no difference between a AED-team or a regular ambulance team regarding emergency intervention and care.
Conclusion: Out-of-hospital defibrillation causes acceptable levels of psychological stress in AED-teams. Women suffer more emotional stress than men and use different coping strategies. The integration of laypersons into defibrillation-teams is well accepted by patients.

GROWTH FACTORS AND CELL PROLIFERATION IN ATHEROSCLEROSIS

P2810 Regulation of vascular cell phenotype by the cell adhesion glycoprotein T-cadherin

M. Philipppova[1], D. Ivanov[1], P. Erne[2], T. Resink[1]. [1]*Basel University Hospital, Department of Research, Basel, Switzerland;* [2]*Kantonsspital Luzern, Division of Cardiology, Luzern, Switzerland*

Cadherins are calcium-dependent surface adhesion molecules that engage in homotypic cell-cell adhesion and regulate morphogenesis and tissue architecture. T-cadherin (T-cad), an unusual GPI-anchored cadherin family member, is highly expressed in cardiac and vascular tissue, but its function in these tissues is unknown. Our immunohistochemical studies in healthy and diseased (i.e. human atherosclerosis, experimental restenosis) blood vessels suggest that expression levels of T-cad might correlate with phenotypic modulation. We hypothesize that T-cad plays an important role in the control of vascular architecture, and have examined the function of T-cad with respect to regulation of vascular cell phenotype.

Methods: Human umbilical vein endothelial cells (HUVEC) and human aortic smooth muscle cells (HSMC) were cultured in the presence of anti-T-cadherin antibodies (ab's). Parameters studied were cell morphology, adhesion and proliferation. HEK293 and L929 cells stably transfected with human T-cad were examined in parallel.

Results: T-cad transfected cells showed significantly reduced proliferation and migration rates (vs. parental and mock-transfectants). Anti-T-cad ab's exaggerated these characteristics, implying an agonistic effect of the ab's. When cultured on a substratum of anti-T-cad antibodies (vs. control surface) HUVEC change from a cobble-stone to an elongated "angiogenic" morphology, while HSMC exhibit a less "spread" morphology and form patchy monolayers. Phalloidin staining revealed associated redistribution of the cytoskeleton to a distinctly peripheral location. HUVEC and HSMC adhesion on anti-T-cad ab-coated substratum is significantly reduced as compared with cells seeded onto uncoated or gelatin-coated surface. When seeded onto a monolayer of stably T-cad-transfected L929 cells, adhesion of HUVEC and HSMC is also significantly reduced as compared to adhesion on a mock-transfected L929 monolayer. Studies are ongoing to determine signalling pathways through which T-cad mediates its effects on cell phenotype.

Conclusion: Homophilic T-cad-T-cad interactions influence the morphology/phenotype of vascular cells. The findings of anti-adhesive properties for T-cad may be relevant to a function for this molecule in negative guidance and definition of tissue architecture.

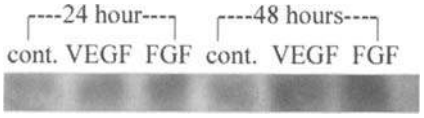
P2811 VEGF and bFGF upregulates endothelial nicotinic acetylcholine receptor

K. Lin, J.P. Cooke. *Stanford University, Cardiovascular Medicine, Stanford, United States of America*

Background: Recently, we have made the novel and serendipitous observation that nicotine is an extraordinarily potent agent of angiogenesis. Nicotine's action, however, seems to be accentuated in sites where vascular abnormalities are present. For instance, using a rat hindlimb ischemia model, we observed that nicotinic acetylcholine receptor (nAChR) is upregulated in vascular tissues from the ischemic leg when compared against the nonischemic leg from the same rat. Accordingly, we sought to determine whether vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), both of which are upregulated by ischemia, could modulate the expression of endothelial nAChR.

Method: HMEC-1, an immortalized human dermal microvascular endothelial cell line was cultured in M199 supplemented with 10% FBS and antibiotics. At subconfluence, 10 ng/mL of VEGF and bFGF were given to HMEC-1. At 24 and 48 hours, cells were lysed and centrifuged. The supernatant was heated at 100°C for 5 minutes and used for Western blotting. Hybond ECL nitrocellulose membranes with proteins transferred from SDS-PAGE gels were incubated with a mouse monoclonal antibody (1:3000) raised against human nAChR alpha-7 subunit. The membrane was then probed with a peroxidase-conjugated anti-mouse antibody (1:2000), detected by ECL.

Result: VEGF and bFGF both upregulated endothelial nAChR within 24 hours. The effect became more conspicuous by 48 hours (Figure 1).



Conclusion: We have demonstrated that VEGF and bFGF are both determinants of endothelial nAChR expression. Henceforth, they can both modulate endothelial sensitivity to nicotine and thus play a major role in the angiogenic pathway mediated through nAChR.

P2812 Short-term exposure of vascular smooth muscle cells (VSMC) to a contrast medium-paclitaxel formulation inhibits proliferation in vitro

B. Scheller[1], H.P. Stoll[1], M. Böhm[1], G. Nickenig[1], U. Speck[2]. [1]*University of Saarland, Internal Medicine III, Homburg/Saar, Germany;* [2]*Department of Radiology, Charite, Berlin, Germany*

Objective: Contrast media (CM) may be novel carriers suitable for intracoronary local drug delivery. This concept is based on the observation that CM form a thin film lining the endothelial surface of a coronary artery over a period of several minutes after bolus injection. A drug with high affinity to the tissue admixed to CM could be delivered at high concentrations to a dilated or stented artery for prevention of restenosis. Systemic drug levels are expected to remain far below toxicity due to rapid dilution after passage through the coronary arteries.

Methods: For investigation of the efficacy of an Iopromide-Paclitaxel formulation we seeded VSMCs at 10,000/cm^2 and incubated them with medium containing additives of either 0.9% NaCl (control), or Iopromide admixed with 25.7 μg/ml Paclitaxel. These specific media were replaced after 60 minutes, 10 minutes, or 3 minutes by neutral media not containing antiproliferative drugs. Cells were further cultivated for 12 days and counted at baseline, and after 3, 6, 9, and 12 days.

Results: The Iopromide-Paclitaxel formulation inhibited VSMC proliferation at all time points significantly (p=0.01). Incubation times of 10 and 3 minutes showed the same efficacy as an incubation over 60 minutes.

Relative increase in cell density

	day 0	day 3	day 6	day 9	day 12
saline	1.0	3.2	6.4	7.2	7.9
60 min	1.0	0.9	1.3	1.5	1.3
10 min	1.0	0.9	1.0	1.0	1.6
3 min	1.0	1.0	1.1	1.2	1.0

SEM < 10%, n=40

Conclusion: Iopromide-Paclitaxel formulations induce inhibition of VSMC proliferation. This effect is sustained over 12 days despite of the short initial exposure time. These data support the concept of CM-based coronary local drug delivery for prevention of restenosis.

P2813 The biomechanically-induced product of the IEX-I gene inhibits proliferation of vascular smooth muscle cells

P.C. Schulze, G.W. DeKeulenaer, R.T. Lee. *BWH, Harvard Medical School, Cardiovascular Research, Cambridge, United States of America*

Mechanotransduction participates in both physiological and pathological processes of the cardiovascular system.

We investigated biomechanically-induced changes in gene expression of cultured human aortic smooth muscle cells (hAoSMC) obtained from human surgical specimens. Using microarray techniques, we identified the irradiation-inducible gene IEX-I as highly expressed in hAoSMC in response to mechanical strain. This finding was confirmed by Northern analysis (maximal induction after 2 hrs; 15 fold induction) and Western analysis (maximal induction after 24 hrs; 3 fold induction). Moreover, expression of IEX-I in hAoSMC was induced by the proinflammatory cytokine IL-1beta (24 hrs; 5 fold induction). The function of IEX-I in hAoSMC was further explored by gene transfer with recombinant adenoviruses that overexpressed wild-type IEX-I. Proliferation of hAoSMC was monitored by ^{3}[H]-thymidine incorporation. After 48 hrs of 4% mechanical strain, adGFP-infected hAoSMC had higher ^{3}[H]-thymidine incorporation as compared to adIEX-I-infected cells (13455±4211 vs. 4733±1121 counts per μg, p<0.001). In addition, proliferation of hAoSMC induced by a combination of PDGF-BB and FGF-2 was reduced by 46% in adIEX-I-infected cells as compared to adGFP-infected SMC (p<0.001).

In an in vivo study of ApoE-/- mice, immunohistochemical staining of carotid arteries using a specific anti-IEX-I antibody revealed strong immunoreactivity in the arterial wall of animals on a high-fat diet as compared to weak staining in vessels from mice on a low-fat diet. In addition, significant immunoreactivity for IEX-1 was found in human carotid atheroma specimens demonstrating an increased expression of this protein in human atherosclerosis.

In conclusion, our findings demonstrate that mechanical strain induces IEX-1 and that the protein product of the IEX-1 gene is overexpressed in diseased vessels. Because IEX-1 has distinct antiproliferative effects in hAoSMC, this novel gene may participate in regulating the vascular response to injury.

P2814 Differential roles for Src, PI-3 kinase and PLC-gamma for platelet-derived growth factor (PDGF)-alpha receptor-induced chemotaxis

S. Rosenkranz[1], M. Wartenberg[2], M. Uebel[1], B. Kuper[1], P. Schnabel[1], H. Sauer[2], J. Hescheler[2], A.T. Bäumer[1]. [1]Universität zu Köln, Klinik III für Innere Medizin, Köln, Germany; [2]Universität zu Köln, Dept. of Physiology, Köln, Germany

Platelet-derived growth factor (PDGF) plays a critical role in the pathogenesis of atherosclerosis and myocardial hypertrophy. Our previous work demonstrated, that activation of multiple receptor-associated signaling molecules including Src, PI-3 kinase (PI3K) and PLCg is essential for efficient PDGF-AA-induced chemotaxis. Cell migration requires the coordinated interplay of several cellular responses including motility, invasiveness and polarization.

Here we investigated the differential roles for Src, PI3K and PLCg for PDGF-dependent induction of chemotaxis-associated transcription factors (Egr-1, Ets-1, c-fos) and the ligand-induced internalization of the alpha-PDGF receptor (aPDGFR). To investigate the role of each of these signaling enzymes, we used mutant receptors in which the specific binding sites for Src, PI3K and PLCg were individually deleted by tyrosine-to-phenylalanine substitutions. Stimulation of Ph cells expressing the wild type (WT) aPDGFR with PDGF-AA (50 ng/ml) led to a 10-fold increase of Egr-1, Ets-1, and c-fos at 60 min, and to a rapid internalization of the receptor at 5 min. Deletion of the binding sites for PI3K and PLCg, but not Src, each led to a 50% reduction of PDGF-dependent induction of Egr-1, Ets-1, and c-fos (mRNA, protein; $P<0.01$). In contrast, deletion of the Src binding sites, but not PI3K and PLCg, completely abolished the ligand-induced internalization of the aPDGFR. Consistent with these findings, restoration of the individual binding sites to a mutant receptor, in which all binding sites were deleted (F7), rescued these responses.

We conclude that redundant signaling pathways involving PI3K and PLCg mediate the PDGF-dependent induction of Egr-1, Ets-1 and c-fos, whereas Src family kinases are required for aPDGFR internalization. Only the coordinated interplay of these cellular responses allows an efficient migratory response towards PDGF.

P2815 IGF-1 modulates cardiac fibroblast migration and adhesion through the expression and synthesis of α1, β1-integrin and collagen

G. Diaz-Araya[1], W. Carver[2], T.K. Borg[2], S. Lavandero[3]. [1]U Chile, Fac Chem & Pharm Sciences, Chemical Pharmacology & Toxicology, Santiago, Chile; [2]University of South Carolina, Biology and Developmental Anatomy, Columbia, United States of America; [3]U. Chile. Fac Chem & Pharm Sciences, Biochem & Mol Biol, Santiago, Chile

The extracellular matrix (ECM) composition and organization change during periods of cardiac tissue remodeling associated with development, aging and disease. Cardiac fibroblast interaction with the surrounding ECM is dynamic and essential for regulation of adhesion and migration. Whether IGF-1 regulates these processes in cardiac fetal and neonatal fibroblasts remains unknown.

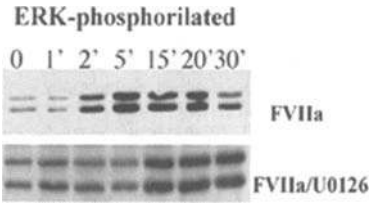
Our aim was to evaluate if IGF-1 regulates cardiac fetal and neonatal fibroblast migration and adhesion and its relation with changes in collagen and integrin expression. Fibroblasts isolated from rat fetal and neonatal hearts were stimulated with IGF-1 and cell adhesion and collagen gel contraction were evaluated. In addition, collagens and their specific integrin receptor levels were determined by Northern and Western blot analysis, respectively.

The results showed that fetal cardiac fibroblasts treated with IGF-1 increased significantly the contraction of collagen gels. Area decreases in collagen gels were 27 vs. 13 and 46 vs. 34% for IGF-1 vs controls, at 24 and 48 h, respectively. In neonatal cardiac fibroblasts, IGF-1 did not produce any change on collagen gel contraction. IGF-1 increased cardiac fibroblast adhesion in 1.4, 1.3 and 1.5 fold over control, using collagen, laminin and fibronectin as substrates, respectively. IGF-1 decreased neonate fibroblast adhesion to collagen, laminin and fibronectin, in 0.8, 0.7 and 0.5 fold over control, respectively. IGF-1 stimulated collagen type-1 secretion in both fetal (1.5 and 1.8 fold over control at 24 and 48 h, respectively) and neonatal fibroblasts (1.9 and 1.4 folds over control at 24 and 48 h, respectively). IGF-1 treatment increased collagen mRNA levels in fetal and neonatal fibroblasts (1.4 and 7.0 fold over control at 24 h, respectively). IGF-1 also increased alpha1 and beta1 integrin levels (1.9-fold respect to control) in fetal fibroblasts. We concluded that IGF-1 differentially modulates cardiac fibroblast adhesion and migration in fetal and neonatal stages, regulating both collagen type-1 synthesis and integrin expression.

P2816 The binding of the FVIIa to the TF promotes smooth muscle cell proliferation in vitro via the extracellular signal regulated kinases

P. Cirillo[1], P. Calabrò[1], G. Calì[2], L. Forte[1], S. De Rosa[1], M. Pacileo[1], F. Scopacasa[3], P. Golino[4]. [1]Cardiology, [2]Biology and Cellular Pathology, [3]Clinical Biochemistry, University of Naples "Federico II", Naples; [4]Second University of Naples, Cardiology, Naples, Italy

Restenosis following PTCA recognizes smooth muscle cell (SMC) proliferation as a key event. However, the mechanisms responsible for this phenomenon are not completely known. Tissue Factor (TF) is a transmembrane glycoprotein which forms a high affinity complex with Factor VII/FactorVIIa (FVIIa), thus activating the extrinsic coagulation pathway. Atherosclerotic plaques contain different cell types, such as SMCs, capable of expressing TF. We have previously demonstrated that binding of FVIIa to TF induces SMC proliferation. In the present study we investigated whether the formation of TF/FVIIa complex leads to SMC proliferation as a result of signal transduction via the extracellular signal regulated kinases (ERKs) pathway, a family of the MAPKs. SMCs from NZW rabbit aortas, grown in Dulbecco's Medium, with 10% Calf Serum, were made quiescent by serum deprivation. Twenty-four hours later SMCs were stimulated with FVIIa (100nM) and then processed for total protein isolation at baseline (no stimulation), and after 1, 2, 5, 15, 20, 30 and 60 min following stimulation. Phosphorylation (activation) of ERKs (pERKs) was assessed by immunoblotting SMC lysates with antibodies that recognize pERKs. To better define the role of pERK in SMC proliferation, in another set of experiments, SMCs were preincubated with U0126 (10μM), a specific inhibitor of ERK phosphorylation and then SMC proliferation and ERK phosphorilation were evaluated (figure).



SMC proliferation appears to be related to ERK phosporilation; UO126 was able to inhibit it. This effect was associated with the late phosporilation of ERK. Thus, TF/FVIIa complex leads to SMC proliferation via the activation of ERKs.

P2817 Severe diffuse coronary aneurysms in acute coronary syndromes are linked to altered serum levels of VEGF and TIMP2

M. Savino[1], D. Cianflone[1], C. Pristipino[2], A. Rebuzzi[1], F. Crea[1]. [1]Policlinico A. Gemelli, Istituto di Cardiologia, Roma, Italy; [2]Servizio Autonomo di Emodinamica, San Filippo Neri Hospital, Rome, Italy

BaBackground: Coronary aneurysms and diffuse coronary ectasia (DCE) are found in Kawasaki syndrome, an inflammatory disease of the young. However, DCE can occasionally be found at angiography in adults without clinical features of Kawasaki disease. The pathogenesis of DCE in the latter is poorly known. Matrix metalloproteases (MMP), tissue inhibitos of MMP (TIMP) and vascular endothelial growth factor (VEGF) are involved in vascular remodelling and might play a role in DCE formation.

Methods: 1280 consecutive coronary angiograms, performed in 1999, were examined and DCE were found in 15 patients (14 male, age 56 years, range 40-64). They all presented with an acute coronary syndromes (8 with acute myocardial infarction, 7 with unstable angina). DCE were defined as >=1.5 fold increase in diameter with polyciclic margins of > 2 coronary segments out of 27 segments. Two patients died during the initial admission, 1 refused blood sampling; 12 patients remained stable and did not need revascularization. Plasma levels of VEGF, MMP2, TIMP1, TIMP2 and of C-reactive protein (CRP) were measured in these 12 patients, in 12 age/sex matched patients (CAD) with stable angina and critical stenoses (>50% reduction of internal lumen diameter) and in 12 age/sex matched patients (NCA) with normal coronaries admitted during the same timeframe.

Results: all data are presented as median and (range). No patient with DCE exhibited coronary stenoses. VEGF levels were higher in patients with DCE than in CAD or NCA: 151 pg/ml (30.1-382.2) vs 66.9 pg/ml (30.1-112.2) and 54.9 pg/ml (15.2-87), respectively, $p< 0.02$. TIMP2 levels were lower in DCE or CAD than in NCA: 5.9 ng/ml (0-182.2) and 5.0 (0-47.6) vs 50.7 ng/ml (0-101.3), respetctively, $p<0.001$. TIMP1 and MMP2 were similar in all groups (p=NS), and CRP was normal (<3 mg/L) in the majority of patients with DCE, CAD and NCA (75%, 66% and 84% respectively, p=NS)

Conclusion: In adults DCE are not associated with systemic signs of inflammation even when associated an acute coronary syndrome. Reduced TIMP2 was found both in CAD and DCE. Elevated VEGF, however, was only found in DCE. The simultaneous occurrence of deficient MMP inhibition and increased vascular permeability in adults with DCE suggest an accelerated extra-cellular matrix turnover faciling aneurysm formation.

P2818 Effect of overexpression of decorin on metalloproteinases and TIMPs production by human coronary artery smooth muscle cells

A. Alhaj Zen[1], B. Gogly[2], C. Brasselet[3], E. Durand[3], G. Godeau[4], A. Lafont[1]. [1]INSERM EMI-U 00-16, Paris, France; [2]INSERM EMI-U 0016, Paris, France; [3]INSERM EMI-U 00-16, cardiology, Paris, France; [4]Paris V University, Non-minerlized Tissues Physiopathology, Paris, France

Background: Metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) are known to play a critical role in the Acute Coronary Syndromes. Additionally, the implication of pro-inflammatory cytokines (particularly TGF-beta) in regulation of MMPs has been previously demonstrated. Since decorin (small leucine-rich proteoglycan) is a natural inhibitor of TGF-beta and inhibits cell migration, we evaluated the direct effect of decorin overexpression on MMPs and TIMPs production by human coronary smooth muscle cells (SMC).

Methods and Results: Cultured human coronary artery SMCs (Clonetics, USA) were either infected with adenoviral vector containing human decorin gene (Ad-Dcn) or beta-Galactosidase (Ad-bataGal) at viral dose 25, 50, 100, 200 and 400 pfu/cell, or remained as uninfected culture controls. Four days after transfection, the supernatant of culture conditioned-medium was collected for protein analysis (decorin, MMP-1, MMP-2, MMP-3, MMP-9, MMP-13 and TIMP-1, TIMP-2, TIMP-3) by Western and dot blotting. Medium decorin concentration was significantly elevated from the viral dose 50 pfu/cell in Ad-Dcn infected-cells and no secreted decorin was detected in the supernatant of control cells. On dot blot, the protein level of MMP-1, MMP-3 and TIMP-3 diminished, respectively (1.4-, 2- and 1.6-fold) in Ad-Dcn infected-cells compared with control cells. In contrast, MMP-2, TIMP-1 and TIMP-2 showed a 1.3-, 1.5- and 1.2-fold increase in Ad-Dcn infected-cells. No significant difference was observed between decorin infected-cells and the control beta-gal cells in the protein level of MMP-9 and MMP-13 (they were not detectable in the uninfected cells). The similar data were obtained from Western analysis. Zymography confirmed the inhibition of MMP-3 activity and the stimulation of MMP-2. Total level of cytokines (TGF-beta, IL-1beta, IL-4, IL-6 and IL-10) in medium were also investigated by ELISA. In Ad-Dcn infected-cells, the level of TGF-beta, IL-1beta & IL-6 was reduced significantly in a dose-dependant manner compared with Ad-betaGal and control cells, whereas, the level of IL-4 & IL-10 was markedly increased.

Conclusion: Our preliminary findings suggest that decorin overexpression would have potential beneficial effect on atherosclerotic plaque stability via inhibition of MMP-1, 3 and stimulation of TIMP-1, 2.

P2819 Regulation of VEGF and its receptor in macrophages-effects of oxidized LDL and PPAR gamma agonists

L. Salomonsson, O. Wiklund, S. Pettersson, B. Ohlsson. *Sahlgrenska University Hospital, Wallenberg Laboratory, Göteborg, Sweden*

Increased vascularisation and inflammation in the atherosclerostic plaque may lead to destabilisation and rupture of the plaque. Vascular Endothelial Growth Factor (VEGF) and its receptor VEGFR-1 may play a central role in this development, since VEGF may promote formation of intraplaque microvessels and also is chemotactic for monocytes. The aim of this study was to investigate the effect of oxidised LDL (oxLDL) on VEGF and VEGFR-1 expression in human monocyte-derived macrophages. The VEGF and VEGFR-1 mRNA expression in these cells were estimated by RT-PCR and the VEGF protein secretion was measured by ELISA. Chemotactic activity was determined using a microchamber technique.

OxLDL increased the VEGF mRNA expression and protein secretion in a time and dose dependent manner. This was partly due to an increased VEGF mRNA stability. The gene for the VEGF receptor, VEGFR-1, encodes two polypeptides, a soluble (sVEGFR-1) and a membrane protein. The soluble form is supposed to block biological effects of VEGF, while the membrane bound form mediates the chemotactic response to VEGF. The mRNA expression of VEGFR-1, and protein secretion of sVEGFR-1 was decreased by oxLDL. Similar effects were obtained when cells were incubated with 9-HODE, which is a component of oxLDL and a physiological stimulator of PPAR-gamma. Similar results were also found with darglitazone, another PPAR-gamma agonist. The decreased VEGFR-1 mRNA expression coincided with a decreased binding of ATF-2/c-jun to the positive regulatory element, which is essential for VEGFR-1 gene transcription. Macrophages stimulated with oxLDL were less prone to migrate towards VEGF than untreated cells. Since chemotaxis of macrophages towards VEGF is mediated through the membrane bound VEGFR-1 this indicates a reduced expression of this receptor. Together these results indicate that oxLDL increases the amount of biologically active VEGF by increased VEGF secretion and a decreased secretion of sVEGFR-1. On the orther hand a decreased expression of membrane-bound VEGFR-1 in macrophages may contribute to entrapment of macrophages in the lesion.

P2820 Circulating human smooth muscle cell progenitors

D. Simper[1], P.G. Stalboerger[2], C.J. Panetta[1], N.M. Caplice[1]. [1]Mayo Clinic, Cardiovascular Diseases, Rochester, United States of America; [2]Mayo Clinic, Molecular Medicine Program, Rochester, United States of America

There is now accumulating evidence that smooth muscle cells contributing to vascular disease may originate from bone marrow-derived progenitor cells. Studies using human embryonic stem cells have also suggested a common vascular progenitor for endothelial and smooth muscle cells with evidence that cell lineage can be determined by differential growth factor exposure. However, despite substantial data to support the existence of circulating endothelial progenitor cells (EPC), no direct evidence currently exists for a distinct smooth muscle progenitor cell (SPC) in the blood stream of human subjects.

We evaluated whether growth and selection of adult vascular progenitors obtained from human peripheral blood in PDGF BB-enriched medium would result in smooth muscle cell differentiation. We determined the phenotype of these cells both morphologically and with use of a panel of cell specific antibodies.

Progenitor colonies obtained from human buffy coat mononuclear cells had a heterogeneous morphology consisting of polygonal endothelial-like cells and stellate shaped smooth muscle-like cells. Passage and selection of these mixed colonies in either PDGF or VEGF enriched medium resulted in pure cultures of smooth muscle (SPC) or endothelial (EPC) appearing cells respectively.

SPCs stained positive for alpha smooth muscle actin, smooth muscle myosin heavy chain (SM MHC) and calponin on indirect immunofluorescence, whereas EPCs stained negative for these smooth muscle cell markers. Conversely, EPCs were positively immunoreactive for vWF, VE-cadherin, CD31 and CD36, whereas SPCs showed no expression of these endothelial antigens. Smooth muscle specific protein expression by SPCs was confirmed by positive immunolabeling for alpha smooth muscle actin, SM MHC and calponin on Western blots of SPC lysates.

Together, these data confirm the successful isolation and differentiation, using PDGF BB, of smooth muscle phenotype cells from progenitors in human blood. Our results indicate that SPCs exist in adult human blood and raise the possibility that PDGF BB in the bone marrow, in the blood stream or at the vessel wall/endothelial interface may facilitate smooth muscle cell differentiation from vascular progenitors at these sites.

GENETICS IN ATHEROSCLEROSIS

P2821 Angiotensinogen gene T235 variant: risk of coronary artery disease and myocardial infarction in a German population

H.H. Sigusch, R. Surber, C. Zeiss, D. Reinhardt, H.R. Figulla. *University of Jena, Dept.Internal Medicine/Cardiology, Jena, Germany*

The thymidine to cytosine transition at postion 704 in exon 2 of the angiotensinogen (Ao) gene, which results in an amino acid substitution of threonine for methionine at the protein level, is associated with elevated Ao plasma concentrations. The data on this mutation and an association with coronary artery disease (CAD) are inconclusive. Therefore the aim of this study was to investigate the role of this polymorphism in a large population who underwent coronary angiography at our institution.

Methods: A total of 1282 individuals who underwent coronary angiography were genotyped. In 836 subjects (65.2%) CAD was present. The remaining 446 (34.8%) – with excluded CAD – served as controls. In the entire population the genotype frequencies were 30.3, 51.6 and 18.1% for the AA, Aa and aa genotype, respectively (A=wildtype allele, a=mutant allele). The results are summarised in the Table.

Results:

	AA	Aa	aa	P
Age (yrs)	60.7 (10.5)	60.4 (9.5)	59.9 (9.4)	n.s.
BMI (kg/m^2)	27.1 (3.8)	26.8 (3.5)	27.4 (3.6)	n.s.
LDL-C	4.23 (1.23)	4.17 (1.22)	4.29 (1.19)	n.s.
Smoking (pyrs)	12.7 (18.2)	12.2 (17.0)	12.1 (17.3)	n.s.
Sex (%male)	67.6	72.5	72.8	n.s.
Diabetes (%)	25.5	23.1	22.0	n.s.
Hypertension (%)	57.1	59.5	64.7	n.s.
CAD (%)	64.8	64.8	61.2	n.s.

Date are given as mean (SD) or as %. Comparison by ANOVA with Bonferroni correction or chi-square testing.

The multivariate analysis showed that neither the A nor the a allele carries an independent risk for the development of CAD. In contrast, CAD patients who carry the A allele had a significantly increased risk for myocardial infarction, OR=1.5 (95% CI 1.003-2.25).

Conclusion: In conclusion, our data indicate that the Ao T235 variant is not an independent risk factor for CAD. The A allele however, is in CAD patients significantly associated with myocardial infarction.

P2822 Identification of autosomal dominant heritability of myocardial infarction

B. Mayer[1], M. Fischer[1], J. Erdmann[1], S. Holmer[1], P. Nürnberg[2], H. Löwel[3], C. Hengstenberg[1], H. Schunkert[1]. [1]*Universität Regensburg, Klinik für Innere Medizin II, Regensburg, Germany;* [2]*MDC, Gene Mapping Center (GMC), Berlin, Germany;* [3]*GSF, Epidemiologie, München, Germany*

Myocardial infarction (MI) is considered to be a multifactorial disease that results from an integrated vascular response to common cardiovascular risk factors. Interestingly, some families show a high incidence of MI that cannot be explained by these traditional risk factors. Thus, the aim of this study was to investigate whether MI can be also inherited in a Mendelian pattern.

Methods: In cooperation with 17 in-hospital cardiac rehabilitation centers, the Regensburg MI family study group screened over 200.000 medical reports of MI patients in order identify extended MI families.

Results: We identified 124 MI families with at least 3 or more affected living MI siblings. In 18 of these families without bilinearity, 101 living MI patients and 375 unaffected family members were recruited. Moreover, 43 patients had died from MI in these families. The largest MI family had 64 family members and 22 affected individuals in five generations. In the age group from 50 to 70 years, on average 50% of the family members were affected and nearly 100% of MI patients had parents carrying the disease. Traditional cardiovascular risk factors, such as smoking, hypercholesterolaemia, hypertension and diabetes mellitus, had the same frequencies as a population-based sample of sporadic MI (KORA-Augsburg, Germany, n=609, $p>0.1$ for all risk factors). However, the predominance of male gender as usually seen in MI registries was less pronounced in MI families (71.5% vs. 87.4%, in the population based KORA MI registry, $p<0.001$). Furthermore, the patterns of inheritance argued against imprinting or a X-chromosomal disorder. In the MI families, power simulation using the SLINK software package and applying several models of potential inheritance revealed consistently the highest theoretical LOD scores under the assumption of an autosomal dominant heritability. A maximal simulated LOD score of 3.0 was obtained in a single large family using the affected only model. After age-adjusted consideration of the non-affected individuals, the maximal simulated LOD score increased to 6.2 and was significant in four of the 18 families.

Conclusion: A minority of MI patients shows an autosomal dominant heritability which cannot be explained with traditional cardiovascular risk factors. The data suggest novel genetic mechanisms resulting in myocardial infarction.

P2823 Dissection of individual contributions of apolipoprotein (a)-gene-polymorphisms to the risk of myocardial infarction

S R. Holmer[1], C. Hengstenberg[1], H.G. Kraft[2], M. Poell[1], B. Mayer[1], H. Loewel[3], G. Riegger[1], H. Schunkert[1]. [1]*University of Regensburg, Internal Medicine II, Regensburg, Germany;* [2]*University of Innsbruck, Innsbruck, Austria;* [3]*GSF-Institute of Epidemiology, München, Germany*

Genetic polymorphisms at the LPA-locus on chromosome 6 determine a large part of the variablity of serum concentrations of lipoprotein(a) [Lp(a)]. The size of Lp(a) particles is variable as well, being largely determined by the kringle IV repeat (KIVR) polymorphism of this gene. The impact of interactions of this polymorphism with polymorphisms of the promoter region (pentanucleotide repeat, PNR) on atherogenicity of Lp(a) particles and cardiovascular risk is not understood.

We determined the association the KIVR polymorphism and the PNR repeat polymorphism with serum Lp(a) levels and myocardial infarction in 786 age and gender matched MI-patients and controls from the general population (50% women). Elevated Lp(a) serum concentrations were associated with increased MI-risk (odds ratio 1.81 in men and 2.52 in women for Lp(a) in the upper quartile; $p<0.0001$). The KIVR polymorphism determined 50% of total Lp(a) variability. However, despite the overall large effect of the KIVR polymorphism on Lp(a) concentration the association with MI was relatively weak. In contrast, the promoter PNR polymorphism which explains only 6% of the total variabilty of Lp(a) was significantly associated with MI in women (adjusted rel. risk for homozygous carriers of 8 PNR 1.39, $p<0.023$). We, therefore, investigated whether interactions of the two polymorphisms may be of relevance. Specifically, we hypothesized that a large number of small Lp(a) particles may be detrimental. Interestingly, in carriers of <25 KIVR the variation of Lp(a) concentrations was very large (median 29.5 mg/dl, interquartile range 68.2). By contrast, in the presence of >25 KIVR this variability was low (median 8.3, interquartile range 17.7 mg/dl). Moreover, we observed a strong linkage disequilibrium between the KVIR and the PNR polymorphism. In particular, 10,11 and 12 PNR are almost exclusively present in individuals that carry <25 KIVR and, thus, express small Lp(a) particles. In these individuals, the PNR polymorphism is the major modulator of Lp(a) concentration [median of Lp(a) in homozygous carriers of 8 PNR 72.6 mg/dl vs. 14.6 mg/dl in 10, 11, 12 PNR; $p<0.0001$].

Polymorphisms of the apolipoprotein(a) gene (KVIR and PNR) modulate both size and number of Lp(a) molecules. Linkage disequilibrium between the KIVR and the PNR polymorphism explains a strong influence of the PNR polymorphism on Lp(a) concentration in individuals expressing small Lp(a) molecules. These individuals may be at particularly high risk, if they carry 8 PNR.

P2824 The methylenetetrahydrofolate reductase polymorphism gene is associated with increased DNA damage in coronary artery disease

M.G. Andreassi[1], N. Botto[1], F. Cocci[2], D. Battaglia[2], E. Antonioli[1], S. Masetti[1], S. Manfredi[1], A. Biagini[1]. [1]*G. Pasquinucci Hospital, CNR Institute of Clinical Physiology, Massa, Italy;* [2]*CNR, Institute of Clinical Physiology, Pisa, Italy*

Background: Somatic DNA damage has been associated to the pathogenesis of atherosclerosis. Recently, it has been also observed that elevated levels of plasma homocysteine (Hcy) can induce DNA damage.

Aim: In this study we investigated whether DNA damage is related to the C677T variant in the methylenetetrahydrofolate (MTHFR) gene as well as to plasma levels of Hcy, B12 and folate in patients with coronary artery disease (CAD).

Methods and Results: Patients (n=46) with angiographically-proven CAD were studied by using micronucleus (MN) test, an accepted method for evaluating genetic instability. TT patients had plasma Hcy levels higher than those with the CT or CC genotypes (27.8±5.2 vs 13.7±2.2 and 12.9±1.9 μmol/L, respectively; p=0.004). Patients with multi-vessel disease had higher plasma Hcy levels (11.6±1.2, 22.0±4.7, 19.3±3.9 μmol/L for one-, two- and three-vessel disease, respectively; p=0.05). The MN index increased with the number of affected vessels (8.4±0.7, 11.1±2.0, 14.2±1.7 for one-, two-, and three-vessels disease, respectively; p=0.02) and was significantly higher in subjects with TT genotype compared with the CC or CT genotypes (15.7±2.4 vs 8.9±1.7 and 9.9±0.8, p=0.017 and p=0.025, respectively). The MN index was also negatively correlated with plasma B12 concentration (r= -.343, p=0.019) and positively with plasma Hcy (r=.429, p=0.005).

Conclusions: These data indicate that increased somatic DNA damage is related to MTHFR polymorphism and elevated levels of Hcy, suggesting an interesting link between coronary atherosclerosis and genetic instability in humans.

P2825 The IL6/G-174C polymorphism modulates the impact of pathogen burden on coronary artery disease

J.L. Georges[1], S. Blankenberg[2], O. Poirier[1], H.J. Rupprecht[2], V. Nicaud[1], C. Bickel[2], J. Meyer[2], L. Tiret[1] on behalf of the AtheroGene Group. [1]*INSERM U525, Paris cedex 13, France;* [2]*Johannes Gutenberg University, Department of Medicine II, Mainz, Germany*

Background: The number of infectious pathogens to which an individual has been exposed (pathogen burden) has been linked to the development and the prognosis of coronary artery disease (CAD). The interaction between infection, genetic host susceptibility and CAD remains unclear.

Objectives: This study was aimed at evaluating the association between CAD and pathogen burden. Modulation of the association by serum levels of inflammatory markers and polymorphisms of the interleukin-6 (IL-6) and tumor necrosis factor (TNF)-alpha genes was also investigated.

Methods: IgG or IgA antibodies to 8 pathogens were determined in 991 CAD patients and 333 control subjects. Serum levels of high sensitive C-reactive protein, fibrinogen, IL-6, TNF-alpha were also measured. All subjects were genotyped for the IL6/G-174C, the TNF/C-851T and the TNF/G-308A polymorphisms.

Results: Single pathogens (C pneumoniae, CMV, H pylori and HSV-1) were positively related to the presence of CAD. A strong association between increasing pathogen burden and CAD was confirmed. The prevalence of a high pathogen burden (>=4 pathogens) was 50.4% in cases and 21.2% in controls ($p<0.0001$). A high pathogen burden was associated with decreased HDL-cholesterol levels both in cases and controls ($p<0.001$). The association between CAD and pathogen burden was modulated by the IL6/G-174C polymorphism, the odds ratio (OR) being higher in GC heterozygotes (OR 3.45, 95% CI 1.99-5.98) than in both types of homozygotes (OR 1.31, 95%CI 1.69-2.50 in GG homozygotes, OR 1.58, 95%CI 0.64-3.91 in CC homozygotes; $p<0.05$ for interaction). This interaction appeared to be mediated by variations in serum IL-6 levels.

Conclusions: Pathogen burden is strongly associated with the risk of CAD. This effect might be partly mediated by a decrease in HDL-cholesterol levels. The IL6/G-174C polymorphism appears to act as a modulator of the effect of pathogen burden on CAD risk, through variations in circulating IL-6 levels, and possibly local production of IL-6.

P2826 Gene-environment interaction in coronary artery disease: protective effect of eNOS-Glu-298-Asp-polymorphism in non-smokers, but not in smokers

G. Taubert[1], B.R. Winkelmann[1], R. Winkler[1], B. Klein[1], A. Kunkler[1], M.M. Hoffmann[2], W. Maerz[2], J. Senges[1]. [1]*Herzzentrum, Cardiology Dept., Ludwigshafen, Germany;* [2]*Clinical Chemistry, University, Freiburg, Germany*

Background: Asp-homozygosity of the eNOS Glu298Asp polymorphism has been previously associated with elevated risk of coronary artery disease (CAD) or myocardial infarction (MI).
Objective: Impact of eNOS Glu298Asp-polymorphism on prevalence of CAD and MI in relation to smoking habits in consecutive patients scheduled for coronary angiography.
Methods: Analysis of participants of the Ludwigshafen Risk and Cardiovascular Health (LURIC) study, which comprises a coronary angiography and thorough evaluation of cardiovascular risk factors. Analyis of eNOS genotype by restriction analysis.
Results: Multivariate odds ratios (95%-CI) adjusted for age, gender, and concomitant cardiovascular risk factors:
Multivariate odds-ratio for CAD: Smoker 1.14(0.84-1.54), n=955; Non smoker 0.89 (0.63-1.25)n=689
Multivariate odds-ratio for MI: Smoker 1.06 (0.76-1.49), n=618; Non smoker 0.48 (0.28-0.82)n=333
Conclusion: In non-smoking subjects with stable CAD the eNOS Glu298Asp polymorphism is associated with lower prevalence of MI. This protective effect has been not observed in smoking subjects.

P2827 Stromelysin-1 gene promotor 5A/6A polymorphism and C-reactive protein in patients with coronary artery disease

J.R. Jeng, K.M. Chu, C.C. Lin, W.B. Wang, D.P. Tsau, S.P. Yang. *Tri-Service General Hospital, Division of Cardiology, Taipei, Taiwan, Province of China*

The purpose of this study was to compare the 5A/6A polymorphism of the stromelysin-1 gene promoter between patients with coronary artery disease (CAD) and healthy control subjects, and to explore the relation of 5A/6A genotypes with high sensitivity C-reactive protein (CRP).
This study included 336 Chinese patients with CAD diagnosed by coronary angiogram of at least 50% stenosis in vessels and 389 matched healthy controls. High sensitivity CRP levels were measured in fasting plasma samples. Stromelysin-1 5A/6A genotypes were determined by the polymerase chain reaction and restriction enzyme analysis.
The CAD patients showed significantly higher 5A/5A genotype percentage (18.3% vs. 7.7%, $p < 0.001$) and greater 5A-allele frequency (0.335 vs. 0.279, $p < 0.05$) than healthy control subjects. High sensitivity plasma CRP levels were also significantly elevated in CAD patients than in controls (2.62 ± 3.53 vs. 0.86 ± 1.01 mg/L, $p < 0.001$). Patients with 5G/5G genotype had significantly higher plasma CRP (3.93 ± 4.72 vs. 2.81 ± 3.01 and 1.94 ± 2.42 mg/L, $p < 0.05$) than those with 5A/6A and 6A/6A genotypes.
The study showed that the 5A/5A genotype of the stromelysin-1 gene promoter was associated with higher risk for CAD and increased CRP level in a Chinese population. It suggested that the 5A/5A stromelysin-1 gene variant could be a genetic risk factor associated with atherothrombosis and inflammation.

P2828 Premature coronary artery disease shows no evidence of linkage to locus encoding for human alpha oestrogen receptor

M.F. Dorsch[1], R.A. Lawrance[2], N.P. Durham[2], J. Barrett[3], N.J. Samani[4], S.G. Ball[2], A.J. Balmforth[2], A.S. Hall[2] on behalf of The British Heart Foundation Family Heart Study Investigators. [1]*Leeds General Infirmary, Institute for cardiovascular Reseach, Leeds, United Kingdom;* [2]*University of Leeds, Institute for Cardiovascular Research, Leeds, United Kingdom;* [3]*ICRF, Clinical Centre, Leeds, United Kingdom;* [4]*University of Leicester, Division of Cardiology, Leicester, United Kingdom*

An association between a dinucleotide repeat polymorphism in the upstream region of the human alpha oestrogen receptor gene with premature coronary artery disease has been reported (BMJ 2000;321:273-4). We examined the relevant locus using a linkage approach.
Sibling pairs recruited as part of the BHF Family Heart Study and affected with premature coronary artery disease (Myocardial Infarction, Coronary Artery Bypass Grafting, Percutaneous Coronary Intervention or definite Angina before the age of 65) were examined. DNA was extracted from whole blood by a standard method. The region of interest was amplified by polymerase chain reaction using the same pair of markers that was used in the initial study that reported the association. Products were analysed by capillary gel electrophoresis. Single-point linkage analysis based on the likelihood ratio test was performed using SPLINK software.
416 families were genotyped consisting of 382 sibling pairs, 29 trios and 5 sets of 4 siblings. No significant linkage was observed in the whole cohort (equivalent LOD score 0.14, p=0.27) or in the pre-specified subgroups of male sib pairs (n=287 independent sib pair comparisons, LOD= 0.18, p= 0.23) or sibs with acute myocardial infarction (n= 173 sib pairs, LOD= 0.02, p= 0.58).
We were unable to detect linkage to the locus encoding for the oestrogen receptor. Population differences, differences between genetic predisposition towards fatal versus non-fatal coronary disease and statistical problems (spurious associations, power) may explain differences between studies.

P2829 Deletion polymorphism of the angiotensin I-converting enzyme gene is a potent risk factor for coronary artery ectasia

S. gulec[1], O. Aras[2], Y. Atmaca[1], O. Akyürek[1], T. Altýn[1], N.Q. Hanson[2], M.Y. Tsai[2], D. Oral[1]. [1]*Ibn-i Sina Hospital, Cardiology, Ankara, Turkey;* [2]*University of Minnesota Medical School, Laboratory Medicine and Pathology, Minneapolis,MN, United States of America*

Background: Coronary artery ectasia (CAE) is characterized by irregular, diffuse, saccular, or fusiform dilatation of the coronary arteries. The mechanism(s) involved in the genesis of CAE are not fully understood. In this study we sought to assess the role of insertion/deletion (ID) polymorphism of angiotensin converting enzyme (ACE) gene,in the development of CAE.
Methods and Results: We prospectively evaluated 3427 consecutive patients who underwent coronary angiography for diagnostic purposes and found that 152 (4.4%) had CAE. Of the 152 patients, 108 (71%) had coexisting significant coronary artery disease (>50% diameter stenosis in any of the major epicardial arteries), whereas 44 (29%) had either no or nonsignificant coronary artery stenosis. Clinical examinations and laboratory investigations revealed no evidence of a collagenosis, connective tissue or inflammatory disease as an underlying etiology. Of the 152 ectatic patients, 82 (53.9%)had the DD genotype, 49 (32.3%) had the ID genotype and 21(13.8%) had the II genotype. Control group consisted of 158 age and sex matched patients with significant coronary artery disease but without any evidence of ectasia. No significant differences were noted between the two groups when features such as hypertension, diabetes, hypercholesterolemia, family history of coronary artery disease, cigarette consumption, incidence of prior myocardial infarction, and left ventricular ejection fraction were examined. The ACE genotype frequencies were significantly different between the two groups, DD genotype beeing more prevalent among patients with CAE (p= 0.0046). Multivariate analysis demonstrated the ACE DD genotype as the only significant risk factor for CAE development in this population. The adjusted odds ratios were 2.16 (95% CI 1.34-3.41, p=0.0027) for DD patients versus II/ID patients and 2.16 (95% CI 1.12-4.14, p=0.02) for DD patients versus II patients.
Conclusion: The ACE DD genotype seems to be a potent risk factor for the development of CAE. The implications of our findings and the underlying mechanisms need to be fully assessed and investigated.

STEM CELLS: METHODOLOGY

P2830 VEGF did not improve left ventricular function after transplantation of fetal cardiomyocytes after myocardial infarction in the rat

E. Skobel[1], A. Schuh[1], E.R. Schwart[2], A. Franke[1], C. Weber[3]. [1]*RWTH Aachen, Med. Klinik I, Aachen, Germany;* [2]*Harvard Medical International, Dr. S. Fakeeh Hospital, Jeddah, United Arab Emirates;* [3]*RWTH Aachen, Molecular Cardiovascular Research, Aachen, Germany*

Objectives: Recent studies have demonstrated feasibility of transplanting fetal cardiomyocytes after myocardial infarction (MI) with improvement of LV-function. The mechanism of improvement is not understood yet due to release of angiogenetic factors by fetal cells in ischemic myocardium-
Methods: Male ventricular fetal cardiomyocytes were injected into marginal regions of MI, 4 weeks after suture occlusion of the left coronary artery in adult female rats with and without VEGF. Sham-operated hearts received VEGF with IMDM or without VEGF. Two months after transplantation(Tx), engrafted cells were traced by fluorescence-in-situ-hybridization (FISH) for Y-chromosomes, LV-dimensions and function was assessed by 2-D and 3-D echocardiography. LV-pressure and coronary flow was measured ex vivo in a Langendorff-perfusion-system and capillary density by factorVIII-staining (n=12 each).
Results: FISH revealed presence of transplanted cells in infarcted host myocardium in association with neovascularization with and without VEGF. Enddiastolic LV-diameter and LV-volumes (3-D-echocardiography) slightly increased in sham-operated rats with and without VEGF, but markedly decreased after Tx with and without VEGF-application (not $p<0.001$ compared to sham-operated). Conversely, fractional shortening declined in sham-operated rats with and without VEGF ($p<0.005$), however gradually increased after Tx with and without VEGF ($p<0.005$).
Conclusions: Transplanted cardiomyocytes-rich graft cells persist in host myocardium and mediate continuous improvement of LV-function and survival in rat model of MI without effect of VEGF-co-transplantation.

P2831 In vitro stimulation of murine pluripotent P19 stem cells by dimethylsulfoxide using the embryoid body-method

S G. Molhoek[1], C F M. Klok[2], R. van Dijk[2], W H. Bax[2], D E. Atsma[2], E E. van der Wall[2], M J. Schalij[2], A. van der Laarse[2]. [1]*Leiden University Medical Center, Cardiology, Leiden, Netherlands;* [2]*Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Background: In various studies DMSO has been described as a differentiation factor for P19 cells (mouse teratocarcinoma cells); one of the differentiated cell types induced by DMSO are cardiomyocytes. In this study differentiation was accomplished by cultivating P19 cells into embryoid bodies, in which the cells have contact with nothing else than the cells in the embryoid body.
Methods: The effects of 1% DMSO on differentiation response of P19 cells were studied after incubation in hanging drops (volume of each drop 20 il) containing cultivation medium (DMEM) supplemented with 20% FBS, 1% DMSO and approximately 400 cells each for 3 days. Cell aggregates, further referred to as embryoid bodies, were transferred from the hanging drops into 24-wells tissue culture plates (1 embryoid body/well) containing normal cultivation medium (DMEM + 10% FBS + 1% Penicilline/Streptomycine + 1% Amino acids), in which the embryoid bodies attached to the bottom and cells started to grow out.
To prove that P19 cells actually differentiated into cardiomyocytes, heart-specific proteins (such as á-actinin) in the differentiated cells were demonstrated using immunofluorescent microscopy. Next to this technique, the embryoid bodies were observed daily, using a microscope, to detect spontaneous contractions.
Results: On day 13 (3 days in hanging drops (DMSO+) and 10 days in the 24-well tissue culture plates (DMSO-)), spontaneously beating cells and cellgroups were observed. With the use of immunofluorescent microscopy, fluorescent cell groups were observed, which indicate the presence of á-actinin in the cells.
Conclusion: The observation of spontaneously beating cells and á-actinin positive cells showed differentiation of the pluripotent P19 stem cells into cardiomyocytes.

P2832 Monocyte transplantation – New tool for in vivo augmentation of collateral vessel growth

R.C. Braun-Dullaeus[1], J. Herold[1], F. Pipp[2], M. Heil[2], B. Fernandez[2], Z. Xing[3], W. Schaper[2]. [1]*Giessen University, Internal Medicine/Cardiology, Giessen, Germany;* [2]*Max Planck Institute, Dpt. of Experimental Cardiology, Bad Nauheim, Germany;* [3]*Mc Master University, Dpt. of Pathology, Hamilton, Ontario, Canada*

Therapeutic augmentation of collateral vessel growth (arteriogenesis) is of tremendous interest for alleviation of morbidity and mortality from ischemic deseases. Monocytes/macrophages (Mo) represent key players of arteriogenesis. They home to sites of hemodynamically relevant stenoses thereby locally creating a highly arteriogenic environment through secretion of growth factors and cytokines. We thought to exploit Mo homing for augmentation of arteriogenesis via ex vivo engineering and injection into rabbits after ligation of their right femoral artery. Monocytes were isolated from rabbit blood by modified Ficoll-Paque gradient centrifugation and plated in medium supplemented with 200 U/ml granulocyte macrophage-colony stimulating factor (GM-CSF) for 24 h. Different amounts of GM-CSF-activated Mo were then intravenousy injected into rabbits 24 h after ligation. 7 days later maximal adenosine-induced conductance (C= flow/mean arterial pressure - mean peripheral pressure, ml/min/100 mmHg) was determined using an ultrasonic flow probe placed around the right external iliac artery. Injection of 3x107 Mo resulted in a 22% rise of C from 105±5 to 128±5 (n= 5, $p<0.05$). Increasing their number to 1.5x108 led to a further augmentation of C to 202±11 (+92%, $p<0.05$) beeing close to values determined in unligated control vessels (262±10, each n=5). Angiographic evaluation of the right thigh demonstrated a significant increase of collateral vessels (no ligation: 5±1; ligation: 11±2, ligation + 3x107 Mo: 16±2; ligation + 1.5x108 Mo: 21±2). The homing of injected Mo was demonstrated by their ex vivo viral infection with the reporter LacZ and later histologic visualization close to collateral vessels. GM-CSF plays an imortant role in arteriogenesis. We, therefore, infected 3x107 Mo with an adenoviral vector coding for GM-CSF (25 pfu) 24 h prior to injection. C was determined 69% elevated (178±8) at day 7 compared with control-infected Mo (122±7, n=5, $p<0.05$). Mo represent an intriguing tool to augment arteriogenesis. Ex vivo activation is able to increase their arteriogenic properties. Furthermore, they can additionally serve as vehicles for genetherapeutic approaches.

P2833 Atorvastatin inhibits the senescence of human endothelial progenitor cells

B. Assmus, C. Urbich, L. Roessig, A M. Zeiher, S. Dimmeler. *J. - W. - Goethe-University, Molecular Cardiology, Frankfurt, Germany*

Endothelial progenitor cells (EPC) play an important role in postnatal neovascularisation of ischemic tissue. Ex vivo expansion of EPCs might be useful for potential cell therapy of myocardial ischemia. However, cultivation of EPCs leads to cellular aging (senescence) which is associated with a reduced proliferative capacity. Therefore, we investigated whether statins might be able to prevent senescence of EPCs.
Results: EPCs were isolated out of peripheral blood and cultivated in EBM medium (medium and supplementary growth factors, Cell Systems) and 20% FCS. FACS analysis revealed that more than 80% of adherent cells stained positive for the endothelial marker proteins KDR, eNOS and VE-cadherin. However, already 2 days after cultivation, EPCs become senescent as determined by acidic β-galactosidase staining (day 2: 88 ± 6.6%, day 4: 100 ± 0.6% senescent cells). Atorvastatin (AT) dose-dependently (1nM-1μM) inhibits the onset of EPC senescence in culture (day 2: 38 ± 12% p=0.01; day 4: 11 ± 4%, $p<0.001$). Similar results were obtained with mevastatin, which demonstrates a class effect of statins. Moreover, AT increased the proliferation of EPCs as assessed by BrdU proliferation assay. Consistent with the increase in proliferation, the cell cycle regulator cyclin F was upregulated in AT-treated EPCs.
To gain further insight into the mechanism of the senescence inhibitory effects of statins, we investigated the role of NO. However, inhibition of the NO-synthase (LNMMA, 1mM) did not reverse the effect of AT. Likewise, exogenous NO (SNAP, 20μM) did not prevent the onset of senescence. Because inhibition of the HMG-CoA reductase also reduces the formation of the products geranylgeranyl- and farnesylpyrophosphate (GGPP and FPP) and, thereby, abolishes Rho-kinase activation, we determined the effect of the above named substrates and the Rho-kinase inhibitor HA1077 (10μM). GGPP and FPP (10μM) reversed the effect of AT (day 4: 77 ± 6.6%, $p<0.001$ and 61 ± 8%, $p<0.001$ senescent cells, respectively), whereas inhibition of the Rho-kinase alone could not prevent the onset of senescence (day 4: 91 ± 3% senescent cells).
Conclusions: Atorvastatin inhibits the senescence of EPCs independent of NO and Rho kinase but dependent on GGPP and FPP. AT-mediated prevention of EPC senescence might be due to a regulation of cell cycle proteins. The inhibition of EPC senescence and improvement of EPC proliferation by statins in vitro may importantly contribute to improve functional activity of EPCs for potential cell therapy.

CONTRACTILE FUNCTION

P2834 Adrenomedullin: calcium dependent inotropic effects in isolated human myocardium

E. Bisping[1], P. Barckhausen[1], G. Dembowski[2], B. Pieske[1]. [1]*Georg-August Universitaet Goettingen, Cardiology and Pneumology, Goettingen, Germany;* [2]*Bayer AG, Leverkusen, Germany*

Adrenomedullin (ADM) is a recently discovered endogenous peptide with potent vasodilatory effects. In heart failure, plasma levels of ADM are elevated, but it is unknown whether ADM directly affects cardiac contractile functions. We tested functional responses to ADM in human atrial and ventricular myocardium.
Methods: Isolated atrial (n=11), ventricular non-failing (n=10) and ventricular failing (n=18) trabeculae were electrically driven at 1 Hz, 37°C. Application of ADM 0.1 μmol/l or 1 μmol/l and simultaneous registration of contractile force and calcium transients (Aequorin light signal (AL)). Application of Isoproterenol (0.003 μmol/l) or $[Ca^{2+}]_o$ 3.2 mmol/l for comparison.
Results: ADM significantly increased contractile force in atrial myocardium (by maximally 33 ± 6% at 1 μmol/l; $p<0.05$) with an overproportional increase in AL (by 69 ± 15%, $p<0.05$). In non-failing ventricular muscles force increased by 8 ± 2% ($p<0.05$; AL not done). In failing ventricular muscles the inotropic effect was marginal (increase by 5 ± 1%; $p<0.05$), but also associated with an overproportional increase in AL (by 18 ± 5%; $p<0.05$; dF/dL= 0.3 ± 0.2). Isoproterenol (equiactive concentration: 0.003 μmol/l) increased force in ventricular muscles by 5 ± 2% and AS by 15 ± 5% ($p<0.05$; dF/dL = 0.3 ± 0.1) whereas $[Ca^{2+}]_o$ (3.2 mmol/l) resulted in proportional changes (force increased by 25 ± 3%, AL by 24 ± 5%; dF/dL = 1.0 ± 0.1). As with Isoproterenol ADM slightly decreased relaxation times.
Conclusions: ADM exerts marked positive inotropic effects in atrial and slight inotropic effects in ventricular myocardium. These effects are associated with overproportional increases in intracellular calcium transients. We suggest a potential cAMP-dependent mechanism of action of ADM in human cardiac muscle.

P2835 Mutation of the calcineurin binding site in FKBP12.6 leads to loss of the FKBP12.6 mediated increase in contractile performance

T. Seidler, A. Kania, J. Prestle, N. Teucher, H. Kögler, G. Hasenfuß.
Georg-August University Goettingen, Dept. Cardiology and Pneumology, Goettingen, Germany

In heart failure, Ca^{2+} release from sarcoplasmic reticulum (SR) is impaired. The 12.6 kDa FK-506 binding protein (FKBP12.6) binds to and modulates the cardiac SR calcium release channel (ryanodine receptor, RyR2) and plays an important role in the pathogenesis of heart failure. We have recently shown that overexpression of FKBP12.6 in cardiomyocytes reduces spontaneous Ca^{2+} leak and increases contractility. Despite binding to RyR2, FKBP12.6 also binds to the Ca^{2+}-dependent protein phosphatase Calcineurin (CAN), but it is not clear whether CAN plays a role in the FKBP12.6 mediated regulation of RyR.
We have constructed a mutant form of FKBP12.6 (FKBP12.6M), which is unable to bind CAN, by exchange of two amino acids (G89P, V90K). Lack of CAN binding was demonstrated in a CAN phosphatase assay using recombinant FKBP12.6M. In this assay, absence of FK506 mediated CAN inhibition by FKBP12.6M was observed and rotamase assays showed preserved binding of FK-506 to FKBP12.6M. We used adenovirus mediated gene transfer for overexpression of FKBP12.6M in isolated rabbit cardiomyocytes. RT-PCR showed the presence of FKBP12.6M RNA and antiserum, raised against the mutated region of FKBP12.6M, confirmed overexpression of FKBP12.6M in western blots.
While overexpression of FKBP12.6 increases contractility, FKBP12.6M did not enhance relative shortening (RS) at a multiplicity of infection (MOI) of 10 when compared to beta-galactosidase control transfected myocytes (2,7±0,1% RS n=117 vs 2,8±0,1% RS n=120, p=0,528). At MOI 50, RS was even significantly diminished (3,9±0,2% RS n=121 vs. 4,4±0,2% RS n=117, p=0,02). Thus, the positive inotropic effect of FKBP12.6 requires an intact Calcineurin binding site. This points to an important role of Calcineurin in the regulation of myocardial contractility.

P2836 Adenoviral overexpression of the Na^+/Ca^{2+}-exchanger in adult rat cardiomyocytes reduces contractile performance and Ca^{2+}-transient

B. Boelck[1], P. Mackenstein[2], G. Muench[3], K. Brixius[2], M. Ungerer[3], R.H.G. Schwinger[2]. [1]*Clinic III of Internal medicine, Lab. of Muscle Re. & Mol. Cardiology, Cologne, Germany;* [2]*Lab. of Muscle Res. & Mol. Cardiology, Clinic III of Internal Medicine, Cologne, Germany;* [3]*Fa. Procorde, Munich, Germany*

The influence of the Na^+/Ca^{2+}-exchanger (NCX) on the Ca^{2+}-homeostasis of the cardiomyocytes and its functional relevance during the contraction cycle is discussed very controversially. The present study aimed to study the effect of the NCX in a NCX-overexpressing model; i.e. isolated rat cardiomyocytes with adenovirus mediated (Ad5NCX/GFP) NCX-overexpression. To reveal dominant changes via the transgene NCX-overexpression, the rat was chosen as a model with a small physiological influence of the NCX on Ca^{2+} handling.
Protein expression was studied by Westernblot analysis with specific antibodies; NCX activity was analyzed with Na^+-dependent 45Ca-uptake. Functional studies were performed with a video edge detection system and after stimulation of cells with increasing frequency, Ca^{2+}, and CPA (Cyclopiazonic Acid, inhibitor of SERCA 2a) in isolated myocytes. Cardiomyocytes infected with Ad5GFP served as the control group.
Westernblot analysis showed a significant increase of the NCX (more than five fold DU) 48h after transfection (10 MOI) whereas other calcium-modulating proteins (SERCA 2a, PLB, Calsequestrin) were unchanged. NCX specific 45Ca-uptake was increased threefold.
In NCX-cells basal and Ca^{2+}-stimulated contractile performance and Ca^{2+}-transients (FURA 2a) were diminished with a more negative force-frequency behavior ($p<0,05$). Inhibition of SERCA 2a by CPA resulted in a significant better diastolic relaxation in NCX-cells compared to control.
Thus, NCX-overexpression might result in depletion of systolic intracellular Ca^{2+}-availability due to activation of Ca^{2+}-extrusion during diastole. Diastolic Ca^{2+}-extrusion by the NCX is especially supported in a condition with reduced SERCA 2a activity.

P2837 Atorvastatin impairs contractile function in engineered heart tissue

O. Zolk[1], U. Mühlhäuser[1], F. Muenzel[1], U. Laufs[2], T. Eschenhagen[1].
[1]*Universität Erlangen, Institut für Pharmakologie, Erlangen, Germany;*
[2]*Universitätskliniken des Saarlandes, Innere Medizin III, Homburg/Saar, Germany*

It is not known whether HMG-CoA reductase inhibitor therapy interferes with cardiac myocyte contractile function. We examined the effects of atorvastatin (ATOR) on isometric force of contraction (FOC) and contraction kinetics in engineered heart tissue (EHT). Myocytes isolated from neonatal rat hearts were reconstituted in a collagen matrix. Resulting EHTs were cultivated for 6 d before treatment with ATOR (1 μM) for additional 5 d. Thereafter, EHTs were placed into organ baths and FOC, time of contraction (T1) and time of relaxation (T2) were recorded under electrical stimulation. Basal FOC was not altered by ATOR compared to vehicle treated controls. However, the response to cumulative concentrations of Ca^{2+} (increase in FOC over basal 0.41±0.03 vs. 0.52±0.03 mN, n=26) and isoprenaline (0.21±0.01 vs. 0.30±0.02 mN, n=26) was significantly diminished. In addition, T1 (ISO 1nM: 43±1 ms vs. 40±1 ms, n=26) was significantly prolonged whereas T2 was not changed. Co-administration of mevalonic acid (MA, 200 μM) completely reversed the effects of ATOR. MA alone had no significant effects. 14C-Phenylalanine incorporation assays revealed that ATOR diminished protein synthesis in EHTs by 17% ($p<0.05$). Interestingly, ATOR significantly reduced the naturally occurring loss of cells in EHTs during cultivation. Immunofluorescence staining of sarcomeric actinin showed no obvious differences in cardiomyocyte morphology and sarcomere organization. The current findings for the first time demonstrate impaired contractile response after ATOR treatment in reconstituted heart tissue. This occurs despite a general cytoprotective effect of ATOR as suggested by increased cell count. This study sheds a new light on HMG-CoA reductase inhibitor actions besides the well established beneficial effects on atherogenesis and endothelial function.

STRESS ECHOCARDIOGRAPHY

P2838 Noninvasive assessment of left anterior descending artery coronary flow reserve by transthoracic echocardiography: feasibility and results

F. Rigo[1], W. Curtaia[1], M. Richieri[1], F. Di Pede[1], P. Della Valentina[1], E. Pasanisi[2], A. Raviele[1], E. Picano[2]. [1]*Mestre Hospital, Cardiology Division, Mestre, Italy;* [2]*Institute of Clinical Physiology, PISA, Italy*

Background: Coronary flow reserve (CFR) is a key physiological parameter which can be evaluated noninvasively by transthoracic echocardiography (TTE) during vasodilator stress. Aim: To assess the feasibility and physiologic meaning of TTE assessment of CFR. Methods: Starting June 1, 2000 to August 1, 2001, 239 consecutive patients (147 males; age=67±19 years) were referred for stress echocardiography. In all, TTE (S12-S8 probe, HP 5500, Agilent technology) evaluation of distal left anterior descending (LAD) coronary artery was attempted at baseline and following dipyridamole (0.84 mg/kg). Wherever color-coded LAD blood flow from the baseline could not be obtained, contrast enhancement with Levovist (Schering AG) was used. Peak diastolic coronary flow velocity of LAD was recorded by pulsed Doppler under the guidance of Color Doppler flow mapping. CFR was calculated as the ratio of dipyridamole/rest peak diastolic flow velocity. Results: The overall feasibility was 93% in the first 100 patients and rose to 98% in the latter 139 ($p<.05$). The need for contrast injection was 38% in the first 100 and 18% in the latter 139 patients ($p<.01$). In patients with complete clinical and angiographic characterization, CFR values were 3.2±0.3 in control group (n=14); 2.4 ± 0.4 in Syndrome X (n= 43); 2.5±0.3 in patients evaluated early after CABG with left internal mammary artery on LAD (n=28); 2.3 ± 0.4 in patients evaluated early after PTCA (n=45); 1.4±0.2 in critical (>70%) native LAD stenosis (n=24); 1.85±0.22 in dilated cardiomyopathy (n=8); 2.01±0.2 in hypertrophic cardiomyopathy (n=9); 1.8±0.3 in aortic stenosis (n= 7). Conclusion: Noninvasive evaluation of CFR by TTE is highly feasible in the echo lab during vasodilator stress echo. After a limited learning curve, contrast injection is rarely needed - further simplifying and reducing the cost of examination. Physiologically congruent results of potential clinical value can be obtained during vasodilator stress echo in different pathophysiological conditions, ranging from coronary artery disease to cardiomyopathy.

P2839 Stress-echo, coronary flow reserve and color tissue Doppler after coronary angioplasty in patients with previous anterior myocardial infarction

M. Galderisi[1], S.C. Silvana Cicala[2], G.S. Giancarlo Scognamiglio[3], A.D.E. Arcangelo D'Errico[4], M.D. Michele Damiano[3], P.G. Paolo Gallo[3], P.G. Pasquale Guarini[3], O.D.D. Oreste de Divitiis[4]. [1]*Federico II University, Clinical and Experimental Medicine, Naples, Italy;* [2]*Second University of Naples, Cardiology Dept., Caserta (Naples), Italy;* [3]*Villa dei Fiori Hospital, Cardiology Dept., Acerra (Naples), Italy;* [4]*Federico II University, Clinical and Experimental Medicine, Naples, Italy*

Aim of the study was to identify possible associations between coronary flow reserve (CFR) and myocardial functional indexes measured by color Tissue Doppler (cTD) after secondary percutaneous transluminal coronary angioplasty (PTCA) in patients with previous anterior myocardial infarction (MI).
Methods: Twenty men (age = 55 ± 5 years) affected by previous anterior MI, 3-6 months after secondary PTCA of left anterior descending coronary artery (LAD), underwent: noninvasive CFR estimation in distal LAD (ratio between hyperemic and basal coronary diastolic flow velocities) by high-frequency Doppler-echo; dobutamine (Dob) stress-echocardiography with determination of wall motion score index (WMSI) on 16 segments and normal myocardium percentage (number of segments with score = 1/16 segments × 100); cTD of middle posterior septum with quantitative analysis of myocardial systolic (Sm) and diastolic (Em and Am) peak velocities, both at baseline and at high Dob dose. According to CFR, patients were divided into 2 groups: 10 with CFR considered as normal according to the reference values of intracoronary Doppler flow wire after MI (> 1.6) and 10 with reduced CFR (< 1.6).
Results: The 2 groups were comparable for age, blood pressure, heart rate, left ventricular (LV) ejection fraction and WMSI at rest. Patients with impaired CFR showed an increase of WMSI and a reduction of normal myocardium percentage at high-dose Dob (both $p<0.01$) in comparison to the group with normal CFR. cTD displayed comparable septal Em/Am ratio both at rest and at high-Dob but Sm, similar between the 2 groups at rest, was lower in patients with CFR < 1.6 at low-Dob ($p<0.05$) as at high-Dob ($p<0.01$). In the overall MI population, CFR had negative relation with high-Dob WMSI ($r = -0.54$, $p<0.01$) and positive association with high-Dob septal Sm ($r = 0.66$, $p<0.001$). This last relation remained significant even after adjusting for diastolic blood pressure, heart rate and high-Dob WMSI (standardized β coefficient = 0.56, $p<0.01$).
Conclusions: The function of coronary microvessel circulation predicts the recovery of myocardial reserve in LV segments corresponding to the coronary artery (= LAD territory) involved into the re-perfusion procedure after MI. The combined use of Doppler-echo derived CFR and cTD applied to stress-echo is promising for evaluating the successful results of secondary PTCA.

P2840 Prognostic significance of grafted left internal mammary artery flow reserve estimated by noninvasive dobutamine Doppler

G. Athanassopoulos[1], N. Koutsogiannis[2], A. Motsi[1], M. Papadakis[2], G. Karatasakis[2], D.V. Cokkinos[2]. [1]*Onassis Cardiac Surgery Center, First Dept. of Cardiology, Athens, Greece;* [2]*Onassis Cardiac Surgery Center, Cardiology Dept., Athens, Greece*

In pts post CABG with LIMA grafted to LAD, interrogation of underlying ischemia in LIMA/LAD territory may be performed using LIMA flow reserve (CFR) by noninvasive Doppler using either adenosine or dobutamine. We assessed the relative contribution of LIMA/LAD CFR by dobutamine (CFRdob) for prediction of cardiac events (CE) compared to the respective SPECT Tl201 and dobutamine stress echo (Dob-echo) outcome.
Methods: 52 consecutive pts (age 66±9) were studied within a range of 1-15 years (6±4) post CABG. LIMA CFR was estimated (proximal LIMA:supraclavicular fossa) during the dobutamine 30μg/kg/min stage of Dob-echo protocol. All pts underwent coronary angiography and SPECT Tl201 within a period <3months. The cut off point of 1.27 for CFRdob was predictor of LIMA/LAD patency, derived from receiver operating curve analysis (area: 0.79, p: 0.002, sens: 0.71, spec: 0.90)
Results: 12 pts had a significant stenosis (>70% diameter) either in the LIMA or in LAD distal to the anastomosis. During a follow up period of 18±11 months, 11 pts had CE(death, myocardial infarction, angina, revascularization). Pts had a telephone interview and coronary risk profile/treatment were obtained from chart review.
Pts with or without CE had similar age (66±7 vs 62±9), time elapsed from CABG (years:7±4 vs 6±3), EF (%:44±10 vs 49±8) and follow up (months: 18±10 vs 18±11). The two groups had similar incidence of CAD risk factors and use of B-blockers, CEI, statins during follow up. In stepwise logistic regrsession analysis (SLRA) for prediction of CE including SPECT outcome for LAD territory and CFRdob, then CFRdob had an independent contribution ($R=-0.32$, $p=0.03$ with $exp(b)=0.09$, thus implying a 11 odds ratio for CE when CFRdob<1.3). When Dob-echo outcome for LIMA/LAD ischemia was included with CFRdob in SLRA, then CFRdob had an independent contribution ($R=-0.36$, $p=0.03$ with $exp(b)=0.05$, thus implying a 20 odds ratio for CE when CFRdob<1.3). When EF was considered, the contribution of CFRdob remained unchanged ($R=-0.21$, $p=0.06$, $exp(b)=0.13$, odds ratio=7.7). Consideration in SLRA of two different models, one including CAD risk factors and the other the use of b-blockade/CEI/statins during follow up, did not influence the importance of CFRdob for prediction of CE (for CFRdob: $exp(b)=0.07$, $p=0.01$ and $exp(b)=0.02$, $p=0.01$ respectively).
Conclusion: Functional evaluation of LIMA/LAD territory by noninvasive CFRdob provides important information for CE in pts post CABG which is independent from the respective Dob-echo or SPECT outcome, as well as from LV function.

P2841 Coronary flow reserve and brachial artery reactivity in patients with chest pain and "false positive" exercise-induced ST segment depression

F. Rigo[1], V. Cutaia[1], M. Richieri[1], C. Zanella[1], L. Venneri[2], E. Picano[2]. [1]*Mestre Hospital, Cardiology Division, Mestre, Italy;* [2]*Institute of Clinical Physiology, PISA, Italy*

Normal coronary arteries may coexist with a physiologically significant impairment in coronary flow reserve (CFR) and with systemic endothelial dysfunction. Aim of this study was to establish the ultrasonically assessed CFR and systemic endothelial function correlates of exercise-induced "false positive" ischemic-like ST segment depression. We studied 13 control subjects and normal coronary arteries (Group 1, controls), and 53 patients with history of chest pain, positive (>1.5 mm) exercise-electrocardiography test and angiographically normal coronary arteries (Group 2, microvascular angina). All patients underwent stress echocardiography prior to angiography. After angiography, CFR and endothelial function were assessed on different days and in random order. Transesophageal (n=16) or transthoracic (n=50) echocardiographic evaluation of left anterior descending coronary artery peak diastolic flow was performed at baseline and following vasodilatory stimulus (dipyridamole up to 0.84 mg/kg in 10 min). Brachial artery flow-mediated vasodilation (FMD) was assessed by measuring the change in brachial artery diameter in response to hyperemic flow by high frequency vascular ultrasound. All patients had normal resting and stress induced left ventricular function by 2D - echocardiography. Controls showed higher values of CFR than patients with microvascular angina did (Group 1=3.2±0.3 vs Group 2=2.3±0.6, $p<0.0001$). FMD was lower in patients with microvascular angina (Group 1= 11.7±1.5% vs Group 2= 4.2±3.4%, $p<0.01$). There was a weak, albeit significant, correlation between CFR and FMD ($r=0.33$, $p<0.01$). Conclusion: ischemic-like stress-induced ST segment changes may be associated to a physiologically significant, but extremely variable reduction in CFR and systemic endothelial dysfunction in patients with normal coronary arteries.

P2842 Combined assessment of contractility and flow reserve in patients with prior coronary bypass surgery by dipyridamole echocardiography

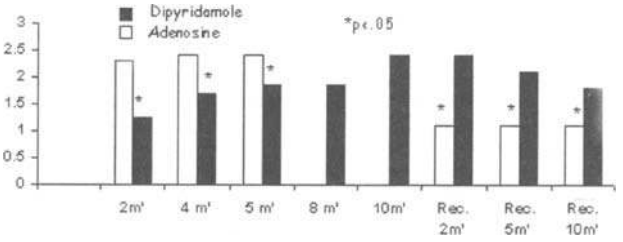
F. Chirillo, A. Bruni, A. De Leo, Z. Olivari, C. Cavallini, E. Franceschini, R. Mantovan, P. Stritoni. *Ospedale Ca' Foncello, Cardiology Dept., Treviso, Italy*

Recent advance in ultrasound systems enables measurement of coronary flow reserve (CFR) of mammary artery and saphenous vein coronary artery bypass grafts (CABG) using transthoracic Doppler echocardiography (TTDE). However little is known about the relationship between the hyperemic response and regional asynergy induced by stress echo. We evaluated 106 consecutive patients (83M/23F; mean age 67±14 years) scheduled for coronary angiography because of recurrent ischemia after CABG surgery. After evaluating the segmental left ventricular wall motion using tissue harmonic imaging, mammary artery grafts were assessed placing a 5-7 MHz probe in the supraclavicular area sampling the graft flow few cm distal to the takeoff from the subclavian artery. Saphenous vein grafts to left anterior and circumflex coronary artery were detected in the area anterior to the right ventricular outflow; grafts to the right coronary artery were detected anterior to the right ventricular wall with the patient in right lateral decubitus. Dipyridamole (0.84 mg/Kg/8 min) and atropine (1mg) were administered. CFR (ratio of the hyperemic to baseline peak diastolic velocity) <2.0 and <1.6 was considered abnormal for arterial and saphenous grafts, respectively. All patients underwent coronary angiography 2-48 hours after stress echo. CFR feasibility was 94.5%. Wall motion analysis was feasible in 95.9%. Abnormal CFR showed 98% sensitivity, 83% specificity and 89.7% accuracy for the detection of significant (>70%) graft or distal recipient artery stenosis. Stress-induced wall motion abnormalities had 87% sensitivity, 97% specificity and 88.1% accuracy for significant stenosis. False positives of CFR were found in diabetic and hypercholesterolemic patients who had reduced vasodilating capacity and in presence of poor distal runoff of the recipient artery. Inaccauracies of stress echo were observed in presence of baseline wall motion abnormalities, conduction disturbance, blunt pressure and heart rate response to stressors. In 11 patients findings of both techniques integrated to achieve a correct diagnosis. In conclusion the simultaneous assessment of CFR and contractility by TTDE dipyridamole echo is highly feasible and allows to increase significantly the sensitivity and the accuracy of the test.

P2843 Coronary flow reserve by tranthoracic stress echo: adenosine or dipyridamole?

F. Rigo[1], W. Cutaia[1], E. Pasanisi[2], F. Di Pede[1], A. Raviele[1], E. Picano[2]. [1]Mestre Hospital, Cardiology Division, Mestre, Italy; [2]Institute of Clinical Physiology, PISA, Italy

Background: Coronary flow reserve (CFR) is a key physiological parameter which can be evaluated noninvasively with unsurpassed temporal resolution by transthoracic echocardiography (TTE) during vasodilator stress. Aim: To assess the entity, time course and feasibility of TTE assessment of CFR with high dose adenosine (ADO) and dipyridamole (DIP).
Methods: Starting June 2001, 16 patients (9 females; age=58±12 years) with angiographically normal coronary arteries were referred for stress echocardiography. In all, TTE (S8 or S12 probe, HP 5500, Agilent technology) evaluation of distal left anterior descending (LAD) coronary artery was attempted at baseline and following dipyridamole (0.84 mg/kg over 8') and adenosine (140 mcg/kg in 5'), within 24 hours. Wherever color-coded LAD blood flow from the baseline could not be obtained, contrast enhancement with Levovist (Schering AG) was used. Peak diastolic coronary flow velocity of LAD was recorded by pulsed Doppler under the guidance of Color Doppler flow mapping. CFR was calculated as the ratio of dipyridamole/rest peak diastolic flow velocity.
Results: Values of coronary flow reserve over time are reported in figure.



CFR values over time.

Conclusion: High dose ADO and DIP elicit similar and high coronary vasodilatory response, more long- lasting with DIP, which is therefore ideally suited for prolonged acquisition times and integrated imaging modalities requiring sampling on different coronary arteries and/or of different parameters (wall motion and coronary flow).

P2844 Use of transthoracic Doppler assessment of coronary flow reserve for 6 month follow-up post percutaneus coronary intervention

A. Ochala[1], P. Sanecki[2], B. Gabrylewicz[1], A. Pyrlik[1], P. Garbocz[1], K. Maslankiewicz[1], P. Kardaszewicz[2], M. Tendera[1]. [1]Silesian Medical School, 3rd Dept. of Cardiology, Katowice, Poland; [2]Provincial Hospital, Cardiology Dept., Czestochowa, Poland

Background: Advances in ultrasound equipment enable measurement of coronary flow reserve (CFR) of the left anterior descending artery (LAD) with transthoracic second harmonic Doppler echocardiography (TTHDE). CFR at rest and after pharmacologically induced vasodilatation and with contast enhancement could assessed the presence of a significant (>70%) LAD stenosis. Sensitivity and specificity of commonly used noninvasive methods are not satisfying in detecting restenosis after percutaneus coronary intervention (PCI).
Purpose: We have therefore tested the ability of TTHDE technique to be precise noninvasive method to control the angiographic patency of the LAD during 6 month follow-up.
Methods: In 30 consecutive patients (pts) age 56,5±7,2 years, after coronary angiogram confirming severe LAD stenosis, TTHDE was performed. Control measurement was done post PCI and final evaluation 6 months later or during recurrent ischemia. This final evaluation was followed by control CA. Echocardiogarphy was performed with Acuson Sequoia unit by use of broad band transducer with second harmonic capability (3v2c). Each pts underwent a color-guided pulsed-wave Doppler recording of coronary blood velocity in LAD in baseline conditions and after dipyridamole administration. The Doppler signal was enhanced by echo-contrast agent Levovist (Schering). Contrast infusion was performed both before and after dipyridamole. The normal CRF value known from the previous studies is >2,0. All CA results were blinded to TTHDE performing team.
Results: All pts had abnormal CFR values before PCI - both for mean systolic velocity (MSV) and peak systolic velocity (PSV), 1,35±0,6 and 1,49±0,4 respectively. During follow-up 9 pts had recurent ischemia, 7 had patological MSV and PSV values with restenosis confirmed with CA in 6. Those pts were included to group A - with restenosis and 24 others to group B - without. In group A CFR increased after PCI from 1,13±0,22 to 2,66±0,85, p=0,15 and in group B from 1,54±0,37 to 2,82±0,56, p=0,0003. Nonsignificant CFR increase post procedure could be a predictive factor of restenosis.
Conclusions: The sensitivity of TTHDE assessment of LAD patency in 6 month follow-up was 100%, specificity 97%, being most accurate noninvasive method for monitoring LAD patency post PCI. We conclude that statistically nonsignificant CRF increase after PCI could be a predictive factor of restenosis, that could bring useful clinical information for prognosis and clinical decision making e.g. planned rePCI with stent deployment.

P2845 Coronary flow velocity reserve of the left circumflex coronary artery with transthoracic second harmonic Doppler echocardiography

T. Hasegawa[1], Y. Kawase[1], K. Okajima[1], K. Hato[1], M. Nishimoto[1], J. Yoshikawa[2]. [1]Izumi municipal hospital, Cardiovascular Medicine, Izumi, Japan; [2]Osaka City University, 1st Department of Internal Medicine, Osaka, Japan

Background Coronary flow velocity reserve (CFR) assessment is a clinically useful method to assess coronary function. It has been assessed as CFR by noninvasive methods with a transthoracic doppler echocardiographic (TTDE) probe. we can assess CFR in the anterior decending coronary artery by TTDE. The purpose of this study is to evaluate the feasibility in the assessment of CFR in the left circumflex coronary artery (LCX) by TTDE.
Methods We studied 11 patients who underwent coronary angiography. With TTDE, diastolic coronary flow velocity in the proximal LCX were recorded at rest and during hyperemia induced by intravenous infusion of adenosin (0.14 mg/kg/min) under the guidance of color Doppler flow mapping. Intravascular velocity mesurement in the proximal LCX was attained by Doppler guide wire at rest and after hyperemic stimulas by intravenous infusion of adenosin. We compared CFRs for peak and mean diastolic coronary flow velocities (PDV and MDV) determined by TTDE to Doppler flow wire (DFW).
Results There was close agreement between CFRs for peak and mean diastolic velocity by TTDE and DFW (CFR for MDV; r=0.872, p=0.0001. CFR for PDV; r=0.810, p=0.0014.). The peak and mean diastolic coronary flow velocities at baseline determined by TTDE was not correlated to those determined by DFW significantly.
Conclusions Transthoracic echo Doppler with the harmonic mode is a feasible for assessing diastolic CFR.

P2846 Noninvasive assessment of coronary flow reserve by intravenous myocardial contrast echocardiography: comparison with magnetic resonance imaging

P.H. Jung[1], T. Borgmann[1], J. Strotmann[2], C. Wacker[2], C. Dueren[2], F. Fidler[2], W. Bauer[2], C.E. Angermann[1]. [1]University of Wuerzburg, Dpt. of Cardiology, Wuerzburg, Germany; [2]Med. Klinik der Universität Würzburg, Cardiology, Würzburg, Germany

Data from our working group suggest that quantitative myocardial perfusion imaging is feasible by magnetic resonance imaging (MRI). The aim of the present study was to assess feasibility and reliability of measurements of coronary flow reserve (CFR) performed with intravenous echocardiographic myocardial perfusion imaging (EMPI) by comparison to MRI measurements of CFR in the same individuals.
Methods: 10 healthy volunteers (24±4 years, 7 male) underwent adenosine stress testing at two occasions: MR perfusion imaging using saturation recovery T1 based spin-labeling technique (SRTFL) and EMPI. During EMPI, before and during infusion of 140µg/kg/min adenosine up to 15 loops of the 3 apical standard views were stored digitally (HDI 5000, ATL Philips) during infusion (90ml/h) of the transpulmonary contrast agent SonoVue (Bracco Byk-Gulden). To avoid contrast destruction during real time imaging, low emission power (MI 0.12-0.18) and a contrast specific imaging modality, power pulse inversion, was used. Non linear curve fitting (y=A*(1-e(-beta*t)) of the replenishment in a representative septal segment provided the value beta, which describes the deflection of the curve. ECHO-CFR was calculated as the quotient of the value beta during adenosine infusion and at rest, respectively. MRI-CFR was evaluated from absolute quantitative perfusion using two-compartment model analysis.
Results: Adenosine infusion was well tolerated by all participants. The EMPI data of one volunteer was not evaluable due to insufficient image quality. Mean beta at rest was 0.3±0.4 s-1 and 0.85±0.6 s-1 during adenosine stress. Mean ECHO-CFR was 3,23±1.1 and showed a close correlation with MRI-CFR. The value A (plateau) showed a higher diversity (0.7-4.0 at rest, 1.8-9 during adenosine stress) compared to beta and a worse correlation with MRI results.
Conclusion: Assessment of CFR by contrast perfusion echocardiography is feasible and results correlate well with MRI-CFR given by quantitative spin-labeling perfusion measurement.

P2847 Transthoracic echocardiographic assessment of coronary artery flow and reserve in the 3 major coronary arteries: feasibility and results

F. Rigo[1], M. Richieri[1], V. Cutaia[1], C. Zanella[1], E. Pasanisi[2], A. Raviele[1], E. Picano[2]. [1]*Mestre Hospital, Cardiology Division, Mestre, Italy;* [2]*Institute of Clinical Physiology, Pisa, Italy*

Background: Coronary flow reserve (CFR) can be measured by transthoracic echocardiography (TTE) during vasodilator stress on mid- distal left anterior descending (LAD). Left circumflex (LCx) and Posterior Descending (PD) have remained off- limits for this technique so far. **Aim:** To assess the feasibility and results of TTE assessment of CFR in the 3 coronary arteries. **Methods:** Starting June 1 2001, 66 consecutive patients (42 males; age=64 ±12 years) were referred for stress echocardiography. In all, TTE (S8 probe, second harmonic 7 MHz, HP 5500, Agilent technology) imaging of 3 coronary arteries was attempted. Mid - distal LAD coronary artery was imaged from a modified apical two-chamber view; PD artery from apical 2- chamber with counterclockwise rotation and anterior angulation of the transducer; LCx from apical 4- chamber with a clockwise 50 - 80 degrees rotation from LAD imaging and posterior angulation of the transducer. Wherever color-coded blood flow from the baseline could not be obtained, contrast enhancement with Levovist (Schering AG,300 mg/ml/min) was used. Peak diastolic coronary flow velocity of each coronary artery was recorded by pulsed Doppler under the guidance of Color Doppler flow mapping. CFR was calculated as the ratio of dipyridamole/rest peak diastolic flow velocity. **Results:** Interpretable signals (at baseline and during stress) were observed in 65 patients for LAD, 35 for LCx and 44 for DP, yielding a feasibility of 98, 53 and 66% respectively. The time needed for successful coronary artery imaging was 92±18 s for LAD, 350±30 for LCx and 260 ±33 s for PD. In the 27 patients with angiographically confirmed normal coronary arteries and interpretable signals from all 3 arteries, CFR values were not different on LAD (2.5±0.4), LCx 2.5±0.5(p=ns) and PD (2.5±0.5; p=ns). **Conclusion:** With last generation, high frequency,second-harmonic, contrast-enhanced transthoracic echocardiography, imaging of coronary artery flow and assessment of flow reserve can be feasible in all major coronary arteries.- albeit with different success rates, highest for LAD and lowest with LCx. In the absence of epicardial coronary artery disease, coronary flow reserve values are comparable in the 3 coronary arteries.

P2848 Long-term prognostic value of pharmacological stress echocardiography in diabetics patients: a single center experience

A. D'Andrea[1], S. Severino[1], P. Caso[1], L. De Simone[1], B. Liccardo[2], M. Scherillo[1], N. Mininni[1], R. Calabrò[2]. [1]*Ospedale Vincenzo Monaldi, Cardiology Dept., Naples, Italy;* [2]*Second University of Naples, Cardiology Dept., Naples, Italy*

Patients (pts) with diabetes mellitus have an increased risk of cardiovascular morbidity and mortality. Data on the prognostic value of pharmacological stress echocardiography (PSE) in diabetic pts are still lacking. The purpose of this study was therefore to assess the prognostic significance of PSE and its incremental role in diabetics pts with known or suspected coronary artery disease. **Methods:** We studied 325 diabetics pts who underwent PSE with either Dobutamine (185 pts) or Dypiridamole (140 pts) in our institution from July 1995 to December 2000. 12 pts who underwent coronary artery revascularization within 3 months from the PSE, and 10 lost to follow-up were censored. Pts outcome and clinical evaluation for the presence of cardiac risk factors were finally assessed in 303 pts through review of patient's hospital record or by phone interview, for a mean period of 32.9 (range 4-60) months. Spontaneous hard events (death; combined endpoint: death + myocardial infarction) were considered as endpoints. **Results:** no major complication occurred during the tests. The PSE was positive in 122 pts (40.3%). During the follow-up 75 hard events occurred, including 40 death (13.2%) and 35 non-fatal acute myocardial infarction (11.5%). At univariate analysis, the following variables resulted significantly predictive for hard events (in descending order): peak stress left ventricular ejection fraction (peak EF) < 40%, wall motion score index (WMSI) at rest, PSE time duration, previous myocardial infarction, age and positive PSE for ischemia. By multivariate analysis, the combination of clinical and stress test variables identified age, peak EF < 40% ($p<0.001$) and PSE duration ($p<0.01$) as strongest independent predictors of cardiac death (global chi-square: 68.3; $p<0.0001$). On the other hand, peak EF ($p<0.001$), WMSI at rest and previous myocardial infarction appeared to be the only independent determinants of the combined endpoint (global chi-square: 58.2; $p<0.0001$). The mean survival time free of hard cardiac events was 43.9 months in pts with peak EF < 40%, and 55.4 months in pts with peak EF > 40% (Log Rank:12.4; $p < 0.0005$). **Conclusions:** our findings suggest that different DSE variables should be considered when assessing the likelihood of future events in diabetic pts. A PSE response positive for ischemia does not predict a worse outcome in diabetic pts. Conversely, global left ventricular function at peak stress is the strongest independent predictor of hard cardiac events, combined with other clinical and echo variables.

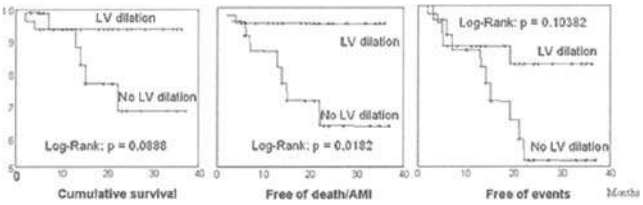
P2849 Prognostic information of left ventricular dilation in those patients with a positive stress echo

D. Villagomez, J. Zamorano, R. Moreno, J.L. Rodrigo, C. Almería, A. Aubele, J.L. Aznar, L. Sánchez-Harguindey. *Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain*

It is well known that left ventricular dilation in those patients during stress echo is a sign of ischemia. Our aim was to analyze if among those patients with a positive stress echo result, left ventricular dilation is associated with a worse long-term prognosis.

Patients and methods: 63 patients undergoing stress echo (29 dypiridamole, 22 dobutamine, and 2 adenosine) in which test showed positivity at echocardiography were studied. Patients were followed-up during a mean of 18±10 months. Left ventricular dilation during stress echo was defined as the presence of increasing in left ventricular end-diastolic volume measured at apical 4-chamber view. The outcome of patients with and without left ventricular dilation was compared (Kaplan-Meier survival curves, that were compared with the Log-Rank test).

Results: Mean age was 68±9 years, and 76% were male gender. During stress echo, end-diastolic left ventricular volume decreased from 96±37 to 87±40 ml (paired t-test: $p = 0.003$), and end-systolic volume from 44±28 to 39±27 ml ($p = 0.004$). Left ventricular dilation occurred in 23 patients (36.5%). Prognosis at 3-years was worse in patients with left ventricular dilation: Cumulative survival 69±12% vs. 95±3.5% (Log-Rank: p=0.0888), probability of being free of death and myocardial infarction 62.9±11.7% vs. 95±3.5% (Log-Rank: p=0.0182), and free of any event (death, infarction, revascularization or admissions due to angina or cardiac failure) 52.4±11.9% vs 87.5±5.2% (Long-Rank: $p = 0.1038$) (see figure).



Prognosis after stress echo.

Conclusion: Left ventricular dilation is not only an indirect sign of ischemia during stress echo. Left ventricular dilation implies by itself a worse long-term prognosis among those patients with a positive stress echo.

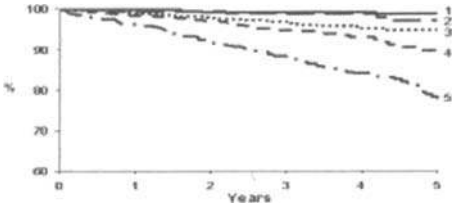
P2850 Validation of a model for prediction of all causes of mortality by exercise echocardiography

A. Elhendy, D. Mahoney, K. Burger, J. Seward, P. Pellikka. *Mayo Clinic, Cardiovascular Division, Rochester, United States of America*

Rationale. The aim of this study was to validate a model for prediction of mortality by combined clinical, exercise stress and echocardiographic data.

Methods: We studied 5679 patients (age 62 ± 12 years, 3231 men) who were followed up for a mean of 3 years after treadmill exercise echocardiography. Patients were randomly divided into 2 groups of equal size: 1) The modeling group; In these patients multivariate analysis was performed using clinical, exercise stress ECG and echocardiographic data to define independent predictors of mortality. To determine parameter coefficients, 300 bootstrap resamplings were performed. Patients were divided into 5 risk categories according to their composite score. Survival rate in each of these risk categories was estimated by kaplan-Meyer method. 2) The validation group. In this group, the risk model was applied. Patients were divided into 5 risk categories based on data obtained from the modeling group.

Results: During follow-up, there were 315 deaths (151 in the modeling group). Independent predictors of mortality in the modeling group were exercise wall motion score index ($\chi^2 = 22.4$, $p < 0.0001$), workload ($\chi^2 = 17.1$, $p < 0.0001$), male gender ($\chi^2 = 15.4$, $p<0.0001$) and age ($\chi^2 = 5.5$, $p=0.02$). Survival curves in each of the predefined risk categories in the validation group are shown in the figure.



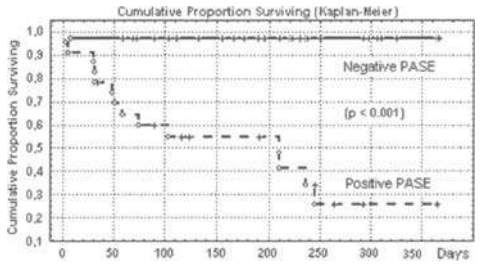
Mortality in the validation group according to risk factor.

Conclusion: This study provides a model for categorical risk assessment by combining clinical, exercise stress and echocardiographic data.

P2851 Prognostic value of noninvasive pacemaker stress echocardiography in patients with permanent pacemakers: a multicenter study

V. Chubuchnyy, E. Plonska, U. Baldini, L. Fonseca, H.R. Villaraga, A. Alaimo, E. Hoffmann, E. Picano on behalf of PASE (Pacemaker Stress echo) study group. *Institute of Clinical Physiology, PISA, Italy*

Background: Noninvasive pacemaker stress echocardiography is an effective option for noninvasive diagnosis of coronary artery disease (CAD) in the expanding population of patients with permanent pacemakers.
Aim: To investigate the value of pacemaker stress echocardiography in risk stratification of patients with permanent pacemakers and suspected CAD.
Methods: Fifty seven patients (41 men, age 66 ± 11 years) with permanent pacemakers underwent noninvasive pacemaker stress echocardiography by external programming (10 bpm increment up to ischemia or target heart rate) to evaluate suspected or known coronary artery disease. All 8 contributing laboratories passed the quality control for stress echo reading before entering the trial. All patients have follow-up for 6 ± 3 months. Both soft (coronary revascularization, unstable angina) and hard (myocardial infarction, cardiac death) end points were recorded and analyzed.
Results: Pacing stress was well tolerated and echo images were interpretable in all patients. A positive echocardiographic result (evidence of ischemia) was detected in 23 (40%) patients. During follow-up, there were 3 cardiac deaths, 2 myocardial infarctions, 4 unstable angina and 8 coronary revascularizations. The overall event-free survival was 39% in the ischemic group and 97% in the nonischemic group ($p<0.001$)(Picture). In a multivariate analysis positive result of stress echocardiography was independently associated with increased risk of end points (hazard ratio = 11.9; 95% confidence interval: 5.5 to 18.3; p = 0.01).



Pacing stress echo and prognosis.

Conclusions: In patients with permanent pacemakers and suspected or known CAD a positive noninvasive pacemaker stress echocardiography is a strong prognostic predictor.

P2852 Early low-dose dobutamine echocardiography in patients with acute myocardial infarction treated with facilitated percutaneous coronary intervention-preliminary results

N. El-Massri[1], A. Okraska[1], J. Zalewski[2], U. Czubek[1], G. Gajos[1], D. Dudek[3], K. Zmudka[2], W. Piwowarska[1]. *[1]Dept. of Coronary Disease, Jagiellonian University, Kraków, Poland; [2]Jagiellonian University, Dept. of Interventional Cardiology, Kraków, Poland; [3]Jagiellonian University, II Cardiology Department, Kraków, Poland*

Facilitated percutaneous coronary intervention intervention (PCI) combines pharmacotherapy (reduced dose thrombolysis and full dose platelet GP IIb/IIIa inhibitor) and immediate PCI in acute myocardial infarction (AMI).
The aim of this study was to evaluate global and regional contractile function at rest and contractile reserve during dobutamine echocardiography (DE) in patients with AMI treated with facilitated PCI.
Data of 90 pts (70% males, 30% females, mean age 56,84 ± 9,9 years) were analyzed, 11(12,2%) had prior MI, 7(7,8%) in a different region, 4(4,5%) in the same region. All pts received in local hospitals intravenous thrombolytic therapy (rt-PA 15mg bolus + 60-min infusion of 35 mg) and intravenous GP IIb/IIIa inhibitor (abciximab 0,25mg/kg bolus + 12-h infusion 0,125μg/kg/min). PCI was performed after immediate transfer of pts to a regional cardiology center with a Cathlab. Mean transfer time was 76 ± 25 min.
Echocardiography was performed 3,6 ± 1,7 days after AMI. Contractility was assessed using a 16-segment model and wall motion score index (WMSI) was calculated. A contractile reserve was defined as an improvement of wall motion by at least 1 grade in 2 or more contiguous segments during dobutamine infusion (5-15μg/kg/min).
At baseline regional contractility was normal in 10 (11,1%) pts. From the visible 1420 segments 68,7% were normokinetic, 16% hypokinetic, 14,7% akinetic, 0,5% dyskinetic. Preserved left ventricular (LV) function defined as ejection fraction (EF)>50% was observed in 74 (82,2%) pts. Mean EF was 57,8±9,2%. DE was performed in 69 (76,6%)pts. During DE significant improvement of regional contractility and WMSI was observed (1,509±0,28 at baseline to 1,316±0,28 at maximal dose of dobutamine; p<0,0001) (table). A contractile reserve was observed in 49 pts(71,01%). No major adverse events during DE occurred.

	WMSI p<0,0001	Seg. analyzed	Normokinetic	Hypokinetic	Akinetic	Dyskinetic
Baseline	1,509	1093	712 (64,1%)	197 (18%)	183 (16,7%)	1(0,1%)
Dobutamine Echocardiography	1,316	1091	853 (78,2%)	132 (12,1%)	105 (9,6%)	1(0,1%)

Conclusions: Early low-dose dobutamine echocardiography is a safe way to assess contractile reserve in patients with AMI and patent infarct-related artery. A high percentage of patients with AMI treated with facilitated PCI have well preserved LV function and contractile reserve.

P2853 Real time myocardial contrast echocardiography predicts left ventricular wall motion recovery after reperfused acute myocardial infarction

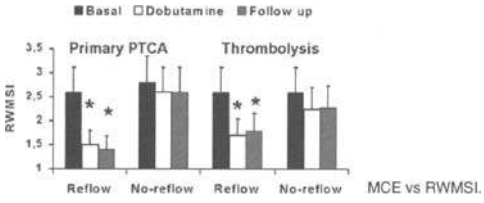
R. Perez, J. Peteiro, I. Rodriguez, R. Soler, E. Rodriguez, L. Monserrat, A. Castro-Beiras. *Juan Canalejo Hospital, Cardiology, A Coruña, Spain*

Real time myocardial contrast echocardiography (RT-MCE) is a recently developed method that avoid some of the limitations of intermittent triggered imaging. We sought to determine whether: 1) perfusion by RT-MCE would predict recovery of LV function after acute myocardial infarction (AMI), and 2) data are comparable to perfusion by Technetium-99m-sestamibi single photon emission computed tomography (SPECT) and contrast-enhanced magnetic resonance (CMR).
Methods: We studied 34 consecutive patients (pts) with AMI submitted to percutaneous transluminal coronary angioplasty. MCE was performed (up to 3 intravenous slow injections containing 1 cc of Optison and 9 cc of saline each) 6±3 days after AMI. 2-dimensional echocardiography (2-DE) was performed at the time of the MCE study and at follow-up (9±2 weeks) to measure wall motion score index (WMSI). SPECT and CMR were performed before discharge in 16 and 5 pts respectively. A 10-segment LV model was used for perfusion analysis, scoring 0=absence of perfusion; 0.5=partial perfusion; and 1=complete perfusion. Regional (AMI-related territory) and global WMSI were calculated using a 16-segment model.
Results: Follow-up 2-DE was available for 32 pts that were subdivided in 2 groups: Recovery (RG) (n=22) and no recovery group (NRG) (n=10). No significant differences in clinical, angiographic and 2-DE variables were found between groups at baseline. Global and regional WMSI improved from 1.5±0.3 to 1.2±0.2 ($p<0.001$) and from 1.9±0.5 to 1.5± 0.4 ($p<0.001$) in the RG, and impaired from 1.5±0.3 to 1.6±0.2 ($p<0.05$)) and from 1.9±0.5 to 2.0±0.4 ($p=0.06$) in the NRG. Regional and global MCE perfusion score were 0.8±0.3 and 0.9±0.1 in the RG; and 0.5±0.4 and 0.7±0.3 in the NRG ($p=0.06$ and $p=0.11$, respectively). Intersegment concordance for perfusion defects between RT-MCE and SPECT was 81% ($p<0.001$, k= 0.38) and between RT-MCE and CMR was 77% ($p=0.29$, k=0.17). A regional perfusion score >0.65 was the more accurate RT-MCE value to predict LV recovery with positive predictive value of 81% and negative predictive value of 60% ($p<0.05$).
Therefore, RT-MCE has high positive predictive value for recovery of LV function after reperfused AMI.

P2854 Microvascular status after acute myocardial infarction: the effect of no-reflow in patients treated with primary PTCA or intravenous thrombolysis

P. Colonna[1], C. Cadeddu[1], R. Montisci[1], L.J. Chen[1], A.H. Selem[1], M. Ruscazio[1], L. Meloni[1], S. Iliceto[2]. [1]*University of Cagliari, Cardiovascular and Neurological Dept, Cagliari, Italy;* [2]*University of Padua, Division of Cardiology, Padua, Italy*

Background: In patients with acute myocardial infarction (AMI), early recanalization obtained with thrombolysis or primary PTCA, results in smaller infarcts and better clinical outcome. However, despite early recanalization, some patients suffer from microvasculature damage (no-reflow phenomenon). This study aimed to verify the effect of no-reflow on clinical outcome in patients treated with primary PTCA or intravenous thrombolysis.
Methods: We studied 55 patients with a first AMI (21 treated with primary PTCA and 33 with intravenous thrombolysis, all with no residual stenosis in the infarct artery) with: basal echocardiogram on the first day and at 90-days follow-up, intravenous myocardial contrast echocardiography to assess microvascular perfusion 2.1±1.3 days after AMI and low dose dobutamine echocardiography 3.8±1.6 days after AMI. Regional wall motion score index (RWMSI) analysis was performed in all echocardiographic studies.
Results: Patients with microvascular reflow at contrast echocardiography showed RWMSI recovery from basal to dobutamine and follow up both when treated with primary PTCA (2.6±0.4 vs 1.5±0.4 vs 1.5±0.5, *p<0.001) or with thrombolysis (2.6±0.2 vs 1.7±0.5 vs 1.8±0.5, *p<0.001). In all patients with No-reflow phenomenon the RWMSI did not change significantly.



Conclusion: The presence of microvascular reflow at contrast echocardiography predicts RWMSI recovery at dobutamine and follow up echocardiography, independently from thrombolytic or PTCA therapy.

P2855 A comparison between intracoronary and intravenous myocardial contrast echocardiography in the study of myocardial viability after acute myocardial infarction

C. Palagi, G. Mengozzi, D. Giorgi, R. Dell'Anna, C. Nardi, A.S. Petronio, V. Di Bello, M. Mariani. *Ospedale Cisanello, Dipartimento Cardio Toracico, Pisa, Italy*

Aim: This study sought to determine serial changes in microvascular integrity using myocardial contrast echocardiography (MCE) in patients with acute myocardial infarction (AMI). In addition, the aim of study was to define the optimal time for assessing microvascular integrity to predict late recovery of LV regional function.
Patients and methods: We studied 43 pts (40 male, mean age 52 years) with first AMI who underwent successful primary coronary angioplasty. The study protocol included the acquisition of intracoronary MCE shortly after reflow (15 minutes), intravenous MCE two days and 15 days later. Regional wall motion (RWM) was assessed by 2D-echo 6 months later. Intravenous MCE was performed with venous Levovist administration and intermittent Harmonic Power Doppler (HPD). In each pt the contrast score index (CSI) for the infarct related area was calculated according to the standard protocol.
Results: A total of 220 segments of the infarct related area were analysed. In the table is shown myocardial perfusion on a segment by segment basis as detected by MCE at different time. A change in microvascular perfusion at 15 days MCE was detected in 76 segments (34%): an improvement in myocardial perfusion was detected in 46 segments (suggesting recover of microvascular dysfunction), while a contrast defect newly appeared in 30 segments (suggesting a progressive miscrovascular damage). Mean CSI was 0,69±0,26 (intracoronary MCE); 0,74±0,22 (2 days MCE) and 0,69±0,30 (15 days MCE). At 6 months follow-up a statistically significant correlation was found between intracoronary CSI and RWM variation (r 0,35; p< 0.05); between 2 days CSI and RWM variation (r 0,44; p< 0.01) and between 15 days CSI and RWM variation (r 0,75; p< 0.0001).

	intracoronary MCE	2 days MCE	15 days MCE
normal perfusion	131	113	128
moderate perfusion defect	39	78	69
severe perfusion defect	50	29	23

MCE: myocardial contrast echocardiography

Conclusions: microvascular damage after reperfusion may be either reversible or progressive and may occur even after 2 days. Late assessment of myocardial perfusion (15 days MCE), when microvascular damage has reached his final and full extent, best predicts recover of function.

P2856 Use of myocardial contrast echocardiography in identifying patients with failed reperfusion after thrombolysis in acute myocardial infarction

L. Agati[1], M.P. Madonna[2], F. Celani[2], S. Musarò[2], P.F. Corvo[2], D. De Maio[2], R. Adorisio[2], S. Funaro[2]. [1]*"La Sapienza" University of Rome, Cardiology Dept., Rome, Italy;* [2]*La Sapienza University of Rome, Cardiology Dept., Roma, Italy*

Background: The diagnosis of failed reperfusion after thrombolysis still remains a daily unsolved issue. At present, the decision of different level of aggressiveness in treating acute myocardial infarction (AMI) is only based on clinical, enzymatic and ECG data. The role of intravenous myocardial contrast echocardiography (MCE) in the assessment of the efficacy of reperfusion therapy is still being evaluated.
Method: At this aim, 22 consecutive patients with AMI, treated with iv t-PA within 6 hours from symptom onset, underwent, on day one after reperfusion therapy, coronary angiography and MCE using real-time Power Modulation Imaging (Philips, Sonos 5500) during continuous infusion of SonoVue® (Bracco). A prototype (Bracco Imaging) rotating infusion pump at 120-180 ml/h infusion rate was used. According to TIMI myocardial perfusion grade, patients were divided into two groups: Group A (n = 16) TIMI grade 0-1 and Group B (n= 6) TIMI grade 2-3. The endocardial length of residual contrast defect (apical 4- 5- and 2- chamber views) after thrombolysis, contrast score index (3 grade scale) and clinical markers of reperfusion were calculated. Successful reperfusion after iv t-PA was defined as an early (<12h) peaking of creatine kinase and a rapid decrease of at least 50% of ST-segment elevation (within 2 h after thrombolysis), and as a residual MCE perfusion defect < 10%. Left ventricular ejection fraction and wall motion score index on day 1 were also calculated.
Results: Patients in group A and B had similar ejection fraction and wall motion score on day 1 (46±6% vs 45±8%, and 1.8±0.4 vs 1.5±0.3, respectively, ns). On the contrary, the contrast score index and the extent of contrast defect were significantly higher in group A as compared to group B (3.6±0.3 vs 3.2±0.2, p<0.03, and 30±8% vs. 4±6%, p<0.001, respectively). Failed reperfusion (TIMI grade 0-1) was correctly identified by clinical criteria (ECG+enzyme) in 12/16 patients, and by MCE criteria in 16/16 patients. Thus, MCE showed higher predictive values of failed reperfusion as compared to clinical markers (PPV 100%, NPV 67%, vs 85% and 50%, respectively)
Conclusions: Real-time perfusion imaging with SonoVue® can accurately determine reperfusion success at tissue level and may be an important adjunctive tool for a better indication to a more aggressive treatment in AMI

P2857 Effects of rescue PTCA after acute myocardial infarction on tissue level perfusion: a myocardial contrast echocardiography study

L. Agati[1], S. Funaro[2], M.P. Madonna[2], A. Di Roma[2], C. Iacoboni[2], R. Adorisio[2], G. Veneroso[2], F. De Maio[2]. [1]*"La Sapienza University of Rome, Cardiology Dept., Rome, Italy;* [2]*La Sapienza University of Rome, Cardiology Dept., Roma, Italy*

Background: The clinical usefulness of rescue PTCA in patients with acute myocardial infarction (AMI) is still under discussion. In particular, no data are available on the effects of late infarct-related artery (IRA) reopening on microvascular perfusion. Echocardiographic assessment of microvascular integrity is now feasible by intravenously injected contrast agents and real time myocardial contrast echocardiography (rt-MCE). Previous MCE studies showed the efficacy of primary PTCA in reducing microvascular damage. We sought to determine if even rescue PTCA may improve tissue level perfusion

Method: We studied 14 patients with first anteroseptal AMI, treated with iv t-PA within 6 hours from symptom onset, undergoing on the basis of clinical symptoms left anterior descending (LAD) angioplasty, within 12 and 24 h after thrombolysis. MCE was performed using real-time Power Modulation Imaging (Philips Sonos 5500) during continuous infusion of SonoVue® (Bracco). A prototype (Bracco Imaging) rotating infusion pump at 120-180 ml/h infusion rate was used. The endocardial length of contrast defect (apical 4- 5- and 2- chamber views), the contrast score index (3 grade scale) after thrombolysis and soon after rescue PTCA, were calculated. Left ventricular ejection fraction and wall motion score index were also calculated before LAD reopening.

Results: In all selected patients coronary angiography showed a TIMI myocardial perfusion grade 0-1 after thrombolysis and a successful LAD reopening (TIMI grade 3) after rescue PTCA. In 71% (10/14) of patients a significant reduction in contrast score index and in the length of contrast defect was observed after rescue PTCA (3.6±0.2 vs 3.1±0.3 and 35±11% vs 14±10%, $p<0.005$, respectively), whereas in the remaining 29% (4/14) a slight increase in microvascular damage was found (3.6±0.1 vs 3.8±0.3 and 30±11% vs 32±10%, ns, respectively). The two groups of patients had similar contrast score, length of contrast defect, ejection fraction, wall motion score and coronary artery disease severity before coronary revascularization.

Conclusions: This study shows that MCE may play a crucial role in acute coronary syndrome. Our preliminary data suggest that in the majority of patients, even rescue PTCA in still unstable patients after thrombolysis may be effective in reducing microvascular damage. Larger studies are needed to better understand the main determinants of the successfully myocardial flow restoration after late IRA reopening

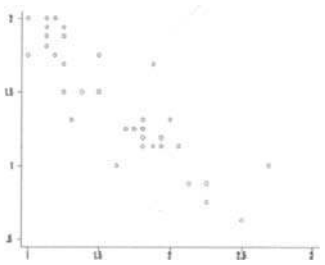
P2858 Real time myocardial contrast echocardiography early after acute myocardial infarction accurately predicts late functional recovery

R. Janardhanan, J. Swinburn, K. Greaves, R. Senior. *Northwick Park Hospital, Cardiology, Middlesex, United Kingdom*

Background: Microvascular integrity is a pre-requisite for ensuring viability early after acute myocardial infarction (AMI). Myocardial contrast echocardiography (MCE) can be used to detect presence of intact microvasculature and hence viable myocardium. Real-time MCE is a relatively simple and new bedside technique that may be utilised to identify viable myocardium.

Methods: 50 patients underwent Real-time MCE using Optison® one week after AMI. Myocardial perfusion (2= homogeneous, 1=reduced, 0=absent) and wall motion (1=Normal, 2=hypokinetic, 3=akinetic) were assessed at baseline using a 16- segment LV model. Contrast score index (CSI) representing global perfusion was also calculated at baseline. Both regional and global wall motion were re-assessed after 3 months.

Results: Of the 93 dysfunctional segments that showed functional recovery, MCE had demonstrated homogeneous perfusion in 65 segments (70%)at baseline. Of the 204 segments that failed to recover, MCE showed reduced perfusion in 192 segments (94%). Thus the positive and negative predictive values of MCE for predicting late functional recovery were 84% and 87% respectively. There was an excellent correlation ($r= 0.91$, $p<0.001$) between global perfusion (CSI) at baseline and recovery of global LV function assessed by wall motion score index (WMSI) [see fig.1]

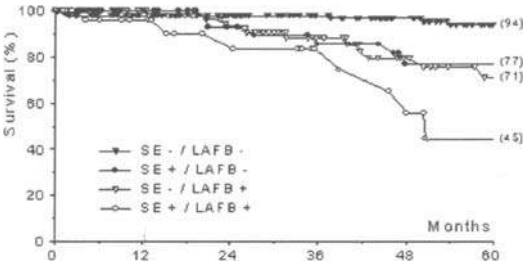


Conclusion: Real time MCE is an accurate bedside technique to identify viable myocardium post AMI. This technique may be utilised to reliably predict late recovery of function in dysfunctional myocardium after AMI.

P2859 Prediction of mortality in patients with complete right bundle branch block. A multicenter stress echocardiography study

L. Cortigiani[1], R. Bigi[2], C. Coletta[2], E. Mariotti[2], G. Gigli[2], C. Dodi[2], C. Astarita[2], E. Picano[2]. [1]*Lucca Hospital, Cardiology Div, Lucca, Italy;* [2]*Institute of Clinical Physiology, PISA, Italy*

Complete right bundle branch block (RBBB) is an independent predictor of mortality in unselected patients referred to noninvasive evaluation of coronary artery disease (Hesse, Am J Med 2001). Aim of this study was to investigate whether different levels of risk could be assessed in RBBB patients. The study group consisted of 343 RBBB patients (age 66±9 yy; 267 men) who underwent stress echo (SE) with either dipyridamole (n=231) (up to 0.84 mg over 10'+atropine up to 1 mg) or dobutamine (n=112) (up to 40 mgr/kg/min+atropine up to 1 mg) at 8 different italian cardiology centers; 102 (30%) patients also had left anterior fascicular block (LAFB). SE was positive for ischemia (new or worsening of preexisting wall motion abnormality) in 109 (32%) patients. During follow-up (38±32 months), 35 deaths occurred. In addition, 73 patients (48 with ischemia at SE) underwent revascularization and were censored at the time of the procedure. Of 14 clinical, electrocardiographic and echo variables analyzed, ischemia at SE (HR=2.9; 95% CI=1.5-5.7; p=0.002), LAFB (HR=2.8; 95% CI=1.4-5.6; p=0.002), age > 65 years (HR=2.1; 95% CI=1.0-4.3; p=0.047), and resting wall motion score index (HR=2.5; 95% CI=1.0-6.5; p=0.057) were multivariate predictors of mortality. From the interaction of SE result and presence/absence of LAFB, a low-risk group (with neither ischemia nor LAFB), two intermediate-risk groups (with ischemia only, and with LAFB only, respectively), and a high-risk group (with both ischemia and LAFB) were identified (Figure).



Kaplan-Meier survival curves.

In conclusion, an effective stratification of risk can be obtained in RBBB patients by means of SE and LAFB information.

P2860 Exercise stress echocardiography differentiates ischaemic from non-ischaemic dilated cardiomyopathy

L. Monserrat, J. Peteiro, R. Calviño, J.M. Vazquez, E. Vazquez, R. Perez, J. Salgado, A. Castro-Beiras. *Juan Canalejo Hospital, Cardiology, A Coruña, Spain*

Previous work has shown the usefulness of dobutamine echocardiography to differentiate ischemic dilated cardiomyopathy (IDC) from nonischemic dilated cardiomyopathy (NIDC), but no studies have been made using exercise echocardiography (EE). We hypothesized that most of the patients (pts) with NIDC may have some contractile reserve and therefore increase LV ejection fraction (LVEF) during exercise, as opposed to IDM pts. Between March 1, 1995 and March 1, 2001 we performed 4133 EE studies to 3830 pts. Among 289 (8%) having moderate or severe LV dysfunction (biplane LVEF <41% and left ventricular end-diastolic diameter >5.2 cm), 207 were excluded due to: history of myocardial infarction, 111; scarring on echocardiography (regional akinesia/dyskinesia with thinning and/or increased brightness), 28; previous revascularization procedures, 13; aortic valve disease, 9; known cause of cardiomyopathy, 11; no submission to angiography, 35. The study group was therefore composed of 82 pts encouraged to perform maximal treadmill EE. EE criteria for IDC were either regional wall motion (RWM) impairment or LVEF decrease/no change from baseline to peak exercise, while criteria for NIDC were RWM improvement/no change and LVEF increase. The IDC group was formed by 39 pts having >69% diameter stenosis in a major epicardial coronary artery or major branch vessel. The remaining 43 pts constituted the NIDC group.

Results: The number of coronary risk factors (IDC 2.0±1.1; NIDC 1.9±1.1), baseline LVEF (IDC 30±7; NIDC 30±8) and exercise-induced angina (IDC 23%; NIDC 14%) were not different between groups (p=NS); whereas IDC pts achieved less Mets (6.6±3.1 vs 8.3±2.8, $p<0.05$) and product heart rate x systolic blood pressure x 10^3 (22±5 vs 27±7, $p<0.001$), and developed regional and/or global LV dysfunction more frequently (79% vs 28%, $p<0.001$). Sensitivity, specificity, positive and negative predictive values and global accuracy for IDC detection were 79% (CI: 70-88), 72% (CI: 63-81), 72% (CI: 63-81), 79% (CI: 67-85), and 76% (CI: 69-83), respectively.

In conclusion,a global and/or regional LV function impairment with exercise is accurate to identify patients with IDC. This method may, therefore, reduce the need for invasive procedures

P2861 Dobutamine-stress echocardiography in children: diagnostic value of myocardial ischaemia

S. Di Filippo, M.J. Raboisson, B. Semiond, F. Sassolas, A. Bozio. *Hôpital Cardiovasculaire, Cardiologie Pédiatrique, LYON cedex 03, France*

Detection of myocardial ischemia is required in children with congenital, acquired or postoperative coronary artery diseases.The aims of this prospective study were to determine the safety and feasability of DSE in children, and to assess its reliability for detection of myocardial ischemia and coronary disease.

Methods: DSE was performed according to the standard protocol used in adults. Selective coronary angiography and/ or Thallium scintigraphy were performed for comparison. Seventy-five DSEs were performed in 71 patients (31 females, 30 males, median age= 11 years). Cardiac pathologies were: posttransplant monitoring (40 cases), postSwitch operation monitoring (13), abnormal origin of the left coronary artery from the pulmonary trunk (6), Kawasaki aneurisms (6), coronary fistulae (5), left ventricle aneurism (1) and miscellaneous (4). Sixty-two were performed routinely and 13 were motivated by: chest pain (8), dyspnea (2), LV dysfunction (1) or syncope (1). Fourteen were receiving antihypertensive medication but none with beta adrenergic antagonistic therapy.

Results: The maximum dose stage of 40 mcg/kg/mn was reached in 72/75 cases (96%) and 30 mcg/kg/mn in 3 (chest pain). The most frequent clinical side effect was palpitations (15%). Maximum heart rate was 90 to 183/mn (30 to 351% of basal and 43 to 90% of theoretical maximum), with no difference between transplanted and non-transplanted patients. Maximum blood pressure was 100 to 194mmHg (7 to 109% of basal); increase was lower in transplanted versus non-transplanted patients with antihypertensive medication (p= 0.005). No sustained supraventicular or ventricular arythmia, nor significant ST segment change, occurred. Twenty (27%) DSEs were abnormal: 8 posttransplant, 2 Kawasaki, 4 postSwitch, 4 non-operated coronary origin from pulmonary trunk, 1 non-operated coronary fistulae and 1 left ventricle aneurism (15 of them were clinically asymptomatic). DSE sensitivity and specificity were respectively 100% and 76% when compared to Thallium scintigraphy (31 cases) and 70% and 90% when compared to coronary angiography (40 cases).

Conclusion: DSE is safe and well tolerated in children. DSE is probably the best method of monitoring coronary artery disease in children, combining both reasonable sensitivity and specificity without being invasive, requiring hospitalization or engendering significant morbidity.

P2862 Influence of left ventricular geometry, myocardial abnormalities and wall stress on the accuracy of dobutamine stress echocardiography

Y. Satoshi[1], V. Khoury[2], T. Marwick[2]. [1]*University of Queensland, Department of Medicine, Brisbane, Australia;* [2]*University of Queensland, Department of Medicine, Brisbane, Australia*

Background: Recent work has suggested that the sensitivity of dobutamine stress echocardiography (DSE) is reduced in patients with concentric remodeling, but the cause of this finding is unclear. We sought whether wall stress or myocardial abnormalities could explain the influence of left ventricular (LV) morphology on the accuracy of DSE.

Methods: We studied 161 patients with no wall motion abnormalities at rest (age 60±11 years, 105 men) who underwent DSE and coronary angiography within 6 months, without an intervening event. Echocardiograms were measured for relative wall thickness (RWT), LV chamber size and LV mass. All patients underwent gray scale and color tissue Doppler imaging from three apical views, which were stored and analyzed off line. Increased RWT and increased LV mass were defined as >=0.45 and as >131 g/m^2 in men and >100 g/m^2 in women, respectively. Patients were classified into four groups according to RWT and LV mass; normal geometry, concentric remodeling, concentric hypertrophy and eccentric hypertrophy. Significant coronary artery disease was defined as >=50% stenosis. Circumferential (cESS) and meridional end-systolic wall stress (mESS) at rest and peak DSE were calculated according to previously published methods. Integrated backscatter and strain rate (SR) imaging were used to detect changes in structure and function; average cyclic variation (CV) of integrated backscatter, SR and peak systolic strain were calculated by averaging each segment.

Results: Both false negative and false positive results for DSE were present in 35 patients (22%). The accuracy of DSE in patients with concentric remodeling (61%) was lower than that in patients with normal geometry (85%, $p<0.05$) or concentric hypertrophy (86%, $p<0.05$), and the accuracy with eccentric hypertrophy (64%, $p<0.05$) was lower than with concentric hypertrophy. Although, sensitivity, specificity and accuracy were comparable among each quartile in CV, SR and peak systolic strain, patients with lowest quartile of cESS and mESS at peak DSE had significantly lower sensitivity and accuracy than those in the highest quartile, respectively. Multivariate logistic regression analysis demonstrated that a reduced cESS at peak DSE (p=0.012), presence of concentric remodeling (p=0.044) and eccentric hypertrophy (p=0.012) were significant predictors of both false-negative and false-positive results for DSE.

Conclusions: The accuracy of DSE is influenced by wall stress at peak and the geometric pattern of the LV, but not myocardial abnormalities.

P2863 Factors that have an impact on the interobserver agreement differences for the interpretation of dobutamine stress echocardiograms

M S. Dolan[1], S. Puri[2], D. Kumar[2], T. Huckin[2], A. El Shafei[2], S. Herrmann[2], A. Maniet[2], A. J Labovitz[2]. [1]Saint Louis University Hospital, Internal Medicine/Cardiology, St. Louis, United States of America; [2]Saint Louis University School of Medic, Internal Medicine/Cardiology, St. Louis, United States of America

Background: Dobutamine Stress Echocardiography (DSE) is widely used for detection of Coronary Artery Disease. However, there are still some agreement differences between the observers over the interpretation. Identifying factors which impact the interobserver variability will be beneficial for lowering the interobserver differences.
Methods: We therefore evaluated total of 366 randomly selected DSE's from our institution for interpretation by 3 cardiologists who were blinded to each other. Reading agreement was determined as ranging from equal assessment on test positivity and negativity for ischemia by 2 or 3 readers to 3 of 3 readers for each study. Agreement levels were compared to each other with respect to heart rate (HR), blood pressure response, extent and severity of the wall motion abnormality, beta blockers usage, and wall motion score indices (WMSI). Extent was determined by the number of segments with new onset of wall motion abnormalities. Severity was defined by the presence of new wall motion abnormality during peak stress. Heart rate response was accepted as blunted when peak heart rate is less than 85% of age related predicted heart rate. All parameters were compared between agreement groups.
Results: Mean agreement between the 3 readers on normality and abnormality of DSE resulted with a kappa level of 0.55. More extensive and more severe wall motion abnormality during DSE led to better agreement level achievement. Agreement level increased with appropriate heart rate response. See Table.

Factors that have an impact on the interobserver agreement difference for the interpretation of dobutamine stress echocardiograms

	3 out of 3 readers	2 out of 3 readers	P
Rate pressure product(10 3 mmHg min-1)	25.5 ± 5.8	19.7 ± 8.1	0.01
Extent (Segments)	3.2 ± 2.8	2.2 ± 1.8	0.05
Severity	26%	8%	<0.001
Beta-blocker	9%	34%	<0.001
WMSI	1.5 ± 0.4	1.2 ± 0.2	0.06

Conclusion: Major determinant of disagreement between observers during DSE is inadequate heart response. Cessation of beta-blocker prior to DSE and perhaps more liberal use of atropine will lead to better interobserver agreement.

P2864 Myocardial contrast echo and radionuclide scintigraphy in patients with left bundle branch block with or without coronary arteries disease

S. Felis[1], W. Deste[1], A. Ragusa[1], P. Colonna[2], S. Scandura[1], S. Mangiafico[1], S. Iliceto[3], G. Giuffrida[1]. [1]University of Catania, Division of Cardiology, Ferrarotto Hos, Catania, Italy; [2]University of Cagliari, Cardiovascular and Neurological Dept, Cagliari, Italy; [3]University of Padua, Division of Cardiology, Padua, Italy

Background: The association between left bundle branch block (LBBB) and coronary arteries disease (CAD) increases mortality for cardiovascular disease, but patients with no evidence of heart disease have an excellent two years prognosis. Among LBBB patients, the non-invasive diagnostic investigations (ECG exercise test, echocardiography or radionuclide myocardial scintigraphy) show low specificity in excluding patients with CAD, compared to coronary artery angiography.
Aim: To compare myocardial perfusion obtained with myocardial contrast echocardiography (MCE) or myocardial scintigraphy in LBBB patients with normal or diseased coronary arteries at angiography and anteroseptal myocardial infarction (MI).
Methods: We consecutively studied 30 unselected LBBB patients (mean age 56 ± 8 years) and normal coronary arteries (15 patients) or anteroseptal chronic MI and left anterior descending CAD (>70% stenosis) (15 patients) at coronary angiography. All patients underwent MCE for assessment of myocardial perfusion (intermittent harmonic power Doppler with intravenous Levovist) and performed 99mTc-Tetrosfosmin SPECT scintigraphy.
Results: Among the 15 pts with LBBB and normal coronary arteries, MCE showed normal perfusion in 14 pts and impaired septal perfusion in 1pt, while in this same group, scintigraphy showed impaired septal perfusion in 14 pts and normal perfusion in 1 pt (MCE specificity 93.3% vs scintigraphy 6.6%). Among the 15 pts with LBBB MI and CAD, the two techniques significantly discriminated myocardial perfusion in distal septum (concordance rate 73.3%), posterior (73.3%), lateral (73.3%) and anterior wall (80% anterobasal; 86.6% mid-anterior; 80% distal-anterior). Conversely, there was a low concordance in the basal (33.3%) and midventricular septum (66.6%), with high accuracy of MCE. Comparing both groups of pts, rate of concordance significantly decreased, particularly in septal evaluation. Thus the two techniques significantly discriminated anterior wall and distal segments of inferior and lateral wall (83.3%), while scintigraphy poorly evaluated basal septum (16.6%), mid septum (33.3%) and distal septum (33.3%).
Conclusion: In pts with LBBB, myocardial scintigraphy is less accurate than MCE, showing a low specificity on patients with normal coronary arteries and a low accuracy in patients with MI and CAD.

INTERVENTIONAL CARDIOLOGY

P2865 High 2.5 year mortality among patients with "normal" angiograms: the ACRE study

S. Philpott[1], G. Feder[2], A.M. Crook[3], S. Shah[3], A.D. Timmis[4], H. Hemingway[3]. [1]Westminster PCT, Research and Development, London, United Kingdom; [2]Queen Mary University, General Practice and Primary Care, London, United Kingdom; [3]Research and Development, London, United Kingdom; [4]Barts and the London Chest, Cardiothoracic Directorate, London, United Kingdom

Background: Mortality among patients with normal angiograms is thought to be low (e.g. less than <1% per year). However this assumption is based on studies of patients undergoing angiography in the 1970s and 1980s.
Ojective: To determine the contemporary survival experience of patients with normal coronary arteries.
Design: prospective cohort study with 2.5 years follow up.
Setting: London Chest and St Bartholomews Hospitals, London, UK.
Patients: 4020 consecutive patients undergoing coronary angiography in 1996-7, recruited without exclusion criteria as part of the Appropriateness of Coronary Revascularisation (ACRE) study. The number of diseased vessels was defined as 0 (normal) in the absence of any narrowing in any of the 27 arterial segments defined in the Coronary Artery Surgery Study, < 1 in the presence of <75% narrowing, and 1 + in the presence of >=75% narrowing, or >0 50% in the left main stem.
Main outcome measures: all cause and coronary mortality (follow up complete in >99%, n=344 deaths).
Results: 19.4% of patients had 0, 10.0% <1 and 70.7% 1+ diseased vessels. Patients with 1+ diseased vessel compared with those with 0 had a higher age adjusted hazard ratio for coronary mortality (hazard ratio 4.52, 95% confidence interval 2.22-9.22). The crude risk of death from any cause at 2.5 years was 10.2% among patients with at least one diseased vessel and 6.5% among patients with normal coronary arteries. The mortality among patients with normal coronary arteries was more than twice that expected among the age and sex matched general population of England and Wales (3.1%).
Conclusion: In this contemporary study, patients with a normal angiogram had a mortality more than twice that of the age – sex matched general population. Reasons for this high mortality require elucidation.

P2866 Effect of direct stenting on outcome in patients treated with percutaneous coronary intervention on saphenous vein graft

L. leborgne, E. cheneau, A. Pichard, A. Ajani, D. cha, L. satler, K. Kent, R. waksman. *washington hospital center, Medstar research institute, Washington, United States of America*

Objectives: We sought to determine whether direct stenting (DS) defined as stenting without pre-dilatation might prevent CK-elevation and the major adverse cardiac events associated with percutaneous coronary intervention (PCI) in saphenous vein graft (SVG) and to compare it with conventional stenting (CS) defined as stent implantation following balloon pre-dilatation.
BACKGROUD: Angioplasty of SVG is associated with frequent post-procedural enzyme elevation and late cardiac events. Therefore, evolving strategies are attempted to improve outcomes in SVG angioplasty.
Methods: From January 1994 to June 2001, 527 patients have been treated with PCI and stent implantation for SVG stenosis. One hundred and seventy patients with 229 lesions were treated with DS and 357 patients with 443 lesions were treated with CS without debulking. The study end-points included in-hospital and six months follow-up events.
Results: Baseline clinical and post-procedural angiographic characteristics were similar between the two groups. In the DS group, the prevalence of thrombus containing lesions before the procedure was greater (25.9% vs. 19.3%, p=0.047). The maximum CK-MB elevation post-procedure (9.5 ± 18.1 vs. 19.6 ± 47.8 mg/dL, p <0.001), CK-MB elevation more than four times the upper normal value (13.6 vs 23%, p = 0.012) and non Q wave Myocardial Infarction (MI) (10.7 vs. 18.4%, p = 0.024) were smaller in the DS group. Multivariate analysis showed that unstable angina was associated with non Q wave MI (odds ratio [OR] = 1.8; confidence interval [CI], 1.1 to 3.2, p = 0.03) and DS was inversely associated with Q wave MI (OR= 0.65; CI, 0.41 to 0.88; p = 0.04).
At six months, the TLR-MACE (including target lesion revascularization, death and Q wave MI) was significantly lower in the DS group (13.8% vs. 25.4%; p = 0.004). Multivariate analysis showed that DS (OR = 0.46; CI 0.27 to 0.77, p = 0.003) and diabetes (OR 1.62; CI 1.05 to 2.51, p = 0.03) were predictors of TLR-MACE.
Conclusions: Since DS decreased the enzyme release following PCI and reduced the TLR-MACE at six months, when technically feasible, DS should be considered as a viable option for treatment of SVG narrowing.

P2867 Direct coronary stenting (DS) compared to stenting after PRE dilatation (PRE) yields similar in-hospital outcome at lower costs

A.J.J. IJsselmuiden[1], D. van der Heijden[1], T. Slagboom[1], R. van der wieken[1], F. Kiemeneij[1], G.J. Tangelder[2], P.W. Serruys[3], G.J. Laarman[1]. [1]*OLVG, Intervention Cardiology, Amsterdam, Netherlands;* [2]*Vrije Universiteit, Physiology, Amsterdam, Netherlands;* [3]*University Hospital Dijkzigt, Intervention Cardiology, Rotterdam, Netherlands*

Current stent delivery systems make direct stenting (stenting without predilatation) possible, but few controlled trials have been performed to evaluate the success, safety and cost-effectiveness. We conducted in a single center, a large prospective randomized clinical trial using the Medtronic AVE S670 stent to investigate whether on balance direct stenting (DS) has advantages over stenting with predilatation (PRE).
Four-hundred eligible patients undergoing elective coronary interventions were randomized either to DS (n=200) or to PRE (n=200). Treatment groups were similar regarding to demographics, anginal class, risk factors and lesion characteristics. Left anterior descending artery was in 40.3% involved. Lesion class B2/ C existed in 33%. Primary access was attempted in 94.5% via the transradial route with a successful radialis puncture of 91.5%.
Direct stenting was successful in 88.3% of cases. The failed direct stented lesions crossed over and were stented after predilatation resulting in an overall procedural success of 97.9%. Direct stenting did result in a similar acute angiographic result without increased complications. The rate of oversizing of the stent length was similar between DS (1: 1.64 mm) and PRE (1: 1.67 mm) as lesion length and stent length did not differ between groups. There was a trend of 4% more dissections occurring after initial stent placement in DS. Troponine I rise of more than 0.15 μg/L, used as a measure of distal embolization, was similar in both groups (DS: 17.8% vs. PRE: 17.1%). In-hospital major adverse cardiac events (MACE) of 3.0% and 30 days MACE of 2.6% were equal in both groups. There were modest savings in fluoroscopy time, contrast usage, and a reduction in angioplasty balloon usage (0.4 vs. 1.17 balloons/ patient; p <0.001). Although more stents were used in the PRE group there remained a cost saving of 190 Euro/ patient (p=0.02) in favor of direct stenting.
In conclusion, the AVE S670 stent showed excellent overall performance. DS in selected lesions is a safe and feasible but more demanding technique requiring experienced operators. DS does not lead to longer stent usage. Neither does it result in fewer dissections or distal embolizations. Although DS is highly successful with similar in-hospital outcome it yielded only modest cost-savings if compared to PRE.

P2868 Effect of balloon oversizing in stenting small vessels

G.S. Stankovic[1], F.L. Francesco Liistro[2], K.T. Kostas Toutouzas[1], N.C. Nicola Corvaja[1], R.A. Remo Albiero[1], C.D.M. Carlo Di Mario[1], L.F. Leo Finci[1], A.C. Antonio Colombo[1]. [1]*EMO Centro Cuore Columbus, Milan, Italy;* [2]*San Raffaele Hospital, Milan, Italy*

The aim of present study was to evaluate whether the placement of coronary stents using 3.0 mm balloon size in the vessels with the reference diameter <=2.8 mm favorable affects clinical and angiographic outcome.
Methods: Data from 509 consecutive patients with 610 lesions, with the reference diameter <=2.8 mm determined by QCA, in whom stent was implanted were analyzed. According to final balloon diameter two groups were created, Group I (124 pts) - with the balloon size < 3.0 mm and Group II (385 pts) - with the balloon size 3.0 mm. Two groups were comparable for clinical and procedural characteristics, as well as the incidence of complex lesions (58.9% vs. 65.2%, p = ns). The reference vessel size was 2.15±0.33 mm and 2.43±0.29 mm (p<0.01), the balloon-artery ratio 1.19±0.2 and 1.25±0.16 (p<0.002) in Groups I and II, respectively. Clinical follow-up was obtained for all patients after 12±9 months. All patients had angiographic follow-up after 6±4 months by protocol.
Results: Two groups had similar incidence of in-hospital complications (non-Q-MI 4.0% vs. 3.7%, and Q-MI 1.6% vs. 2.9%, p = ns for both). There were no in-hospital CABG or deaths. Two patients in both groups (1.6% vs. 0.5%) had acute stent thrombosis, whereas subacute stent thrombosis occurred in 3 patients (2.4%) in Group I, and in 1 patient (0.3%) in Group II, p = ns. Long term outcome: Recurrence of angina was similar in two groups (26.6% vs. 25.5%, p = ns). Long-term MACE (myocardial infarction, CABG and deaths) were not different in two groups (8.8% vs. 7.8%, p = ns). Angiographic restenosis rate was 41.1% in group I and 37.4% in group II, p = ns. Target lesion revascularization rate (TLR) was 35.5% in group I and 37.4% in group II, p = ns, and target vessel revascularization rate (TVR) was 41.9% in group I and 40.8% in group II, p = ns.
Conclusions: Despite the presence of more favorable baseline characteristics due to a larger reference vessel size, balloon oversizing in small vessel stenting does not seem to lower the incidence of angiographic restenosis or to improve clinical outcome.

P2869 Are distal protection devices required for PTCA of instent restenosis in degenerated saphenous vein grafts?

D.T. Ashby[1], E.A. Clark[2], I. Iakovou[2], F. Kuepper[2], G. Dangas[2], G. Stone[2], J.W. Moses[2], M.B. Leon[2]. [1]*Cardiovascular Research Foundation, New York, United States of America;* [2]*Cardiovascular Research Foundation, New york, United States of America*

Background: Coronary slow flow/no reflow may occur after percutaneous coronary interventions (PCI) in degenerated saphenous vein grafts (SVG). Distal protection devices have been shown to reduce the incidence of slow flow/no reflow in PCI of degenerated SVGs in de novo lesions. It is unclear whether PCI of in-stent restenosis of degenerated SVGs is associated with slow flow/no reflow.
Methods: Between 2000 and 2001, 54 consecutive patients with instent restenosis of degenerated SVGs underwent PCI without distal protection at the Lenox Hill Hospital Heart and Vascular Institute. Procedural and in-hospital outcomes were examined.
Results: The average age was 68.1 ± 10.4 years and 27.8% of the patients were diabetic. The procedural characteristics and results are shown in the table below.

Characteristic	Results
Angiographic Success	98.1% (53/54)
Lesion Length	13.5 ± 6.4 mm
Cutting Balloon Used	46.3% (25/54)
New Stent Implanted	46.3% (25/54)
Rotational Atherectomy Used	0.0% (0/54)
Gamma Brachytherapy	18.5% (10/54)
Episode Slow Flow/ No Reflow	0.0% (0/54)
Death	1.9% (1/54)
Myocardial Infarction (Q and Non Q wave)	0.0% (0/54)

Results

Conclusions: In this consecutive series of patients with instent restenosis of degenerated SVGs undergoing PCI without distal protection there were no episodes of slow flow/no reflow and no procedure related myocardial infarction. It would appear that distal protection devices may not be necessary for PCI of instent restenosis in degenerated SVGs.

P2870 Safety and efficacy of Angioguard protection device for prevention of distal embolization during percutaneous coronary intervention in patients with unstable angina

S. Bartus, D. Dudek, J. Legutko, L. Rzeszutko, G. Heba, M. Chyrchel, K. Zmudka, J S. Dubiel. *Jagiellonian University, Institute of Cardiology, Krakow, Poland*

The use of IIbIIIa receptor blockers decreases the number of major adverse cardiac events during PCI. However, microinfarcts (post procedural CK-MB elevations) occur despite optimal antithrombotic treatment. In patients (pts) with increased risk of atheroembolization during PCI the use of additional mechanical protection of embolization could be considered.
The purpose of the study was to determine safety and efficacy of additional use of first generation Angioguard (coronary filter) for prevention of microembolization during PCI in pts with unstable angina (UA).
Methods: 31 pts with UA (Braunwald IIB, IIIB) undergoing urgent coronary angioplasty (PCI) with stenting, were randomized in the cath lab for additional use of Angioguard coronary filter. All pts were treated with aspirin, ticlopidine (500 mg/d), heparin (60U/kg, ACT 200-300sec.) and eptifibatide (bolus 2x 180ug/kg i.v. and 2ug/kg/min. infusion for 18-24h). We analyzed the extend of microembolization (serial CK-MB) and presence of embolic material in the device after procedure. We also assessed the frequency of technical problems and major cardiac events (death, myocardial infarction (MI), urgent target vessel revascularization (TVR)).
Results: PCI was successful in all pts. There was no death, Q wave MI or urgent TVR. Angioguard was successfully installed in 100% pts, however balloon predilatation was necessary in 9(60%) pts. In 9 pts (60%) there was no possibility to prevent big side branches originated closely to the culprit lesion. Presence of embolic material in the filter was confirmed in microscopic analysis of each device. However maximum CK-MB level was 34±10 U/L in Angioguard goup vs 9±5U/L in the group without protection device.
We conclude that first generation Angioguard protection device does not successfully prevent distal embolisation during PCI in pts with UA and its use is associated with many number of technical problems.

P2871 Initial experience with a new concept 8 French compatible directional coronary atherectomy catheter: in-hospital and 30-day clinical outcome

G.S. Stankovic, T.T. Takuro Takagi, A.C. Alaide Chieffo, K.T. Konstantinos Toutouzas, N.C. Nicola Corvaja, R.A. Remo Albiero, C.D.M. Carlo Di Mario, A.C. Antonio Colombo. *EMO Centro Cuore Columbus, Milan, Italy*

Background: The Fox Hollow (FHT, Fox Hollow Technologies Inc.,Redwood City,CA) is a new atherectomy device designed for more efficient and easy plaque removal. Device is compatible with a large lumen 8 French guiding catheters and has a 4mm long cutting window which allows negotiation in complex anatomy. The FHT catheter does not need an urging balloon to establish vessel wall contact and can be advanced over routine PTCA wire as a monorail device.
Methods and Results: To assess safety and efficacy, the FHT catheter was utilized in 30 lesions in 24 patients (mean age 59±14 years; diabetes mellitus 21%; unstable angina 25%, prior CABG 29%). 87% of lesions were B2 or C type, 27% were in-stent restenosis and 57% of lesions were located in mid or distal part of coronary artery. Mean reference vessel diameter was 2.71±0.65 mm and mean lesion length was 11.4±7.1 mm. Successful atherectomy with tissue retrieval was performed in 29 lesions (96.7%). One calcified lesion could not be crossed with the device.
Atherectomy alone was utilized to treat 4 lesions and adjunctive treatment was performed in 26 (87%) lesions (stenting in 23 and POBA in 3). Following atherectomy mean diameter stenosis was reduced from 66% to 28% and further to 11% following adjunctive treatment. Acute gain was 1.9±0.9 mm. In one lesion adventitial staining was observed following atherectomy and was successfully treated with stent implantation. Four patients (16.7%) had in-hospital non-Q-wave myocardial infarction (MI). No deaths, Q-wave MI and repeat revascularization (percutaneous or CABG) occurred in-hospital and at 30-day follow-up. Six-month angiographic follow-up is scheduled for all patients.
Conclusion: Plaque debulking with the FHT catheter can be performed safely and effectively in the relatively small vessels and lesions located in mid-distal artery segment. A larger case series with 6-month clinical and angiographic follow-up will be available at the time of presentation.

P2872 Reduced wall stretch after DCA and stent deployment: a serial intravascular ultrasound evaluation of the mechanisms of lumen enlargement

T. Pawlowski[1], F. Prati[1], C. Di Mario[2], R. Gil[3], A. Labellarte[1], A. Gziut[3], A. Manzoli[1], A. Colombo[2]. [1]*European Imaging Laboratory, Roma, Italy;* [2]*Centro Cuore Columbus, Milan, Italy;* [3]*Department of Cardiology, Warsaw, Poland*

Background: Stenting preceded by directional coronary atherectomy (DCA) reduces the occurrence of in stent restenosis. The aim of the study was to compare the mechanism of lumen enlargement after stenting preceded by DCA with predilatated stenting using intravascular ultrasound (IVUS) assessment.
Methods: 20 patients treated with DCA followed by stenting (Gr 1) were compared with a second group of 30 patients who underwent stenting after balloon angioplasty (Gr 2) The two groups were similar, regarding demographic, clinical, angiographic and ultrasonographic characteristics. Serial IVUS studies, pre-intervention, and post-stenting were performed. External elastic membrane (EEM), lumen, and plaque cross-sectional area were measured at 1-mm intervals through the entire stent length and in the proximal and distal reference segments (5 mm from the stent edge).
Results: There were no differences in clinical, angiographic, IVUS and procedural characteristics between the 2 groups. The increase in mean EEM area was significantly smaller in Gr1 than in Gr2 (3,05±0,8 mm^2 vs 4,28±1,98 mm^2 respectively, $p<0,001$). The increase in lumen area was slightly greater in group 1, although the difference was not statistically significant (7,10±2,23 mm^2 vs 6,31±3,42 mm^2; respectively, p=NS). Axial plaque shift into the reference segments was significantly reduced with the DCA use (0,77±0,55 mm^2 vs 1,55±0,94 mm^2 respectively, $p<0,01$).
Conclusion: Plaque removal by means of DCA followed by stent deployment reduces vessel stretch and plaque shift into reference segments as compared to stenting with predilatation.

P2873 Serial Lumen dynamics after Debulk-stenting assessed by intracoronary ultrasound: comparison with optimal lesion debulking

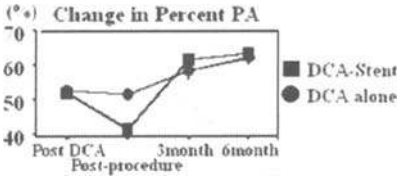
E. Tsuchikane, Y. Takeda, N. Awata, T. Kobayashi. *Osaka Medical Center, Cardiology, Osaka, Japan*

This study aim was to compare the lumen dynamics after debulk-stenting assessed by serial intracoronary ultrasound (ICUS) examinations with debulking alone. After optimal ICUS guided directional coronary atherectomy (DCA), 117 lesions were randomly assigned to the DCA-stent group (n=58) or DCA alone group (n=59). Multilink stent(s) was implanted in the DCA-stent group. Follow-up ICUS were performed 3 and 6 months after the procedure. Eligible serial IVUS images were obtained in 83 lesions (DCA-stent: 42, DCA alone: 41). Vessel and lumen area were measured, and plaque area and percent plaque area were calculated. Results are shown in the table and figure.

Serial Lumen Dynamics

	Post LA	d1PA	d1VA	3MFu LA	d2 PA	d2 VA	6MFu LA
DCA-stent	10.2±1.7	4.1±2.0	1.1±2.2	7.2±1.9	-0.1±1.7	-0.7±1.8	6.6±1.7
DCA alone	8.7±2.2	1.3±2.5	0.4±3.0	7.8±3.1	0.2±1.4	-0.7±1.8	6.9±3.1
P value	0.0006	<0.0001	NS	NS	NS	NS	NS

LA = lumen area (mm^2), PA = plaque area (mm^2), VA = vessel area (mm^2), MFu = month follow-up, d1 = 3MFu - post, d2 = 6MFu - 3MFu.



Change in percent plaque area.

Conclusion: Neointimal proliferation after DCA-stenting almost finishes until 3 month follow-up associated with compensatory vascular remodeling as well as DCA alone. However, neointimal proliferation after DCA-stenting is so exaggerated that the bigger immediate lumen gain by additional stenting may be cancelled during the follow-up period.

P2874 First clinical experience with the FX minirail catheter: a novel device for the enhancement of percutaneous coronary intervention in de novo and restenostic lesions

Y. Almagor, D. Meerkin, R. Solar, T. Ischinger. *Shaare Zedek Medical Center, Cardiology, Jerusalem, Israel*

Background: Complex lesion morphology requiring high pressure balloon dilation and instent restenosis remain two scenarios that continue to challenge conventional angioplasty balloons. Application of high pressure can result in increased arterial trauma and major dissections. Balloon slip in instent lesions often results in significant extension of injury. We report on the first clinical experience with a new angioplasty device designed to effect vessel dilation with a precise and low-pressure inflation in both de novo and restenostic lesions. The FX minirail catheter has an integral wire positioned external to a dilating balloon and a short 12mm guidewire lumen distal to the balloon. Upon balloon inflations both wires, being external to the balloon, prevent slippage and introduce high focal stresses longitudinally along the wire length at low inflation pressures.
Methods: A registry study was performed on de novo and restenostic lesions using a staged inflation protocol to assess the stenosis resolution pressure of the lesions with this device as well as its safety and efficacy.
Results: Thirty patients (26 males) undergoing PCI for coronary stenoses were included. They had a mean age of 60.9±11.9 years with the following risk factor profile: smokers 15, hypertension 17, hyperlipidemia 13, family history 10. A total of 37 lesions (25 de novo, 12 instent restenosis) were treated with a mean reference vessel diameter of 2.73±0.49mm, mean stenosis of 77.5±9.5% and mean lesion length of 11.76±4.58mm. The FX, used as the primary balloon, successfully crossed and dilated 100% of the lesions leaving a mean residual stenosis of 26.9±13.3%. The mean stenosis resolution pressure was 4.5±2.9 atm, and no balloon slippage was observed. Eight dissections (type A-2, type B-6) were observed. In 51.5% of lesions a stent was deployed resulting in a final residual stenosis of 15.3±13.1% with a single residual (B) dissection. In hospital MACE was 0. At two week follow-up there remains MACE of 0.
Conclusion: FX minirail design in this initial registry trial appears to provide for a safe and effective low-pressure angioplasty technique in de novo and restenotic lesions.

P2875 Euro-SPAH: a European trial on the anti-restenotic effect of Intravascular Sonotherapy (IST) after multi-vessel stenting of de novo lesions

P.W. Serruys[1], A. Colombo[2], W. Wijns[3], G. Grollier[4], M. Pieper[5], H. Mudra[6], M. Thomas[7], J.O. Symons[8]. [1]*Thoraxcenter, Univ Hospital Rotterdam, Rotterdam, Netherlands;* [2]*Centro Cuore Columbus, Milano, Italy;* [3]*Onze Lieve Vrouw Ziekenhuis, Aalst, Belgium;* [4]*CHU Cote de Nacre, Caen, France;* [5]*Herzzentrum Bodensee, Kreuzlingen, Switzerland;* [6]*Klinikum Muenchen-Neuperlach, Muenchen, Germany;* [7]*King's College Hospital, London, United Kingdom;* [8]*Cardialysis, Rotterdam, Netherlands*

Background: Animal studies have shown that IST inhibits smooth muscle cell proliferation and reduces intimal hyperplasia, % stenosis and mean neo-intimal thickness. The SILENT registry (110 pts) demonstrated that IST is both safe and feasible to prevent coronary restenosis (at 9 mths). Euro-SPAH is a multicenter, double-blind, randomized trial investigating the efficacy of IST to reduce the rate of restenosis after multi-vessel, direct stenting of de novo lesions using the BX™ Velocity™ stent. Efficacy will be measured as angiographic late lumen loss at 6 months post-procedure. Safety will be assessed at 1, 6 and 12 months.
Method: Patients receiving de novo stents in native coronary arteries are randomized to receive either sham treatment (non-activated sonotherapy) or IST. The sample size has a 90% power to detect a late loss (LL) difference of 0.21mm between the sham group (expected LL 0.84mm) and IST group (expected LL 0.63mm) as assessed by off-line QCA at 6 months (primary endpoint). The secondary endpoints are short and long-term safety from MACE (1, 6, 12 mths), neo-intimal hyperplasia from IVUS (6 mths), and late thrombotic occlusion (1 mth). Inclusion criteria: patients with stable or unstable angina (Braunwald 1-3, B-C) or documented silent ischemia with one or more successfully stented de novo or non-stent restenotic lesions at least 2.5mm in diameter and up to 35mm in length.
Results: Between October 2000 and January 2002, 403 patients (1.2 lesions/pt) were randomized to sham or IST at 23 sites in Europe. Approximately 95% of the patients were successfully treated with sham or IST (inability to cross the stented lesion with the study catheter: 14 pts, failure of the catheter or instrument: 23 pts). Preliminary baseline characteristics: age 61.9 yrs, male 78.9%, UAP 29.7%, stable angina 57.2%, silent ischemia 12.8%, previous MI 43.1%, previous revascularization 18.7%, diabetes 17.4%, hypercholesterolemia 81.0%, current smoker 28.6%. Vessels: LAD 40.5%, RCA 37.1%, LCX 22.4%. Before treatment, the mean vessel size was 2.88mm with an MLD of 1.00 mm and a lesion length of 12.37mm. The mean reference diameter post-procedure was 3.01mm with an MLD of 2.49mm, resulting in a diameter stenosis of 17%. The mean stent length per lesion was 16.9mm. MACE up to 30 days: death 0.25%, QMI 0%, non-QMI 3.5%, CABG 0%, target lesion re-PTCA 0%, non-target vessel re-PTCA 0.5%, (sub-)acute occlusion 0.75%.
Conclusion: The primary and secondary endpoint results at 1 and 6 months will be presented at the meeting.

P2876 Cutting balloon angioplasty versus balloon angioplasty for treating diffuse in-stent restenosis

V. Spanos[1], C. Sarais[1], K. Toutouzas[2], S. Moshiri[1], M. Montorfano[1], C. Briguori[1], G. Stankovic[2], A. Colombo[2]. [1]*San Raffaele Hospital, Catheterization Laboratory, Milan, Italy;* [2]*Centro Cuore Columbus, Milan, Italy*

Background: Cutting balloon angioplasty (CBA) has been reported to decrease restenosis rates compared to balloon angioplasty (POBA) in the treatment of focal in-stent restenosis (ISR). The aim of this study was to compare the clinical and angiographic outcomes of CBA compared to POBA in diffuse ISR.
Methods: Consecutive patients with diffuse ISR lesions (lesion length>=10mm or total occlusions) treated with CBA or POBA in our institution between May 1994 and June 2001 were included in this analysis. Lesions at vessels treated with intracoronary brachytherapy or radioactive stents in previous interventions were excluded. Major adverse cardiac events (MACE) were defined as death, myocardial infarction and target lesion revascularization (TLR).
Results: In total 161 lesions treated with CBA and 114 treated with POBA were included. There were no significant differences regarding clinical and angiographic characteristics between the 2 groups. A larger balloon-to-artery ratio was used in the lesions treated with CBA resulting in greater acute lumen gain (table).

	CBA	POBA	
Mean reference, mm	2.69±0.5	2.70±0.5	p=0.91
MLD pre, mm	0.88±0.4	0.97±0.4	p=0.06
Lesion length, mm	16.78±5.5	17.15±6.8	p=0.62
MLD post, mm	2.34±0.5	2.21±0.6	p=0.62
Balloon/artery ratio	1.26±0.2	1.17±0.2	p=0.02
Acute Gain, mm	1.46±0.6	1.26±0.6	p<0.01
Restenosis, n (%)	48 (37,8)	20 (31,7)	p=0.52
TLR at 12 months, n (%)	27 (16.8)	13 (12)	p=0.30
MACE at 12 months, n (%)	33 (20.5)	19 (17.6)	p=0.64

MLD: minimal lumen diameter

During the clinical follow-up period (14.2±10.2 months) there was no difference in angiographic restenosis rate, TLR and MACE rates between the 2 groups. The main limitation of this study stands in a different rate of angiographic follow-up between the two groups (79.9% for CBA and 57.3% for POBA).
Conclusions: CBA has similar clinical and angiographic results with POBA in the treatment of diffuse ISR. Different rates of angiographic follow-up could have affected the propensity to perform TLR.

P2877 A little shorter stents than the culprit length reduce restenosis surrounding stents

H. takano[1], Y.A Yoshihusa Aizawa[2], H.M. Humiaki Masani[1], O.O. Osamu Ogawa[1], S.I. Shunnsuke Imai[2]. [1]*Niigata Prefectural Central Hospital, Cardiology, Joetsu, Japan;* [2]*Niigata School of Medicine, First depertment of Internal Medicine, Niigata, Japan*

It was reported that drug-coated stent reduced restenosis in Europe.But we can not use these stents in Japan, therefore it is necessary to purchase conventional and convinient method for the prevention of restenosis. Objective: We examined whether it contributed to the reduction of restenosis surrounding stents to use a little shorter stent than the culprit lesion length or not. Methods: Ninety-six type A lesions of 96 patients had stenotic (> 75% visual stenosis) lesion length around 10mm. 47 and 49 patients of them were revascularized at random using NIR stents with 9mm length (S group) and 12mm length (L group), respectively. Minimal luminal diameter (MLD), stent-proximal diameter (SPD) and stent-distal diameter (SDD) obtained by QCA, of two groups were compared at post-procedure and 6 months. Results: There was no significant difference in gender, age, distribution of coronary risk factors and culprit lesions, lesion length, pre-reference diameter, pre-MLD, stent-proximal and distal diameter of two groups at post-procedure. Restenosis occurred in 8 (16%) and 1 (2%) patient of L and S group, respectively ($p<0.01$). All restenosis of L group were observed surrounding stent-distal site. There was no difference in SPD of two groups at 6 months. Six-month MLD (1.56 ± 0.23 vs. 2.23 ± 0.33 mm, $p<0.01$) and 6-month SDD (1.88 ± 0.42 vs. 2.46 ± 0.50 mm, $p<0.01$) of L group were significantly less than those of S group. Conclusions: It may cause increase in restenosis of L group that the mismatch between distal diameter of stent and distal vessel diameter of the culprit tends to occur, when a little longer stent than the stenotic lesion length is used. A little shorter stent than the stenotic lesion length may have to be used to prevent restenosis especially surrounding stent-distal site. Using short stent may be one of convenient methods for prevention of restenosis in Japan, where drug-coated stent is unable to be used. μ

P2878 Determinants of the expansion of different coronary stents in curved stenotic lesions: an in-vitro experimental study

T. Poerner[1], B. Ludwig[1], P. Diesing[2], U. Boenick[2], G. Kalmar[1], T. Sueselbeck[1], M. Borggrefe[1], K.K. Haase[1]. *[1]University Hospital of Mannheim, 1st Dept. of Medicine, Mannheim, Germany; [2]Technical University, Institut für Biomedizinische Technik, Berlin, Germany*

Background: Coronary stent implantation in angulated vessels is a challenging issue, as there is currently lack of consensus regarding the type and length of stents best suitable for such lesions.
Aim of this study was to assess comparatively the expansion parameters of several new generation stent types in a curved stenotic phantom.
Methods: Identical silicon models of 3.2 mm diameter with a 55% concentric elastic stenosis were industrially manufactured. A number of 5 stents for each length and type (AVE [Medtronic] 3.5/12, 3.5/18 mm; Penta [Guidant] 3.5/13, 3.5/18 mm; BX-Sonic [Cordis] 3.5/13, 3.5/18 mm; FlexMaster [Jomed] 3.5/12, 3.5/16 mm) were implanted in the stenotic models using appropriate balloon pressures to achieve a full stent expansion. The forces exerted during balloon inflation (Finfl) and after balloon deflation (Fstent) were continuously registered at a rate of 20 measurements per second using a high sensitive dynamometer placed externally on the model wall. The minimal (MLD) and reference luminal diameter (RLD) of the stents and respectivelly of the inflated balloons (BDmin, BDref) were determined by X-ray imaging with direct magnification.
Results: All stents presented a good wall apposition without deformation of the phantom curvature. No significant differences of the expansion parameters related to the stent length were found. The displacement forces on the vessel wall (higher for AVE and Penta) were within a low range for all stents. Expansion parameters are summarized in the table (mean ± SD).

Parameters of stent expansion

Stent (n=10)	Inflation pressure	MLD (mm)	RLD (mm)	BDmin (mm)	BDref (mm)	%Recoil	Finfl (mN)	Fstent (mN)
AVE	10 bar	3.05 ±0.19	3.75 ±0.13	3.69 ±0.05	3.79 ±0.03	17 ±4	133 ±41	34 ±15
Penta	11 bar	2.94 ±0.18	3.78 ±0.07	3.70 ±0.04	3.80 ±0.05	21 ±5	125 ±30	23 ±14
BX-Sonic	12 bar	2.68 ±0.10*°	3.47 ±0.06*°	3.48 ±0.07*°	3.59 ±0.06*°	23 ±3*	113 ±22	13 ±7*
FlexMaster	12 bar	2.53 ±0.08*°	3.28 ±0.05*°"	3.39 ±0.02*°"	3.56 ±0.04*°	25 ±2*	58 ±16*°"	9 ±7*

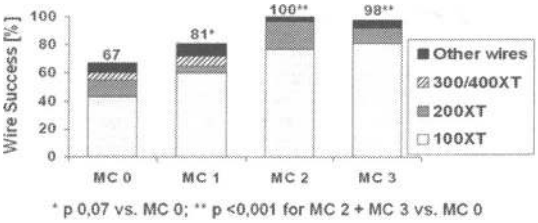
%Recoil = 100*(1-MLD/BDmin). *p < 0.05 compared to AVE; °p < 0.05 compared to Penta; "p < 0.05 compared to BX-Sonic.

Conclusions: In this curved elastic stenotic model AVE stents showed the lowest recoil and reached together with Penta stents the largest MLD, while FlexMaster developed the lowest expansion forces and presented together with BX-Sonic stents significant lower MLD values.

P2879 High success rate in recanalization of chronic total coronary occlusions with a novel guidewire principle using the guidance of micro channels

H.J. Buettner, Ch. Mueller, J. Petersen, F.-J. Neumann. *Herz-Zentrum, Bad Krozingen, Germany*

Background: Vascular micro channels (MC) in chronic total coronary occlusions (CTO) may guide recanalization wires and improve success rates. The new ACS Cross-IT®XT guidewire family has distal tip tapering from 0.014" to 0.010" that eases entrance into MC. Tip stiffness increases gradually from the 100XT-wire to the 400XT-wire.
Methods: We included 204 consecutive pts. with 214 CTO. Age of occlusion was >3 months to 20 years and occlusion length 24.1(5-80)mm. MC as visible on cineangiography were none in 37% (MC 0), incomplete in 26% (MC 1), complete in 14% (MC 2) and complete with distal capillary refill in 23% (MC 3). In all lesions the first attempt was done with the 100XT-wire trying carefully to follow MC. If necessary tip stiffness was stepwise increased to the 400XT-wire.
Results: Success rates for crossing the occlusion were 61% for the 100XT-wire, 76% for all Cross-IT®XT wires and 82% including other additional wire types. Wire success was dependent on visibility and completeness of MC (Figure 1). If MC were visible 60% to 81% of occlusions could be passed with the 100XT-wire. Vessel success rate was 79%. In-hospital events were pericardial tamponade in 0.5%, non-q wave myocardial infarction in 1%; no pt. died.
Conclusions: The use of a new guidewire family with a tapered tip and the concept of stepwise increase of wire tip stiffness is safe and very effective in recanalizations of CTO. Wire success was significantly dependent on the visibility of MC.



* p 0,07 vs. MC 0; ** p <0,001 for MC 2 + MC 3 vs. MC 0

P2880 Five F VS 6F transradial coronary intervention randomised study: no technical advantages for the 5F

F. Gobeil[1], M. Brück[2], Y. Louvard[3], T. Lefèvre[3], M-C. Morice[3], J. Ludwig[2]. *[1]Notre-Dame Hospital, CArdiology, Montreal, Canada; [2]Erlangen Hospital, Cardiology, Erlangen, Germany; [3]Institut Cardiovasculaire Paris-sud, Cardiology, Massy, France*

Background: Smaller guiding catheters (GC) may have some advantages in patients (pts) with small coronary arteries and with transradial (TRA) interventions. However, their efficacy and safety are yet to be demonstrated. We performed a prospective randomised dual centre study to compare a new 0.058" lumen 5F GC vs standard 6F GC in TRA routine PTCA.
Method: All pts eligible were randomised between the 5F vs 6F GC group before the PTCA. Primary end-point was procedural success defined as a procedure performed via the TRA route, done with the randomised GC, adequate stent delivery when needed, residual stenosis of less than 30%, and final TIMI 3 flow. Secondary end-points were also collected.
Results: A total of 216 pts were randomised. Mean age was 64 yrs and there were 81% men. There were no clinical baseline characteristic differences between the groups. Clinical indications for PTCA were stable angina (46% vs 41%; 6F vs 5F), unstable angina (23% vs 29%), post-MI (14% vs 16%), and silent ischemia (17% vs 14%). A mean of 1.5 and 1.4 vessels/pt (6F vs 5F) were dilated. Stents were used in >85% in both groups. There were no differences in stent size (3.0± 0.4 vs 3.0± 0.5;6F vs 5F),length (15.0± 7.3 vs 15.1± 8.5) and direct stenting attempt(71% vs 62%) between the groups. Direct stenting success was achieved in 95% in both groups. Two stents were lost in the 5F vs 0 in the 6F group (p=ns). Mean procedural time, fluoroscopic time, and quantity of contrast used during the procedures were similar between the groups. The number of GC used was also similar (1.3± 0.5 vs 1.4± 0.8; 6F vs 5F). There was one RCA ostium dissection in the 5F group. No other complications occurred. Transfemoral crossover occurred in less than 1% in both groups. Crossover to 5F occurred in 0.9% of the 6F group, because of a small radial artery. Six F crossover occurred in 6.8% of the 5F group (p= 0.05), because of backup insufficiency, GC kinking, or need for a larger stent (5.0mm). Procedural success was obtained in 93% of the 6F group vs 90% of the 5F group, and intention to treat success in 95% vs 97% (p=ns).
Conclusions: Transradial routine PTCA using 5F GC is safe, but necessitates crossover to a 6F GC in 6.8% of the cases, and offers no clear advantages over the 6F GC. It may have potential benefits in pts with small radial arteries.

P2881 NUGGET trial (NIR Ultimate Gold-Gilded Equivalancy Trial): 6 month IVUS follow-up

K.D. Dawkins[1], K-E. Hauptmann[2], G. Guagliumi[3], J. vom Dahl[4], J. Bonnier[5], N. Reifart[6], M-C. Morice[7] on behalf of the NUGGET investigators. *[1]Wessex Cardiac Unit, Southampton University Hospital, Southampton, United Kingdom; [2]Trier, Germany; [3]Bergamo, Italy; [4]Aachen, Germany; [5]Eindhoven, Netherlands; [6]Bad Soden, Germany; [7]Antony, France*

The NUGGET trial was a prospective, multicentre randomised trial comparing the stainless steel NIR PRIMO stent, with a gold-coated NIROYAL stent. The primary objective of the trial was to demonstrate equivalency of the minimal lumen diameter (MLD) at sixth month angiographic follow-up. Secondary objectives included percentage plaque obstruction measured by intravascular ultrasound (IVUS) at 6 months. 603 pts were randomised, of which 111 pts were enrolled in an IVUS substudy which is the subject of this report. Stents were interrogated with the CVIS UltraCross system using a motorized pullback and analysed in an IVUS core laboratory. 6 month IVUS measurements were available on 105 of this subgroup (95%). Mean stent area was similar in the two groups (steel 8.00 ± 1.99 mm^2, gold 7.86 ± 2.24 mm^2). Lumen volume within the stented segment was significantly reduced in the NIROYAL compared with the NIR PRIMO group (steel 99.21 ± 56.42 mm^3, gold 72.87 ± 38.31 mm^3, difference 26.34 mm^3, CI 8.11, 44.56), as was MLD (steel 2.15 ± 0.57 mm, gold 1.92 ± 0.58 mm, difference 0.23 mm, CI 0.01, 0.45). Mean area of neointimal hyperplasia was significantly higher in the NIROYAL group (steel 1.99 ± 1.29 mm, gold 2.37 ± 1.32 mm, difference 0.73 mm, CI 1.22, 0.25). As a consequence, the volume of in-stent obstruction was significantly higher in the NIROYALä group (steel 25.9 ± 16.8%, gold 36.7 ± 18.7%, difference 10.8%, CI 17.5, 4.0).
Thus, the gold-coated NIROYAL is associated with significantly more intimal hyperplasia and instent restenosis than the stainless steel NIR PRIMO stent when investigated by IVUS six months after stent implantation. In this study, these adverse changes documented by IVUS were not associated with an increase in major adverse cardiac events (MACE).

P2882 Low pressure inflation by the GuardWire embolisation protection device causes no harm in native coronary arteries: an angiographic follow-up

G. Sütsch, G. Puippe, F.W. Amann. *University Hospital, Zurich, Switzerland*

Background: Low pressure inflation might cause adverse local effects during percutaneous coronary interventions (PCI) in native coronary arteries. The GuardWire (GW) embolisation protection device was recently introduced in the clinical arena but little is know about short- and long-term follow-up at the site of the temporary distal occlusion balloon.
Methods: By quantitative coronary angiography (QCA) we analysed the vascular segment after final deflation of the GW distal protection balloon (day 1) and compared the identical region in the first 50 patients (pts; mean age 60±12 years, 12 women; left anterior descending: n=26, right coronary artery: n=20, and left circumflex: n=4) that had recatheterisation (day 2) at our institution. Cumulated inflation time, number of inflations and maximal size of the distal balloon were included in the analysis.
Results: Pts were restudied 120±125 days (range 1 to 426 days) after PCI because of reinfarction (n=8) or infarction (n=2), acute coronary syndrome (n = 14), elective study (n = 14), or for other reasons (n=12). Acutely the temporary low pressure inflation balloon did not induce any local changes on day 1 in any patient. Similarly, on day 2 there were no changes and lumen diameter of the region of interest was identical (2.6±0.8 and 2.6±0.7 mm; ranges: 1.61 to 5.11 and 1.55 to 4.75 mm, respectively), and the GW did not cause any stenosis or remodeling. The number and time of inflations (cumulated: mean, 11.7±11.6 minutes; range, 2.1 to 59 minutes) and the size of the balloon did not have any adverse effects as well.
Conclusion: This preliminary follow-up angiographic study suggests that the low pressure temporary occlusion balloon does not cause any harm to the vascular bed at the site of the former inflation.

P2883 Noninvasive assessment of coronary artery stents. A comparison of multislice-CT-angiography and MR-angiography in a phantom study with 19 stents

D. Maintz[1], K.U. Juergens[1], M. Grude[2], M. Stuber[3], W. Manning[3], T. Wichter[2], W. Heindel[1], R. Fischbach[1]. *[1]University of Muenster, Deptartment of Clinical Radiology, Muenster, Germany; [2]University of Muenster, Department of Cardiology, Muenster, Germany; [3]Beth Israel Deaconess Medical Center, Cardiac MR Center, Boston, United States of America*

Purpose: Evaluation of the lumen visibility of several coronary artery stents by MS-CTA and MRA.
Material and Methods: Nineteen different coronary artery stents (materials steel, nitinol, tantalum) were implanted in plastic tubes (inner diameter 3mm). For MS-CTA (Kollimation 4x1 mm; tablefeed 2 mm/rotation, mAs 300, kV 120), the tubes were filled with nonionic contrast medium (200 HU), closed at both ends and positioned in a plastic container with oil (HU –70). For MRA, the tubes were integrated in a flow model, scans with and without flow (TSE-sequence) were obtained and subtracted. By this, only flow appeared signalintense.
Results: During MS-CTA, artifacts caused a complete lumen obscurity in the Wiktor, the Jograft and the Nir Royal stent. In all other products small parts of the lumen were visible (lumen narrowings of 62-94%). During MRA, the lumen was completely visible with high signal intensity in the Wiktor stent. The signal was moderately decreased in the Radius stent and severely to totally decreased in the other devices.
Conclusions: Although parts of the stentlumen were delineable with MS-CTA and/or MRA, a reliable assessment with detection of possible in-stent stenoses appears realistic only for the tantalum stent in MRA.

P2884 The impact of plasma levels of CRP on the restenosis rate after successful coronary stenting. Results from the GENERATION study

M. Zairis[1], S. Manousakis[2], O. Papadaki[2], D. Beldekos[2], C. Fakiolas[2], C. Olympios[2], D.V. Cokkinos[3], S. Foussas[2]. *[1]Piraeus, Greece; [2]Tzanio Hospital, Cardiology Dept., Piraeus, Greece; [3]Onassis Cardiac Surgery Center, Cardiology Dept., Athens, Greece*

Background High plasma C-reactive protein (CRP) levels, has been associated with an increased risk of short and long-term ischemic complications in patients with coronary artery disease. However, the impact of preprocedural plasma CRP levels on the angiographic restenosis rate after succesful coronary stenting (CS) has not been clarified yet. The purpose of this substudy was to evaluate this issue.
Methods The GENERATION study was designed to evaluate globally, the impact of several serum markets estimated upon admittance (CRP, Lpa, homocystein and seropositivity for chlamydial infection) on the long-term cardiovascular morbidity and mortality as well as on the restenosis rate after coronary stenting. For the purpose of this study a total of 483 consecutive patients who underwent successful CS due to stable or unstable coronary syndromes were recruited in a period of 28 months in our institute. Complete clinical follow up was obtained from 465 (96.3%) pts in a period of 3-years.
Results: By 1-year, 121 patients (121/465 24.1%) developed recurrence of symptoms. During this 1-year time period, 309 (309/465 66.5%) patients underwent angiographic restudy, including 114 (114/121 94.2%) symptomatic and 195 (195/344 55.1%) asymptomatic. Pts were classified into four groups A, B, C and D according to the quartiles of plasma CRP values. Angiographic restenosis (>50% in-stent lumen diameter stenosis) was observed in 108 (108/309 35%) pts. The distribution of restenosis among the quartiles of CRP are presented in the table. There was no statistically increased risk of in-stent restenosis with increasing of CRP tertiles (P=0.89)

A (0.5)	B (0.54)	C (0.64)	D (1.01)	P
32.1	33.8	37.3	36.6	0.89

Numbers are presented as %. Values in parentheses represent median CRP value for each quartile of CRP as mg/dl

Conclusions: The results of the GENERATION study suggest that high plasma levels of CRP are not related to the rate of restenosis after successful CS. More studies are needed to elucidate this issue.

P2885 Cytokines and inflammatory markers are released early after coronary stenting and are related to 6-month clinical outcomes

A. Caixeta[1], F.S. Brito Jr[2], C.V. Serrano[3], C. Diniz[4], A.L. Brasileiro[5], B. Tura[6], M. Rati[1], P.L. Da Luz[3]. *[1]Hospital Barra D' Or, Interventional Cardiology, Rio de Janeiro, Brazil; [2]Hospital Albert Einstein, Interventional Cardiology, São Paulo, Brazil; [3]Universidade de São Paulo, Instituto do Coração (InCor), São Paulo, Brazil; [4]Hospital Barra D'Or, Clinical Immunology Laboratory, Rio de Janeiro, Brazil; [5]Hospital Barra D'Or, Cardiology, Rio de Janeiro, Brazil; [6]Universidade do Rio de Janeiro (UERJ), Hospital Universitário, Rio de Janeiro, Brazil*

Circulating levels of inflammatory markers, such as C-reactive protein (CRP) and proinflammatory cytokines have been reported to be present in patients (pts) with acute coronary syndromes and are related to unfavorable short-term outcome. The effect of coronary stenting on cytokines release and cell-mediated immunity is not well known. Purpose: To investigate the systemically detectable inflammatory response and immune system activation in pts undergoing coronary stent implantation. The study also investigates the relationship between inflammatory markers after stenting and major adverse cardiac events (MACE) at 6-month follow-up. Methods: We measured serum concentration of high-sensitivity CRP (hs-CRP), interleukin-6 (IL-6), interleukin-8 (IL-8)(as marker of inflammation)and serum soluble interleukin-2 receptor (sIL-2R) for T-lymphocytes activation(as a marker of cell-mediated immunity). Forty pts were enrolled to single vessel stent implantation in native coronary arteries. Peripheral venous blood samples were taken before stenting and 6 h, 48 h, and 12 weeks(wk) after the procedure. Pts were divided into 2 groups according to their 6-month follow-up: group 1: 6 pts with MACE, and group 2: 34 pts with uneventful course. Nonparametric tests were used; results are expressed as median. $P<0.05$ was significant. Results: The level of hs-CRP was 0.45 mg/dL before, 0.56 mg/dL at 6 h (P=NS) and 2.77 mg/dL at 48 h ($P<0.05$). At 12 wk, a decrease to 0.22 mg/dL was detected ($P<0.05$). IL-6 increased from 7.80 pg/mL to 11.00 pg/mL at 6 h ($P<0.05$), decreasing to 8.90 pg/mL at 48 h ($P<0.05$)and to 2.77 pg/mL at 12 wk ($P<0.05$). IL-8 increased from 6.30 pg/mL to 12.60 pg/mL at 6 h ($P<0.05$), decreasing to 7.30 pg/mL at 48 h ($P<0.05$) and to 6.90 pg/mL at 12 wk (P=NS). There was no change for sIL2-R level at 6 h (baseline: 420 vs 6 h: 430 U/mL;P=NS). sIL2-R increased to 476 U/mL at 48 h ($P<0.05$). There was also an increase in sIL2-R at 12 wk, with a peak value of 495 U/mL ($P<0.05$). When compared to pts with no clinical events, pts with MACE (group 1) presented significant increases in hs-CRP at 48 h (Group 1: 4.94 vs Group 2: 1.84 mg/dL; P=0.043) and IL-8 at 6 h (Group 1: 26.75 vs Group 2: 13.55 pg/mL; P=0.048), representing 2.7 and 2.0-fold increases, respectively. Conclusions: Proinflammatory cytokines and acute phase proteins are released into peripheral circulation early after coronary stenting. Cell-mediated immunity occurs early and at least after 12 wk after stenting. The occurrence of MACE at 6-month is associated with the magnitude of inflammation after the procedure.

P2886 Predictors of event free survival in patients treated for in-stent restenosis. Insight from the RIBS ramdomized trial

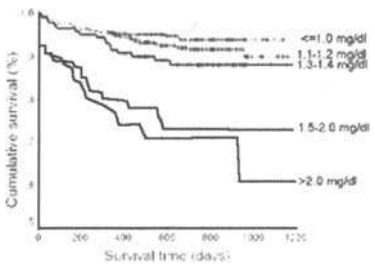
V. Mainar[1], J. Tascón[2], L. Insa[3], N. Vázquez[4], F. Pomar[5], R. Seabra-Gomes[6], J. Mota-García[7], F. Alfonso[8] on behalf of RIBS investigators. *[1]H de Alicante, Interventional Cardiology, Alicante, Spain; [2]H 12 Octubre, Interventional Cardiology, Madrid, Spain; [3]H Clinico, Interventional Cardiology, Valencia, Spain; [4]H Juan Canalejo, Interventional Cardiology, La Coruña, Spain; [5]H General, Interventional Cardiology, Valencia, Spain; [6]H Santa Cruz, Interventional Cardiology, Lisboa, Portugal; [7]H S Joao, Interventional Cardiology., Porto, Portugal; [8]Hospital Clinico San Carlos, Interventional Cardiology, Madrid, Spain*

Background: In-stent (ST) restenosis (RE) constitutes a clinical and technical challenge affecting a growing number of patients (P). Although satisfactory initial results are usually obtained with repeat percutaneous coronary interventions (PCI) the risk of recurrent RE remains high. There is, therefore, still a need to determine predictors of the long-term clinical outcome in these P.
Methods: The RIBS trial (Restenosis Intra-stent Balloon angioplasty vs elective Stenting) was a randomized study where these two strategies were compared in 450 P [224 allocated to ST and 226 to balloon angioplasty (BA)]. The recurrent RE rate was similar in both groups (38% in the ST arm vs 39% in the BA arm). However, in the pre-specified subgroup of P with large vessels (>3mm) RE rate was reduced in the ST arm (27% vs 49%, p=0.007). One-year follow-up (FU) was obtained in all 450 P (with no P lost to FU). Events assessed at FU included death, myocardial infarction (MI) and target vessel revascularization (TVR). By protocol, symptoms or objective evidence of ischemia was required for TVR.
Results: During 1-year FU 15 P died (8 ST arm, 7 BA arm), 19 suffered a MI (6 ST arm vs 13 BA arm, p=0.15) and 99 required TVR [44 (19%) ST arm vs 55 (24%) BA arm, p=0.25). TVR included PCI in 75 P (32 ST arm and 43 BA arm, p=0.2) and CABG in 27 (14 ST arm and 13 BA arm) (non-exclusive events). Any major adverse event occurred in 52 P in the ST arm (23%) and 65 (29%) in the BA arm (RR 0.81, 95%CI 0.58-1.10, p=0.19). On univariate analysis unstable angina (p=0.079), time to RE (p=0.013), diffuse (>10 mm) RE (p=0.08), baseline minimal lumen diameter (MLD)(p=0.05), TIMI flow 1-2 (p=0.029), %diameter stenosis (p=0.036), B2-C lesions (p=0.13), lesions at bifurcation (p=0.15), ostial location (p=0.14) and saphenous vein grafts (SVG)(p=0.005), were predictive of events at FU. In addition, when procedural data and results were examined: BA therapy (p=0.18), cross-over requirement (p=0.09), residual dissection (p=0.003), final pressure (p=0.04) and balloon/artery ratio (p=0.1) were also associated with events. On multivariate Cox regression analysis, time to RE (HR 1.96, 95%CI 1.4-2,9, p=0.001), baseline MLD (HR 0.64, 95%CI 0.4-1.06, p=0.07) and SVG (HR 5.8, 95%CI 2.3-14.5, p=0.003) were independent predictors of events.
Conclusions: P with in-ST RE undergoing repeat PCI have a relatively high event-rate at FU. Clinical, anatomic and procedural variables are predictive of the long-term clinical outcome in these P.

P2887 Mildly elevated serum creatinine levels are associated with impaired long-term outcome after coronary angioplasty

H. Reinecke[1], T. Trey[2], F. Matzkies[2], R. Ammer[1], R. Schaefer[3]. *[1]Universitätsklinikum Münster, Medizinische Klinik und Poliklinik C, Münster, Germany; [2]Münster, Germany; [3]Medizinische Klinik und Poliklinik D, Universitätsklinikum Münster, Münster, Germany*

Patients with moderate renal failure and creatinine (crea) levels of 1.6-2.0 mg/dl were shown to have a significantly higher long-term mortality after PTCA. To evaluate a possible crea threshold for significantly reduced outcome, we performed a retrospective analysis of our PTCA patients from 1998-1999.
During these 2 years, 1,104 patients underwent a total of 1,440 PTCA procedures. Patients with endstage renal failure requiring maintenance hemodialysis (n=51) were excluded. Follow-up of the remaining 1053 patients was 99.6% complete. Patients were divided in 5 groups by their baseline crea: <=1.0 (n=437), 1.1-1.2 (n=376), 1.3-1.4 (n=132), 1.5-2.0 (n=55), and >2.0 mg/dl (n=39). Between these groups, significant differences were found concerning higher age and lower proportion of women with increasing crea levels, whereas risk factors as hypertension, dyslipidemia, smoking and diabetes differed non-significantly between the groups. During follow-up (mean 1184 days; 95% CI 1164-1204 days), 96 deaths and 46 non-fatal infarctions occurred. Univariate analyses identifid age (OR 1.03), multi-vessel disease (OR 1.21), ejection fraction (OR 0.96), previuos PTCAs (OR 0.42), previuos bypass grafting (OR 1.57), crea levels (OR 2.20), use of beta-blockers (OR 0.45) or of statins (OR 0.41) to be associated with death. Cumulative survival was displayed by a Kaplan-Meier model (fig.), with a significantly increased mortality at a crea of 1.3-1.4 mg/dl (p = 0.0108, log rang). Logistic regression analysis confirmed the above factors to be independent predictors of death, with an over-all accuracy of the model of 90.2%. Even mildly elevated crea levels of 1.3-1.4 mg/dl (indicating a 50% reduction in renal function) were associated with significantly higher long-term mortality after PTCA.



Survival after PTCA and creatinine.

P2888 Preprocedural C-reactive protein is associated with death/myocardial infarction but not with repeat revascularization following PTCA

R. DeWinter[1], K.T. Koch[2], G. Heyde[2], M. Bax[2], C.E. Schotborgh[2], G.T. Sanders[3], J.J. Piek[2], J.G.P. Tijssen[2]. *[1]Cardiology B2-137, [2]Cardiology, [3]Clinical Chemistry, Academic Medical Center, Amsterdam, Netherlands*

Background: We investigated the prognostic value of a preprocedural C-reactive protein concentration in patients undergoing percutaneous coronary angioplasty for the prediction of death, non-fatal myocardial infarction or repeat during 14 months follow-up. **Methods and Results:** Preprocedural plasma levels of C-reactive protein (CRP) were measured in 1458 consecutive patients undergoing coronary angioplasty. The incidence of death or myocardial infarction was 6.1%(44/716) in patients with a increased CRP level (>3 mg/L) and 1.5%(11/742) in patients with a normal CRP level (RR 4.35, 95% CI: 2.23 – 8.49). Survival without death or non-fatal MI was significantly lower in patients with an increased CRP versus patients with a normal CRP (log-rank 22.11, p<0.00001). Multivariate logistic regression analysis identified an increased CRP level as a strong independent predictor of event-free survival (RR 3.94; 95% CI 1.99 – 7.79, p=0.0001). Incidence of repeat revascularization was not different between patients with or without an increased preprocedural CRP (21% versus 19%, p=0.46). Statin therapy was associated with a lower mean preprocedural CRP (5.75 mg/L versus 7.17 mg/L, p=0.018) but was not associated with a lower incidence of death, non-fatal MI or repeat revascularization in this study. **Conclusion:** An increased preprocedural plasma C-reactive protein is a powerful independent prognostic indicator for the occurrence of death or non-fatal MI following coronary angioplasty, but it is not associated with the need for repeat revascularization.

P2889 Pre-procedural inflammation markers predict myocardial damage at the time of PCR in patients with stable angina

K. Sautière[1], E. Van Belle[1], P. Amouyel[2], S. Susen[3], C. Bauters[1], B. Jude[3], J. Dalongeville[2], J.M. Lablanche[1]. *[1]Cardiologique, Cardiologie, Lille; [2]Institut Pasteur, Lille; [3]Hopital Cardiologique, Hématologie, Lille, France*

The predictive value of inflammatory markers has been studied in various clinical contexts in patients (pts) with coronary artery disease. Little is known however, on the value of these markers in pts with stable angina treated by PTCA. We studied the predictive value of C reactive protein (CRP) and fibrinogen measured at baseline in 91 consecutive pts who underwent PTCA in year 2000. Pts with a recent (<1 month) myocardial infarction were excluded. Post-procedural rise in troponin I (>0.6 mg/L) and major in-hospital events (death, MI, stroke) were used as endpoints. For analysis, the population was grouped into tertiles according to pre-procedural levels of CRP (1st tertile<2 mg/l; 2nd tertile: 2-5 mg/l; and 3rd tertile>=5 mg/L) and fibrinogen (1st tertile<3.3 g/L; 2nd tertile:3.3-4 g/L; and 3rd tertile>=4 g/L). Tertiles of CRP or fibrinogen were predictors of post-procedural rise in troponin (myocardial damage) (p=0.003 and p=0.02, respectively). The same trend was found for in-hospital cardiac events (p=0.09 and p=0.07, respectively). Importantly, tertiles of CRP and fibrinogen remained predictors of myocardial damage and in-hospital events after exclusion of pts with unstable angina at baseline (see table).

Events according to markers at baseline

	All patients (n=91)		Patients with stable angina (n=63)	
CRP	Troponin rise	Clinical events	Troponin rise	Clinical events
1st Tertile	(0/29) 0%	(0/29) 0%	(0/26) 0%	(0/26) 0%
2nd Tertile	(6/29) 20.7%	(1/29) 3.4%	(2/15) 13.3%	(0/15) 0%
3rd Tertile	(11/33) 33.3%	(4/33) 12.2%	(6/22) 27.3	(2/22) 9.1%
p	0.003	0.09	0.018	0.13
Fibrinogen	Troponin rise	Clinical events	Troponin rise	Clinical events
1st Tertile	(1/30) 3.3%	(0/30) 0%	(1/25) 4.0%	(0/25) 0%
2nd Tertile	(8/29) 27.6%	(1/29) 3.4%	(2/19) 10.5%	(0/19) 0%
3rd Tertile	(8/31)25.8%	(4/31) 12.9%	(5/18) 27.7%	(2/18) 11.1%
p	0.02	0.07	0.06	0.07

Conclusion: In pts with stable angina, baseline levels of CRP and fibrinogen are predictors of myocardial damage and in-hospital events. Our results suggest that in pts usually considered to be at low risk for angioplasty, preprocedural measurement of CRP and/or fibrinogen may help to select a "high risk" group.

P2890 Insulin sensitivity and nitric oxide release during oral glucose tolerance test are strong predictors of restenosis after coronary stenting

F. Sgura[1], P.M. Piatti[2], E. Setola[2], L.D. Monti[2], M. Messa[3], A. Caumo[2], A. Colombo[4], C. Di Mario[1]. [1]Ospedale San Raffaele, Emodinamica, Milan, Italy; [2]Diabetes, Internal Medicine, Milan, Italy; [3]San Raffaele, Emodinamica, Milan, Italy; [4]Columbus Hospital, EMO Centro Cuore, Milan, Italy

Background: Hyperinsulinemia and diabetes mellitus lead to accelerated atherosclerosis and increased restenosis after percutaneous transluminal coronary angioplasty (PTCA) and stent implantation. However, the correlation of the metabolic alterations typical of the Insulin Resistance Syndrome with restenosis after stenting has not been established and was studied in this prospective single center observational trial.
Materials and Methods: An oral glucose tolerance test (OGTT) was performed in all 69 patients (mean age=57±2 yrs, mean body mass index 26.2±0.4 kg/m^2) with normal baseline glucose levels who underwent routine angiographic control 6 months after coronary stent implantation.
Results: Angiographic restenosis (> 50% DS) after stenting was found in 28 pts (group 1), with a Minimal Lumen Diameter (MLD) of 0.93 ± 0.10 mm (3.0±0.31 mm; in the 41 pts without restenosis, group 2, $p<0.0001$). There were no significant differences in MLD between the two groups before-and after intervention.
Group 1 showed higher HOMA (homeostasis model assessment) (2.4±0.2 vs 1.9±0.1, mmol/l x μU/ml $p<0.03$), C-peptide levels (2.4±0.1 vs 2.0±0.1 ng/ml, $p<0.01$) and homocysteine levels (13.3±0.8 vs 11.3±0.6 μmol/l $p<0.03$). Insulin response after OGTT was also significantly increased in group 1: insulin incremental areas were 7733±773 μU/mL in group 1 vs 5595±400 μU/mL in group 2 [(0-120 min); $p<0.01$] while no differences were found measuring incremental areas (0-120 min) of glucose levels after OGTT in both groups. Using a mathematical deconvoluted method, in group 1 insulin sensitivity was decreased (5.0±0.6 vs 7.4±0.8 10^{-4} mmol kg^{-1} min^{-1}/μU ml^{-1}; $p<0.05$) and insulin secretion was increased (1.0±0.1 vs 0.8±0.01/μU ml^{-1}/mg dl^{-1}; $p<0.05$). Group 1 showed also a significant decrease of nitric oxide (NOx) incremental area during OGTT [-480±157 vs 143±117 μmol/l (0-120 min); $p<0.002$. At simple regression analysis, MDL at follow-up was positively correlated with insulin sensitivity during OGTT ($r=0.52$; $p<0.001$), C-peptide ($r=0.26$; $p<0.05$), proinsulin ($r=0.31$; $p<0.03$), HOMA ($r=0.25$; $p<0.05$) and NOx incremental area ($r=0.39$; $p<0.002$). At multiple regression analysis only insulin sensitivity during OGTT ($p<0.001$) and NOx incremental area ($p<0.03$) were independently correlated with MLD.
Conclusions: Insulin sensitivity and NOx release during OGTT predict restenosis after stenting in patients with CAD.

P2891 Increased CD15 on leukocytes and decreased platelet activation in the coronary sinus after coronary intervention: implications for restenosis

U. Rauch, U.M. Wolff, H.P. Schultheiss, P.L. Schwimmbeck. *Universityhospital Benjamin Franklin, Cardiology and Pulmology, Berlin, Germany*

The identification of marker associated with coronary stenosis is necessary for the development of therapeutic strategies that improve the clinical outcome of patients undergoing coronary intervention. The study examined alterations in platelet- and leukocyte-associated adhesion proteins during angioplasty in patients with stable coronary artery disease. The aim was to identify whether the presence of activation-dependent adhesion proteins on platelets and CD15 on leukocytes in the coronary microcirculation was associated with the occurrence of restenosis.
Circulating platelets and leukocytes were obtained from the coronary sinus before and directly after successful coronary intervention (balloon angioplasty (n=8) or stent implantation (n=15). Adhesion protein density on leukocytes (CD 15 and L-selectin) and on platelets (P-selection, thrombospondin and CD41) was flow cytometrically measured. Levels of adhesion proteins pre and post intervention were related to the occurrence of restenosis as assessed by re-angiography after 6-8 months.
CD15 on leukocytes was the adhesion protein marker that was significantly higher pre and post intervention in patients who developed restenosis (n=8) compared to those without restenosis (n=15) (CD15 immunofluoresence for patients with restenosis 187±87 versus 118±55 for patients without restenosis, $p<0.01$). CD 15 on leukocytes and activation-dependent adhesion proteins on platelets were significantly reduced post compared to pre coronary intervention in all patients (for p-selectin-positive platelets 8.1% [9.5;5.1] pre vs 5.2% [6.5;4.6] post PCI; for thrombospondin 31% [37;22] pre vs. 17% [27;9] post PCI). The reduction in adhesion proteins on cells was accompanied by a reduction in the platelet count.
Increased CD15 expression on leukocytes pre and post intervention is associated with the occurrence of restenosis. Leukocyte CD15 expression and platelet consumption contribute to the development of coronary restenosis post intervention. Inhibition of leukocyte adhesion via CD15 antagonism may prove to be useful for preventing restenosis.

P2892 The changes and the prognostic impacts of the levels of secretory type II phospholipase A2 and CRP in CAD patients after coronary intervention

P.Y. Liu[1], J.H. Chen[1], Y.H. Li[1], W.C. Tsai[1], T.S. Chao[1], S.H. Chan[1], L.M. Tsai[1], P.Y. Liu[2]. [1]National Cheng-Kung Univ. Hospital, Cardiology, Tainan, Taiwan, Province of China; [2]National Cheng-Kung University, Institute of Clinical Medicine, Tainan, Taiwan, Province of China

Background: A2 phospholipases are a family of enzymes that can hydrolyze phospholipids at the sn-2 position to generate lysophospholipids, fatty acids, and precursors of various pro-inflammatory lipid mediators. This enzyme might be involved in modifying plaque remodeling after rupture in the artery wall. The circulating levels of secretory type II phospholipase A2 (sPLA2) are found to be increased in patients with CAD. The increased levels of several inflammatory markers as C-reactive protein (CRP) and sPLA2 were known to be strong risk factors for prognosis. These inflammatory markers may play a role in the pathogenesis of acute coronary syndrome with the rupture of an atherosclerotic arterial plaque. The present study was designed to evaluate the changes of the level of sPLA2, inflammatory and cardiac injury markers before and after mechanical plaque rupture created by percutaneous coronary intervention (PCI) in CAD patients and their prognostic impact at future coronary artery events.
Methods and Results: Plasma levels of sPLA2, CRP and other cardiac enzymes were measured in 120 consecutive patients with CAD by ELISA. Five serum samples as: (1) before and (2) after diagnostic angiography, (3) after PCI, (4) 24-hours after PCI and (5) 48-hours after PCI respectively. The sPLA2, CRP didn't change after the procedures of diagnostic angiography ($p=0.7$, 0.1 respectively). However, the level of sPLA2 significantly (average 2-fold, maximally 10-fold, $p<0.0001$) increased after PCI. The level of CRP and the other cardiac enzymes didn't rise up immediately after PCI ($p=0.5$) but elevated significantly later at 24 hours after intervention ($p=0.02$). The levels of sPLA2 and CRP were persistently higher after 48-hour duration but the cardiac enzymes declined rapidly after 24 hour. After a 2-year follow up period, the level of sPLA2 after PCI, severity of CAD, smoking and hypertension remained independent risk factors for furture acute coronary event (OR=2.3, 2.1, 3.4 and 4.1 respectively).
Conclusion: Data from the present study had shown that the procedure of PCI might result in immediate elevation of circulating level of sPLA2 following the mechanical disruption of coronary plaque and the elevated levle of sPLA2 had significant prognosis. The CRP level and the traditional cardiac enzyme such as CK, CK-MB and troponin T didn't rise immediately but increased at 24 hours after PCI. These results strongly suggest that sPLA2 not only played as a pro-inflammatory factor and also might contribute in the pathogenesis of atherosicerosis and acute coronary syndrome.

P2893 Clinical long-term results of coronary angioplasty (PTCA) in degenerated bypass grafts (CABG)

M. Gruetters, G. Herrmann, R. Simon. *1. Medizinische Klinik, Klinik für Kardiologie, Kiel, Germany*

The frequency of coronary artery bypass grafting is still increasing. Prior to 1990, the majority of these patients received venous grafts. However, a moderate cohort suffered from angina petoris or myocardial infarction over time due to either progression of atherosclerosis or degeneration of the CABG.
Between 1988 and 2000 more than 8,000 PTCA procedures were performed at our institution. From these procedures were performed in 424 bypass grafts (5.3%) on 294 patients. This patient group (257M; 37F) had a mean age of 65 (± 10,3) years and the time between CABG and PTCA was 7,1 (±4,8) years.Using a local data base all patients were evaluated for interventional technique, individual risk factors, CCS-classification and angiographic data. Clinical long-term follow up was taken by questionnaire and telephone contact with practitioners and patients.
218 patients (74%) underwent PTCA once, 76 had more than one PTCA. The initial success rate was 94%. A total of 165 (60%) of these underwent control angiography 3 - 6 month later. Restenosis rate (50% diameter stenosis) was found in only 20%.
Clinical follow-up by questionnaire was performed 4,6 (±3,1) years after PTCA and 79% of patients answered the questionnaire. 190 patients with a successful PTCA in CABG were still alive and in CCS-class I - II. Of these, 80% were content with their physical condition. In those patients who died in-between the cause of death was non-cardiac in 56% and cardiac in 44%.
In conclusion, PTCA in degenerated CABG can be performed with a high initial success rate, followed by a moderate restenosis rate of 20%. The late clinical outcome in this high risk group is very satisfying.

PAEDIATRIC ARRHYTHMIA/ELECTROPHYSIOLOGY

P2894 Arrhythmia in children with complex congenital heart defects and functionally single ventricle after Fontan procedure

M. Pitak, B. Zaluska-Pitak, B. Pietrucha, J. Oko-Lagan, E. Olczykowska-Siara, Z. Kordon, P. Werynski, A. Rudzinski. *Polish-American Children Hospital UJ, Pediartic Cardiology, Krakow, Poland*

The ultimate stage of surgical treatment employed in patients (pts) with complex congenital heart defect (CCHD) and functionally SV is a modified Fontan (F) procedure. Arrhythmia (arh) and conduction disturbances are important risk factors influencing SV function, decreasing its efficiency and being among reasons for long term prognosis deterioration.

The aim of the study was a retrospective assessment of the incidence of various types of arh in children with CCHD and SV after Fontan operation in the early and late postoperative period.

Material/methods: Ninety-seven pts with CCHD and SV who underwent F procedures in the years 1982-2000 were examined. Twenty-three of them underwent direct F, while 74 - staged F procedure. ECG tracings after F palliation were analyzed in the following time slots: A) once a week up to 1 mo, B) every 3 mo, up to 1 yr, C) every 6 mo, for 2-5 years, D) every 6 mo, over 5 years. Correlation between incidence of arh and type of the ventricular loop (D or L) were also analyzed.

Results: The results are shown in the table. The percentage of cases with diagnosed arh in patients currently followed up increased in time and in the defined slots: A) 16.5% (16/97), B 27% (26/97), C) 31% (24/77), D) 50% (13/26). Among 36 pts with arh, various forms of sinus node dysfunction were observed in 33 cases while atrial flutter (AF) was diagnosed in 3 pts. Complete atrioventricular block was not observed. In children with ventricular D-loop arrangement or HLHS, the incidence of arh was similar (33%) and it was lower than in pts with CCHD and SV with ventricular L-loop. Three pts with AF needed pharmacological therapy while 2 other pts - pacemaker implantation.

Ventricles	NO	Without arh	New arh				Total arh
			1 mo post op	1 yr post op	2-5 yrs post op	>5 yrs post op	
D-loop	60	40	11	4	2	3	20
L-loop	28	15	5	4	3	1	13
HLHS	9	6	0	2	1	0	3
Total	97	61	16	10	6	4	36

arh- arrhythmia, op - operation

Conclusions: The risk of arh in children with CCHD and functionally SV after F procedure is the highest in the early postoperative period and generally is higher among pts with concomitant L-loop ventricular arrangement. The number of pts with arh increases gradually in the time of observation.

P2895 Predictive value for malignant arrhythmias of echo and signal averaged electrocardiogram indices in repaired tetralogy of Fallot: long-term follow-up

S. Brili, C. Aggeli, C. Gatzoulis, G. Vyssoulis, J. Barbetseas, C. Pitsavos, C. Stefanadis, P. Toutouzas. *Athens, Greece*

We have reported that abnormal signal averaged ECG (SAECG), (RMS<=23mV, LAS>=32.5ms, fltQRS>=148msecs) and echocardiographic (ECHO) variables, (right ventricular diameter/left ventricular diameter: RVD/LVD>=1.05) are associated with potentially malignant ventricular arrhythmias on Holter recordings of asymptomatic patients (pts) with repaired Tetralogy of Fallot. In this study we aimed at detecting the predictive value of the aforementioned indices for the occurrence of sustained VT, after a 5 year follow-up period.

Methods: Forty pts 32±10 years old with repaired Tetralogy of Fallot were followed in our department for a period of 60 months. Pts were divided into two groups; Group A: 8 pts who had abnormal SAECG along with abnormal ECHO indices at baseline and Group B: 32 pts with no abnormal parameters of the SAECG and/or of the ECHO.

Results: Three of group A pts developed sustained VT after a follow-up period of 32, 36 and 40 months, respectively. Positive predictive value was 37%. No one of the group B pts developed abnormal SAECG along with ECHO indices. Also no one developed malignant arrythmias; negative predictive value 100%. The cumulative Kaplan Mayer event-free survival curve differentiated significantly between the two groups (p=0.038).

Conclusions: Our present data indicate that pts with repaired Tetralogy of Fallot and abnormal SAECG and ECHO indices have a 37% PPV to develop malignant arrhythmias. However, pts without abnormal indices have a high NPV for event free follow-up period of 60 months.

P2896 Volume-related mechano-electrical feedback in humans: assessment through monophasic action potential

B. Sarubbi[1], B. Mercurio[1], R. Calvanese[1], G. Santoro[1], M. Cappelli-Bigazzi[1], M.G. Russo[1], M. Carminati[2], R. Calabrò[1]. [1]*Monaldi Hospital, Pediatric Cardiology, Naples, Italy;* [2]*Division of Paediatric Cardiology -, S.Donato Milanese, Italy*

Background: Basic research and animal experiments have shown the development of electrophysiological changes during or after changes in mechanical loading. The aim of the present study was to assess the presence of volume-related mechano-electrical feedback in humans, evaluating dispersion of ventricular repolarization time indexes and monophasic action potentials (MAP) following acute changes in ventricular volume overload in humans.

Methods: The study group comprised 16 consecutive pts (4M/12F, aged 4-36years) affected by ostium secundum atrial septal defect (ASD) with moderate to severe right chambers volume overload signs, who underwent successful ASD device closure. Dispersion of ventricular repolarization time was evaluated before and after the ASD closure through measurement of QT and QTc dispersion (QTD, QTcD), JT e JTc dispersion (JTD,JTcD) and T-peak to T-end interval (Tp-Te). MAP were recorded by contact electrode catheter introduced via femoral vein and advanced into the RV apex. MAP duration (MAPd), determined at a repolarization level of 90% with respect to the MAP amplitude, was measured on the electrophysiological traces recorded before and after volume-overload release.

Results: After ASD closure patients showed a significant decrease in QTD (48.9±24.8 vs 29.7±13.5; p<0.0002), in QTcD(62.5±21.5 vs 45.5±15.6; p<0.0001), in JTD (54.7±22.2 vs 41±14.2; p<0.02), in JTcD (60.4±19.6 vs 47.5±16.9; p<0.02), in Tp-Te (112.3±12.2 vs 106.8±12.6; p<0.02). Furthermore patients showed a significant increase in MAPd (355±24.4 vs 366.8±24.9; p<0.0001)

Conclusion: Changes in haemodynamic loading can produce electrophysiological effects in humans. Acute reduction in ventricular volume overload, following ASD device closure decreases electrical instability, as expressed by dispersion of ventricular repolarization time shortening and monophasic action potential duration increasing.

P2897 Is routine echocardiography valuable after uncomplicated catheter ablation in children?

J.A.E. Kammeraad[1], S. Balaji[2], V. vDriel[1], R. Oliver[2], N. Sreeram[1]. [1]*Wilhelmina Children's Hospital, Dept of Cardiology, utrecht, Netherlands;* [2]*Oregon Health Sciences University, Dept of cardiology, Portland, United States of America*

Introduction: Although the complication rate of radiofrequency catheter ablation (RFCA) procedures in children is low, clinically asymptomatic complications do occur. Transthoracic echocardiographic studies are performed after every RFCA in children in most centers. We determined the clinical value of routine echocardiography performed after catheter ablation of supraventricular tachycardia (SVT) in children.

Methods and Results: Between April 1996 and September 2001, 138 children (75M, 63F), (mean age 13 years; range 0-19 years), underwent 160 uncomplicated radiofrequency catheter ablation (RFCA) procedures for SVT at our two institutions. In every child a transthoracic 2-D echocardiogram (TTE) with Doppler was performed before and after the procedure.

The mechanisms for SVT were Wolff-Parkinson-White syndrome in 48, concealed accessory pathways in 41, AVNRT in 42, PJRT in 2, junctional ectopic tachycardia in 1, sinus node reentry tachcardia in 1 and focal atrial tachycardia in 3 patients. The pre-ablation TTE's in all cases were normal.

After RFCA, in 4 clinically asymptomatic patients the TTE revealed procedure-related complications: one patient (age 15 years) with focal atrial tachycardia, showed mild aortic valve insufficiency. This had resolved spontaneously 6 months later; three other children developed an asymptomatic pericardial effusion. In 2 patients (a 11 year old with a concealed left sided accessory bypass and a 16 year old with AVNRT) this resolved spontaneously, but the third patient (aged 9 years, with a concealed left lateral pathway) required pericardiocentesis. The same 9 year old patient also developed a clinically asymptomatic mild aortic insufficiency, which resolved spontaneously within 6 months.

Conclusion: Echocardiography after uncomplicated RFCA procedures in children may detect asymptomatic complications. This is particularly relevant in the current management involving same-day discharge after uncomplicated catheter ablation in children.

P2898 Long-term follow-up after ablation of atrial tachycardias in patients with congenital heart disease using three-dimensional mapping techniques

N.M.S de Groot[1], N. Sreeram[2], J. Kammeraad[2], F. Wittkamf[2], M.J. Schalij[1]. [1]Leiden University Medical Center, Cardiology, Leiden, Netherlands; [2]Heart Lung Center Utrecht, cardiology, utrecht, Netherlands

Introduction Atrial tachycardias in pts with surgically corrected congenital heart disease (CHD) are often reentrant tachycardias (ART) with complex conduction pathways through scar tissue. 3-Dimensional mapping techniques for selection of target sites and accurate delineation of areas of scar tissue are therefore mandatory. This study evaluated the long-term outcome after ablation guided by 3-D electro-anatomical mapping techniques for identification of the arrhythmogenic substrate in pts with CHD and ART.
Methods Pts (n=52, age 38±14 yr., 22 male) with ART and tricuspid atresia (20), transposition of the great arteries (13), atrial septal defect (13), Fallot (6) referred for catheter ablation of atrial tachycardias were studied using the CARTO or Loca Lisa system. Detailed activation/voltage maps were constructed to localize anatomically and surgically created barriers during ART and to mark sites ablated. Scar tissue was delineated using a cut-off value of 0.1 mV.
Results Mapping was performed during ART (CL 294±79 ms, no. of induced ART per pt: 1.3±0.7). Termination of ART was achieved by creating a line of conduction block 1) between areas of scar tissue (24%) 2) at the cavo-tricuspid isthmus (51%) or 3) both (24%). In 2 pts, IART converted to atrial fibrillation (AF) during RF. Success (non-inducibility after RFCA) was achieved after 1 or 2 (n=4) procedures in 76% of the pts. No complications were observed. During follow-up (14±6 months), 76% of the pts had sinus rhythm, 19% paroxysmal and 5% permanent AF.
Conclusion Pts with ART and CHD can be successfully treated by 3-D electro-anatomical mapping guided ablation. This technique facilitates detailed identification of the arrhythmogenic substrate and selection of target sites for ablation.

P2899 Pacemaker-implantation before 30 years of age – Prevalence, indications, complications and long-term follow-up

C. Hummel[1], M. Brunner[1], S. Dittrich[2], D. Kececioglu[2], M. Zehender[1]. [1]Med. Klinik III, Universitätsklinikum, Freiburg, Germany; [2]Universitätskinderklinik, Abt. Pädiatrische Kardiologie, Freiburg, Germany

In our database of 6465 patients (pts) with pacemaker (PM), 80 pts (1.2%) underwent first implantation before 30 years of age (median age 16.3 years). The morbidity and mortality of these young pts are widely unknown.
The median follow-up was 57.9 months (0.03-346 months); follow-up was performed after 6 or 12-month intervals in all 80 pts (33 women). Indications for implantation were: AV-block in 58% (46 pts), sick sinus syndrome in 33% (26 pts) and other bradyarrhythmias in 6% (5 pts). The causes for arrhythmia were: previous heart surgery (32 pts, 40%) or congenital bradyarrhythmia (8 pts, 10%); etiology was unknown in 50%.
At first implantation a transvenous approach was used in 79%. 41 pts (51%) received a single-chamber system (later dual-chamber system in 22% of these pts); 26 pts (33%) received a dual-chamber system at first implantation.
In long-term follow up 0-8 re-operations were required (mean 0.95; median longevity of PM systems 46.9 months). Indications for re-operation were: battery depletion (55.3%), infection/wound healing problems (10.5%), fracture or dislocation of pacing leads (11.8%) and malfunction of the electric system (5.2%). During follow-up, PM was no longer necessary in 7 pts (8.8%). 16 pts died (20%; 56.3% after heart surgery, 6.3% with congenital arrhythmia, 6.3% with cardiomyopathy, 31.3% with unknown etiology). Pts died 28.5 months after first implantation (1-164 months); sudden death occurred in 9 pts.
Congenital and corrected heart malformations are the main indications for PM implantation before 30 years of age. The mortality rate and the rate of sudden deaths are surprisingly high.

UPDATE ON SURGICAL TECHNIQUES

P2900 Off-pump coronary artery bypass surgery does not reduce lymphocyte activation

C. Blacher[1], J. Neumann[1], B. Fernandes[2], J.A. Jung[1], W.M. Pereira[1], F.A. Lucchese[1], J.P. Ribeiro[3]. [1]Santa Casa de Porto Alegre, Porto Alegre, Brazil; [2]School of Medicine, UFRGS, Department of Medicine, Porto Alegre, Brazil; [3]Hospital de Clinicas de Porto Alegre, Cardiology Division, Porto Alegre, Brazil

Background: Coronary artery bypass surgery is known to be associated with alteration of inflammatory mediators and immune function, with early phase lymphocyte activation, that could be responsible for post-operative lymphopenia and lymphocyte unresponsiveness. In this trial, we test the hypothesis that off- pump coronary bypass surgery might result in less lymphocyte activation than on-pump coronary surgery.
Methods: We studied lymphocyte activation response during the operative and post-operative period in 28 patients randomized to off-pump coronary surgery (n = 13) or conventional on-pump coronary surgery (n = 15) using flow cytometry to determine expression of CD23, CD25, CD26, CD69 and DR on T (CD3+) and B (CD19+) lymphocytes in the peripheral blood.
Results: There were no significant differences in any of the lymphocyte activation markers off-pump compared to on-pump coronary surgery (2 way ANOVA for repeated measures, $P > 0.05$). Considering all patients studied, there was an elevation of the proportional expression of CD69 and CD25 in T (CD3+) and B (CD19+) lymphocytes. In T lymphocytes, the higher proportional median value (± SE) of CD69 was observed 6 hours after completion of anastomosis (+75 ± 476%), and CD25 had a more gradual elevation, with its peak median value (+48 ± 24%) occurring 24 hours after revascularization. In B-lymphocytes, CD69 peak median value (+104 ± 269%) occurred also 6 hours after the end of anastomosis. CD25 had its peak median value (+150 ± 773%) 12 hours after revascularization and its last measured value was elevated. The expression of CD 26 in T lymphocytes had an apparent decrease in proportional median values (-42 ± 32%) 12 hours after end of anastomosis.
Conclusions: 1) Compared to on-pump cardiopulmonary bypass, off-pump surgery does not reduce lymphocyte activation. 2) Coronary bypass surgery results in early activation of lymphocytes, with increased expression of CD69 and CD25 on T (CD3+) and B (CD19+) peripheral blood cells. The early elevation of CD69, and late elevation of CD25, may indicate two parts of a sequence of lymphocyte activation. (Supported by FAPERGS)

P2901 Complete arterial coronary revascularization avoiding median sternotomy for diabetics

V. Gulielmos[1], R. Cichon[1], U. Kappert[1], J. Schneider[1], J. Nicolai[2]. [1]Heart Center Dresden, Dept. of Thoracic and CV Surgery, Dresden, Germany; [2]Heart Center Dresden, Dept. of Anesthesiology, Dresden, Germany

Introduction: The use of both internal mammary arteries (BIMA) in coronary artery bypass grafting (CABG) is proposed for better graft patency, but is related to increased sternal wound complications. Up to now minimally invasive techniques avoiding sternotomy with BIMA grafting were hardly feasible. The introduction of a wrist-enhanced robotic system enables harvesting of BIMA without sternotomy via three one cm stab wounds. A small left lateral chest incision allows complete arterial revascularization using regular cardiopulmonary bypass.
Methods: Fifty patients (37 male, 13 female, aged 65 ± 8.5 years, LVEF 67 ± 10.7%) were treated for coronary artery disease. 72% were diabetics. Both IMAs were harvested via three ports using the da Vinci™ surgical robotic system. Access to the heart for central aortic cannulation for institution of cardiopulmonary bypass and for coronary anastomoses was achieved via a 6 to 8 cm left lateral chest incision at the level of the 2nd intercostal space.
Results: In the series one patient died due to pneumonia on postoperative day 16. Conversion rate to median sternotomy was 4%. Duration of surgery was 237.5 ± 74.5 min, ICU stay was 22 ± 19.1 hrs, ventilation time 4.3 ± 10.9 hrs, and total hospital stay 7 ± 1 days, respectively. Grafts per patient was 2.1.
Conclusion: Total arterial revascularization using BIMA grafting was applied in 72.9%. There were neither sternal instabilities nor deep wound infections.
This minimally invasive approach allows total endoscopic BIMA harvesting using three one cm ports only. Via a small left lateral chest incision the use of BIMA for CABG is possible. Risk of developing sternal wound complications in diabetics is decreased.

P2902 Coronary bypass grafting combined with mitral valve anuloplasty in severe ischaemic dilated cardiomyopathy

D. Tsialtas[1], M. Mariani[1], C. Reverberi[1], D. Albertini[1], R. bolognesi[2], C. Beghi[1], C. Manca[2], T. Gherli[1]. [1]*Università di Parma, Cattedra di Cardiochirurgia, Parma, Italy;* [2]*clinica medica generale, cardiologia, parma, Italy*

Mitral valve surgery combined with bypass grafting in patients with severe dilated ischemic cardiomyopathy (SDIC) is a timely matter. Mitral valve replacement combined with coronary bypass is still associated with high hospital or surgical mortality. Coronary bypass alone seems to be useful when mitral regurgitation is moderate; mitral valve anuloplasty in association with surgical coronary revascularization appears to be promising safe procedure for containing severe mitral insufficiency.

Thus, we have evaluated at six months the influence of surgical myocardial revascularization plus mitral valve anuloplasty on clinical and echocardiographic parameters of left ventricular function in patients with SDIC and severe mitral incompetence. Fifteen patients (group A) aged 68±4 years, with SDIC (at angiography left ventricular ejection fraction (LVEF) = 26.4±5.3%) and severe mitral regurgitation (ERO > 0.2 cm^2) were submitted to coronary bypass and mitral valve repair with Cosgrove ring; 13 patients (group B) aged 64±8 years with SDIC (at angiography LVEF = 27:8±5.3) and mild or moderate mitral incompetence served as control group. Before and six months after operation both groups underwent an echo-Doppler evaluation of left ventricular function parameters.

Operating risk (Euroscore), extracorporeal circulation time and aortic clamping time were significantly higher in group A than in group B (6.5±1.5 vs 3.3±1.6 $p < 0.001$, 144±43 vs 103±50 min $p < 0.005$ and 96±20 vs 53±23 min $p < 0.001$ respectively).

Hospital and perioperative mortality were absent, whereas at 6 months they were 6% in both groups; LVEF increased in both group A (from 31±6 to 42±7% $p < 0.001$) and group B (from 32±7 to 44±7 $p < 0.001$); end-systolic volume and wall motion score index significantly and similarly decreased in both groups (group A: from 139±60 to 121±67 ml $p < 0.05$ and from 1.9±0.4 to 1.5±0.4 $p < 0.01$; group B: from 122±48 to 96±35 ml $p < 0.05$ and from 2.2±0.3 to 1.5±0.4 $p < 0.01$, respectively). Both groups showed a significant and similar increase in peak E velocity and peak E/A velocity ratio.

It is noteworthy that patients with SDIC, who are at very high surgical risk, showed low mortality at 6 months; in addition in these patients mitral valve anuloplasty did not produce a further increase in hospital, surgical or late mortality. Finally a significant improvement of left ventricular systolic and diastolic function was observed in all patients treated with coronary bypass alone or in combination with mitral valve anuloplasty.

P2903 Up to six years performance of in vitro seeded vascular endothelial cells onto small diameter vascular grafts in coronary bypass surgery

W. Konertz[1], P.M. Dohmen[1], C.H. Koch[1], W. Rutsch[2]. [1]*Charité Hospital, Humboldt University, Cardiovascular Surgery, Berlin, Germany;* [2]*Charité Hospital, Humboldt University, Cardiology, Berlin, Germany*

Objective: Each year more than 300.000 coronary bypass operatioms are performed worldwide. As the number of patients with re-operations and insufficient bypass material is increasing, several alternatives to autologous material are under investigation. This feasibility study was performed to investigate the combination of small-diameter polytetrafluorethylene (PTFE) grafts seeded with viable autologous vascular endothelial cells (AVEC) to use in coronary bypass surgery.

Methods: Between September 1995 and December 1998 fourteen patients (median age 71 years, range 61-79 years) received 21 AVEC seeded small-diameter PTFE grafts. Forty-three percent of the performed implantations were reoperations, including one aortic valve replacement. The AVEC were harvested from a patient's forearm vein. At the cell culture laboratory, the endothelial cells were isolated, expanded and characterized until a sufficient number of cells were available. The in vitro seeded grafts were conditioned for 7 days prior to the implantation.

Results: Cumalative total data collected represents 58 patients years and was 100% completed. The seeded AVEC density was 105.000 cells/cm^2 with a cell viability of 95.5%. The patency rate at up to 73 months was 81% confirmed by angiography. Angioscopy and intravascular ultrsonography showed no atheromas or stenosis in 17 out of 21 grafts. Two asymptomatic occlusions were verified at 20 and 66 months post-operatively and two symptomatic occlusions were seen immediately after operation and at 34 months postoperative.

Conclusions: AVEC seeding seems to increase the patency rate of small caliber PTFE grafts.

P2904 Clinical evaluation of a new decellularized pulmonary homograft

M. Bechtel[1], C. Schmidtke[1], M. Mueller-Steinhardt[2], C. Bartels[1], U. Stierle[1], H.H. Sievers[1]. [1]*University of Luebeck, Cardiac Surgery, Luebeck, Germany;* [2]*Institute of Immunology, University of Luebeck, Luebeck, Germany*

Objective: Homograft valve implantation induces a potentially detrimental immunological response. Theoretically, any such response may be aborted by tissue-engineering. A novel cryopreserved decellularized homograft valve [Synergraft™] offers the unique opportunity to gain new insight into the immunology of homograft implantation and its significance for valve function.

Methods: 14 patients (10 male, 4 female; 41.5 ± 10.9 years) were operated upon. Implantation of the pulmary Synergraft (mean diameter 25.3 ± 1.3 mm) was performed as part of a Ross-procedure in 11 patients. Postoperatively, echocardiography and anti-human-leucocyte-antigen [HLA] class I antibody determination were performed 1, 3, and 6 months postoperatively. The results were compared to those in our Ross-operation database.

Results: During follow-up, no patient became positive for anti-HLA antibodies. In contrast, 73% of patients receiving conventional cryopreserved pulmonary homografts are positive for anti-HLA antibodies 6 months postoperatively.

The Synergraft showed good hemodynamic performance: the pressure gradients were low and increased only slightly and non-significantly during follow-up (Dpmean: 3.6 ± 1.6 to 5.2 ± 2.5 mmHg; p=.26). Correspondingly, the effective valve orifice area [EOA] indexed for body-surface area showed only a small, non-significant decrease (1.46 ± 0.30 to 1.30 ± 0.26 cm^2/m^2; p=.30).

Patients receiving a conventional cryopreserved homograft usually show a moderate, increase of the pressure gradients during the first 6 months postoperatively (2.8 ± 1.8 to 5.9 ± 3.1 mmHg; p=.05) corresponding to significant decreases of the EOA.

Conclusions: Implantation of a decellularized, cryopreserved pulmonary homograft appears to be associated with significantly less immunization of the recipient. The short-term hemodynamic performance of the Synergraft is promising. Due to the small patient number and the short follow-up period, it cannot be determined whether the hemodynamic performance of the Synergraft differs from that of conventional cryopreserved homografts.

P2905 Early clinical results of RVOT reconstruction with a tissue engineered pulmonary valve; report of seven consecutive patients

P.M. Dohmen[1], H. Hotz[1], A. Lembcke[2], D. Kivelitz[2], W. Konertz[1]. [1]*Charité Hospital, Humboldt University, Cardiovascular Surgery, Berlin, Germany;* [2]*Charité Hospital, Humboldt University, Radiology, Berlin, Germany*

Objective: Biological and mechanical prostheses for aortic valve replacement have important limitations due to limited durability or thromboembolism and hemorrhage. Viable pulmonary autografts showed that these disadvantages could be overcome. However, the right ventricular outflow (RVOT) tract has to be reconstructed. The aim of the study was to demonstrate for this purpose the safety and feasibility of viable tissue engineered heart valves, seeded with autologous vascular endothelial cells.

Methods: Since April 20, 2000 seven consecutive patients underwent pulmonary valve replacement with a tissue engineered pulmonary valve. A piece of vein was harvested and endothelial cells were isolated, expanded and characterized. After sufficient numbers of viable vascular endothelial cells were available pulmonary allografts were decellularized and seeded with endothelial cells in a bioreactor. Sterility of the heart valves were proved before implantation into the RVOT. Follow-up was performed by clinical evaluation, transthoracic echocardiography (TTE), magnetic resonance imaging (MRI) and multi-slice computed tomography (MS-CT).

Results: Patients age ranged from 28 - 55 years, median 46 years. All patients were male and survived the operation. Preoperative NYHA classification improved in all patients. TTE evaluation of the neo-aortic and tissue engineered heart valve are summarized in the table. MRI showed improvement of the LV-function without RV-functional changes. The leaflets of this tissue engineered valve looked smooth and pliable without functional valve regurgitation. MS-CT showed no calcification up to 1.8 years of follow-up.

	discharge (n=7)	3 months (n=7)	6 months (n=6)	1 year (n=6)
TE heart valve				
MPG (mm Hg)	1.94 ± 0.69	1.66 ± 0.59	1.52 ± 0.41	2.00 ± 0.57
flow velocity (m/s)	0.77 ± 0.16	0.71 ± 0.16	0.59 ± 0.04	0.71 ± 0.08
regurgitation (trivial)	none	one	one	one

MPG = mean pressure gradient

Conclusions: Tissue engineered heart valves seeded with autologous cells showed excellent performance during short term follow-up. As these viable heart valves showed no structural degeneration and are living structures, they might have potential for growth, repair and remodeling. Thus, they may obviate the need for reoperation.

P2906 Early mitral ring annulolasty does not alter postinfarction ventricular remodelling in chronic ischaemic mitral regurgitation

T.S. Guy, S.L. Moainie, J.H. Gorman III, R.C. Gorman. *University of Pennsylvania, Division of Cardiothoracic Surgery, Philadelphia, United States of America*

Introduction: The contribution of progressive ischemic mitral regurgitation to post-infarction left ventricular remodeling and heart failure is not well established.
Methods: Prior to producing a posterolateral infarction known to cause chronic mitral regurgitation in sheep, we performed mitral ring annuloplasty (Carpentier-Edwards PhysioTM) in one group (n=6) and compared them to a control group (n=6) with no annuloplasty. Both underwent an infarction of 24% of the LV mass localized to the posterolateral wall including the entire posterior papillary muscle. In both groups, transdiaphragmatic echocardiograms were obtained pre-infarction, 30 minutes post-infarction, and at 2, 5, and 8 weeks post-infarction to assess for MR and LV geometry and function. MR was graded on a scale of 1+ to 4+.
Results: Echocardiography confirmed that all infarcts were of similar size and location. Control group animals developed significant MR by 8 weeks. Annuloplasty group animals did not develop significant MR. The control and annuloplasty groups both experienced massive LV dilation at 8 weeks as demonstrated by large increases in end-systolic volume (ESV) and end-diastolic volume (EDV). LV ejection fraction (EF) decreased in both groups. LV end-diastolic pressure (LVEDP) rose similarly in both groups.

	Time	R (grade)	ESV (cc)	EDV (cc)	EF (%)	LVEDP (mmHg)
Control	Preinfarct	0.6 (±0.6)	37(±11)	61(±12)	38(±7)	0.9(±1.2)
	8 weeks postinfarct	3.4 (±0.5)	76 (±12)	112 (±15)	32 (±6)	5.1 (±0.9)
Ring	Preinfarct	0.6 (±0.5)	38 (±4)	69 (±12)	38 (±7)	0.4 (±0.6)
	weeks postinfarct	0.6 (±0.5)	78 (±4)	113 (±15)	25 (±4)	5 (±1)

Conclusions: In an ovine model of chronic ischemic mitral regurgitation, ventricular dilatation and dysfunction is not altered by early mitral ring annuloplasty.

P2907 Long-term follow-up 12 months after implantation of a biodegradable iron-zinc hybrid coil into the subclavian artery of New Zealand White Rabbits

M. Peuster, K. Seidler, M. Ehlerding, C. Fink, C. von Schnakenburg. *University of Goettingen, Pediatric Cardiology, Goettingen, Germany*

Objective: We conducted this study to evaluate the safety of the prototype of a biodegradable iron/zinc hybrid coil in a rabbit model. The primary objective of the study was to assess local and systemic toxicity. Secondary study objective was to analyze the primary and secondary occlusion rate of the novel coil.
Methods: 30 New Zealand White rabbits with a mean weight of 4,2 kg were sedated using midazolam and propofol. After intubation, anaesthesia was maintained with isofluorane. A femoral arterial cutdown was performed and the anatomy of the left and right subclavian artery was documented with selective angiographies. The implantation site was chosen distally to collateral vessels to prevent ischemia of the upper extremity. In 15 rabbits conventional MWCE coils (Cook, Bjaeverskov, Denmark) were implanted, 15 rabbits were received one to four hybrid iron/zinc coils. Residual patency of the vessel was documented by selective angiography. The femoral artery was ligated and the skin closed. Blood samples were drawn before and 3,6 and 12 months after the implantation. The rabbits were followed for 3 (n=9), 6 (n=9) and 12 months (n=9). Results: The primary occlusion rate was 100% for the MWCE coils, and 47% for the Fe/Zn hybrid coils. 1 rabbit in the MWCE group died due to pneumonia, 1 rabbit in the hybrid coil group died early postoperatively due to peritonitis, another rabbit of the hybrid coil group was sacrificed prematurely due to progressive palsy of the upper extremity. There was patency of the coil-laden subclavian artery at follow-up angiography in 1/ 14 rabbits of the MWCE coils and in 5/13 rabbits of the hybrid coil group. The mean serum levels for Fe were 31,39 μmol (Zn 49,18 μmol/l) prior to implantation and 31,35 μmol/l (Zn 46,20 μmol/l) at the last follow-up in the hybrid coil group. In the MWCE group the mean serum levels for Fe were 31,12 μmol (Zn 46,17 μmol/l) prior to implantation and 25,94 μmol/l (Zn 38,03 μmol/l) at the last follow-up. No local toxicity was encountered on histopathologic cutting-grinding specimens of the coiled subclavian artery. No excessive inflammatory response to the coil was observed. Examination of the heart, lung, liver, spleen, ovaries and kidneys showed no macroscopic or histopathologic signs of systemic toxicity neither in the hybrid coil nor in the MWCE group. Conclusion: Degradable Fe/Zn hybrid coils show no local or systemic toxicity 3 to 12 months after implantation into the subclavian artery of New Zealand White rabbits. Implantation of Fe/ Zn coils does not result in elevated serum iron or zinc levels.

P2908 Cryopreservation reduces antigenicity in allografts

N. Solanes, M. Rigol, J.M. Marimon, E. Khabiri, E. Agustí, M. Roqué, F. Pérez-Villa, M. Heras. *Hospital Clínic, Barcelona, Spain*

Background: There is a need for arterial grafts in coronary surgery, but donor fresh arterial grafts are useless because rejection. Cryopreservation is useful for banking purposes and may limit vascular damage. Thus, we evaluated the response of cryopreserved (Cryop) small (mean diametre = 3mm) arterial allografts (AL) after its implantation in a pig model.
Methods: Two femoral grafts were implanted. Group 1: a fresh autograft (AU) and a fresh AL (n=5). Group 2: a Cryop AU and a Cryop AL (n=5). Group 3: a fresh AL and a Cryop AL (n=5). All animals received Aspirin 500mg/day for three months and cyclosporine A (cyclo) 15-20mgr/Kg/day was given to those in group 3. Then, the animals were euthanized and the implanted grafts were harvested and fixed in formaldehyde. Cross-sections were obtained from the centre of the graft, stained with H-E and orceine for morphometric analyses and immunostained with anti-CD3 antibody to detect T lymphocytes and anti-MAC387 antibody to detect macrophages.
Results: see table. In the ocluded grafts an organized thrombus was observed in the lumen. Infiltration was observed in all AL and absent in all AU. In group 3, Cryop AL had less infiltration than the fresh AL.

	Patency	Luminal stenosis	CD3+MAC387
Fresh AU	5/5 (100%)	17±15%	-
Fresh AL	0/5 (0%)	Occluded	Occluded
Cryop AU	4/4 (100%)	35±17.6%	-
Cryop AL	2/5 (40%)	38.4±29%	+
Fresh AL (cyclo)	4/5 (80%)	22.2±13.1%	++
Cryop AL (cyclo)	5/5 (100%)	61.7±33.4%	+

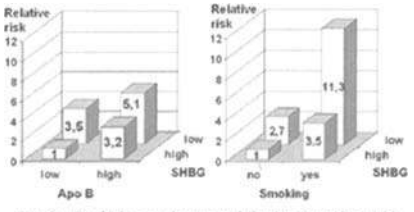
Conclusions: Cryopreservation increases vascular patency and reduces antigenicity of AL, independently of the presence of intimal hyperplasia and immunosupressive therapy.

CARDIOVASCULAR DISEASE IN WOMEN

P2909 Low serum levels of sex hormone binding globulin are associated with coronary heart disease in postmenopausal women

H. Reinecke[1], J. Bogdanski[2], A. Woltering[2], G. Assmann[3], A. von Eckardstein[3]. [1]*Universitätsklinikum Münster, Medizinische Klinik und Poliklinik C, Münster, Germany;* [2]*Münster, Germany;* [3]*Inst. f. Klinische Chemie-Zentrallabor, Universitätsklinikum Münster, Münster, Germany*

Hyperandrogenemia and low levels of sex hormone binding globulin (SHBG) are frequently found in women with metabolic syndrome which is characterized by low HDL cholesterol (C), hypertriglyceridemia, hyperinsulinemia, and obesity. The contribution of these various factors to coronary heart disease (CHD) is controversial. In a prospective study, coronary angiograms of 87 consecutive postmenopausal women were evaluated using two semiquantitative score systems to estimate the extent of focal and diffuse vessel wall alterations. Fasting sera were analysed for levels of glucose, lipids, insulin, dehydroepiandrosterone sulfate, testosterone, and sex hormone binding globulin (SHBG). Obesity was assessed by body mass index, skinfold thickness and body impedance measurement. After adjustment for age, 55 women with CHD differed significantly from 32 women without CHD by higher levels of LDL-C (159±51 vs. 132±39 mg/dl, p=0.011), apo(lipoprotein) B (121±33 vs. 102±29 mg/dl, p=0.005), triglycerides (115 vs. 91 mg/dl, p=0.02), and basal insulin (7.5 vs. 4.6 mU/l, p=0.016) as well as by lower levels of HDL-C (59.9±18.0 vs. 69.0±17.1 mg/dl, p=0.02), and SHBG (44.6 vs. 68.1 nmol/l, p=0.003). Multivariate analysis by logistic regression identified age (OR 1.22, 95% CI 1.09 to 1.37), smoking (OR 11.46, 95% CI 2.56 to 51.39), SHBG (OR 0.98, 95% CI 0.96 to 0.99), and apo B (OR 1.02, 95% CI 1.01 to 1.04) to be independently associated with the presence of CHD. The relative risk for CHD with these factors is shown in the figure, demonstrating the highest risk for smoking patients with low levels of SHBG. For the first time, low plasma levels of SHBG were found to be associated with coronary heart disease in women independently of insulin, obesity markers, and dyslipidemia.



Cutpoints for „high versus low" were defined by the medians with 47.9 nmol l for SHBG, and 112 mg dl for apo B.

Relative risk for CHD.

P2910 Prothrombotic mutations are associated with increased cardiovascular events in postmenopausal women receiving hormone replacement therapy

F. Dragoni, C. Vitale, A. Silvestri, C. Castiglioni, F. Frascà, D. Onorati, M. Fini, G.M.C. Rosano. *San Raffaele, Internal Medicine, Roma, Italy*

Recent studies have suggested that hormone replacement therapy (HRT) in postmenopausal women (PMW) may be associated with an initial increased cardiovascular risk. Recent reports suggest that the prothrombin variant 20210G to A is associated with an increased risk of events in hypertensive PMW with a previous myocardial infarction. To this end 50 PMW with documented vascular event underwent prospective evaluation of antithrombin III, protein C, free and total protein S, activated protein C resistance, fibrinogen, factor VII:C and homocysteine levels. In all the presence of antiphospholipid antibodies was investigated by kaolin clotting time (KCT), diluted Russel's viper venom time (DRVVT) and by measurement of anticardiolipin antibodies IgG and IgM (ACA-G and ACA-M). Prevalence of factor V Leiden, prothrombin variant G20210A and homozygosity for thermolabile variant C677T of the metilenetetrahydrofolate reductase (MTHFR) were evaluated and compared with those of 50 normal matched controls.

Antithrombin III and protein C were normal in all cases. One patient (2%) showed free protein S deficiency and 3 patients (6%) had activated protein C resistance. Homocysteine levels above 15 μmol/L were found in 3 patients (6%). Antiphospholipids antibodies were found in 35 patients (70%). Among women receiving HRT 87% had combined inherited and acquired prothrombotic factors (OR = 37.3, 95% CI = 8.5-564.3) while no combined prothrombotic factors were found in control PMW receiving HRT.

In conclusion vascular events in women receiving HRT are associated with a high prevalence of combined inherited and acquired prothrombotic factors. Therefore screening for prothrombotic factors may be of help in identify those women at increased risk for cardiovascular events with HRT.

P2911 Myocardial blood flow and flow reserve in response to hormone replacement therapy in postmenopausal women with risk factors for coronary disease

C. Duvernoy[1], J. Martin[1], K. Briesmiester[1], A. Bargardi[2], O. Muzik[3], L. Mosca[4]. [1]*University of Michigan, Division of Cardiology, Ann Arbor, Michigan, United States of America;* [2]*Veterans Affairs Medical Center, Cardiology Section, Ann Arbor, Michigan, United States of America;* [3]*Wayne State University PET Center, Nuclear Medicine, Detroit, Michigan, United States of America;* [4]*Columbia University, Preventive Cardiology, New York, New York, United States of America*

Estrogen restores endothelium-dependent vasodilation in response to acetylcholine in postmenopausal women, and has a direct, endothelium-independent vasodilatory effect on coronaries. Short-term cyclical hormone replacement therapy (HRT) does not affect maximal myocardial blood flow (MBF) as measured by positron emission tomography (PET). We studied the effects of combined continuous HRT on endothelium-dependent and -independent MBF and myocardial flow reserve (MFR) in postmenopausal women with risk factors for coronary heart disease (CHD).

Methods: We performed dynamic N-13 ammonia PET in 12 postmenopausal women (60±6yrs) to measure MBF and MFR in a 7-month placebo-controlled crossover trial of continuous conjugated equine estrogen (CEE, 0.625 mg/d)/cyclical micronized progesterone (MP, 200 mg/d on days 1-12). All subjects had elevated total and LDL cholesterol levels, and at least one additional CHD risk factor. All had negative dobutamine echocardiograms. MBF was measured using a 3-compartment model at rest, after sympathetic stimulation with the cold-pressor-test (CPT), and after intravenous adenosine (aden) infusion, in order to determine baseline, endothelium-dependent, and endothelium-independent flow, respectively. MFR was measured as the ratio between MBF aden to MBF rest. MBF and MBF normalized to the pressure rate product (PRP) were analyzed. Subjects took HRT and placebo for 3 months each, with a 1-month washout separating phases.

Results: There was no significant difference in overall resting MBF, CPT MBF, aden MBF, or MFR between the baseline values, placebo or HRT treatment arms. We found no significant differences in baseline risk factors, change in risk factors, or medication profile between HRT responders and nonresponders.

	MBF rest	Nrm MBF rest	MBF CPT	Nrm MBF CPT	MBF aden	MFR
Baseline	1.11±0.34	1.10±0.39	0.97±0.29	0.90±0.31	2.53±0.78	2.46±0.98
Placebo	0.85±0.21	0.92±0.25	0.98±0.26	0.97±0.27	2.19±0.75	2.71±1.28
HRT	1.022±0.28	1.14±0.25	0.99±0.36	0.93±0.27	2.34±0.62	2.51±1.10

MBF in ml/g/min; Nrm, normalized.

Conclusions: In this group of healthy postmenopausal women at risk for CHD, HRT does not exert any significant overall effect on endothelium-dependent coronary vascular reactivity or maximal MBF. HRT may not be a successful strategy to improve endothelial function in the primary prevention of coronary heart disease.

P2912 Effects of the hormone replacement therapy on arterial stiffness, blood pressure and angiotensin-converting enzyme plasma levels in postmenopausal healthy women

V. Ferrero[1], M. Feola[1], F. Ribichini[1], A. Deorsola[1], G. Ugliengo[1], E. Principe[2], P.D. Rattazzi[2], E. Uslenghi[1]. [1]*Ospedale S. Croce, Cardiology Dept., Cuneo, Italy;* [2]*Ospedale S. Croce, Ginecology, Cuneo, Italy*

In postmenopausal women the incidence of coronary events is increased. The cardioprotective effects of hormone replacement therapy (HRT), observed in primary prevention trials, may in part be due to the effects of estrogens on arterial wall stiffness. Angiotensin-I Converting Enzyme (ACE) is involved in the regulation of vascular tone. It has been suggested that the effects of ACE could be enhaned after the menopausal estrogen's drop.

Methods and Results: Between April 1999 and April 2001, 53 postmenopausal healthy women started HRT under the advice of the gynecologist. At baseline ACE plasma level, Pulse Wave Velocity (PWV) of the carotid-femoral segment and 24-hour ambulatory blood pressure monitoring (ABPM) were assessed. The same determinations were obtained after 6 months of HRT. The results obtained at baseline were: age: 53±4, range 44-61 years; basal ACE level: 28±17, range 3-74 U/L; basal PWV: 10,5±3, range 6-15; and 24-hour ABPM: mean systolic 118±7, mean diastolic 74±6 mmHg. No correlation was found between basal ACE level and basal PWV (r=0.06) or basal ABPM (systolic r=0.1, diastolic r=0.2). Arterial stiffness increased with age (r=0.1), although not significantly (p=0.3).

Six-months follow-up was obtained in 38/53 treated women. No differences were observed between the basal and the follow-up paired data as to: PWV (10,49±2 vs 10,42±2; p=0.8), mean systolic pressure (120±8 vs 121±7; p=0.9) and mean diastolic pressure (78±7 vs 76±7; p=0,7). However, HRT caused a significant reduction of the basal plasma ACE level (28,2±18 vs 19,1±16; p=0.03). To determine whether this ACE-lowering effect of HRT was conditioned by the ACE-gene insertion/deletion (I/D)polymorphism, blood samples from all subjects underwent I/D genotyping by PCR technique. The basal plasma levels of ACE were similarly reduced by HRT independently of the I/D genotypes.

Conclusion Arterial distensibility and blood pressure were not modified by the first six months of HRT, but plasma ACE levels were significantly reduced in this population of healthy women. This indirect intervention on plasma ACE level may be involved in the long-term effect of HRT.

P2913 Postprandial hyperinsulinemia and coronary artery disease among nondiabetic women with metabolic syndrome: a case-control study

M. Baltali[1], H.T. Kiziltan[2], M.E. Korkmaz[3], S. Topcu[1], B. Özin[3], H. Müderrisoglu[3]. [1]*Baskent University, CARDIOLOGY, Adana, Turkey;* [2]*Baskent University, Cardiovascular Surgery, Adana, Turkey;* [3]*Baskent University, Cardiology, Ankara, Turkey*

Metabolic syndrome is a typical basis for vascular disease in women. The association between metabolic syndrome and coronary artery disease is complex, and pathways by which the insulin resistant state adversely affects the risk for developing coronary artery disease needs to be elucidated. We planned a case-control study to assess the relation of fasting glucose, fasting insulin, postprandial glucose and postprandial insulin levels with coronary artery disease in nondiabetic women with metabolic syndrome as defined in the National Cholesterol Education Programme Adult Treatment Panel III (ATP III) guidelines.

Among 620 consecutive nondiabetic women screened, 38 with coronary artery disease and metabolic syndrome (42-77 years, mean age 60,6 ± 7) made up the study cohort (group I). Thirty eight age-matched, nondiabetic women with metabolic syndrome but without coronary artery disease (group II), and 38 healthy, age-matched women served as controls (group III, real control group). Demographics, waist circumference, lipids, fasting glucose, postprandial glucose, fasting and postprandial insulin levels were compared among the groups. No differences were identified in terms of prevalences of risk factors between group I and group II. Women with coronary artery disease had higher postprandial insulin level than the women in group II and group III. In reverse stepwise logistic regression analysis postprandial hyperinsulinemia was found to be the single independent determinant for coronary artery disease for women with metabolic syndrome (p=0.02, regression coefficient (RC) per increase by 1 μIU/ml= 1.01, 95% confidence intervall (CI) 1.002 – 1.02 for group I and group II; p<0.0001, RC per increase by 1 μIU/ml= 1.04, 95% CI 1.02-1.06 for group I and group III, respectively).

Our data demonstrate that postprandial hyperinsulinemia is independently associated with coronary artery disease, irrespective of fasting glucose, postprandial glucose, and fasting insulin levels in nondiabetic women with metabolic syndrome.

P2914 Conjugated estrogen administration improves common carotid artery elastic properties in normotensive postmenopausal women

I. Kallikazaros, C. Tsioufis, P. Zambaras, D. Tousoulis, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, State and Athens University Cardiology, Athens, Greece*

Improvement in large arteries mechanics may be one of the mechanisms by which estrogen replacement therapy may protect women against cardiovascular disease.

Methods: Towards this end, we investigate the acute effect of conjugated estrogen on the common carotid artery (CCA) elastic properties in 20 normotensive healthy postmenopausal women (age 54±3 years) at baseline and at 20 mins after the intravenous administration of 1.25 mg conjugated estrogen. CCA distensibility was derived by combination of surface ultrasonographic data and simultaneous blood pressure measurements at the brachial artery. The carotid pulsatility index, a measure of brain impedance, was determined electronically by tracing the CCA doppler waveform.

Results: At baseline, CCA distensibility had a negative correlation with both patients' age and time since menopause (r=-0.57 and r=-0.48, $p<0.05$ for both cases). After estrogen administration, estradiol and estrone plasma levels were restored to the range of usual premenopausal values. Estrogen induced a significant increase in CCA distensibility by 0.92±0.005 dyne-1 $cm^2$10-6 (from 2.03 to 2.95 dyne-1 cm^2 10^{-6}) and a significant reduction in CCA pulsatility index by 0.24±0.06(from 2.17 to 1.93)($p<0.001$ for both cases). The improvement of CCA distensibility had a negative correlation with both patients' age and time since menopause(r=-0.46 and r=-0.44, respectively, $p<0.05$ for both cases).

Conclusions: Acute conjugated estrogen administration induced an improvement in CCA elasticity and a reduction in brain impedance in normotensive postmenopausal women. As the womens' age and the time since menopause increased, the improvement in carotid distensibility decreased in such selected subjects.

P2915 The effects of raloxifene and simvastatin on plasma lipids and endothelium

E. Sbarouni, P. Flevari, C. Kroupis, Z.S. Kyriakides, A. Koniavitou, D.T.H. Kremastinos. *Onassis Cardiac Surgery Center, B' Cardiology, Athens, Greece*

Raloxifene is a selective estrogen receptor modulator and an attractive alternative to estrogen replacement as it obviates the need for a progestin and does not increase C-reactive protein levels. Statin therapy is the gold standard in the management of hypercholesterolemia.

Methods: We treated 12 postmenopausal women with hypercholesterolemia and coronary artery disease with raloxifene 60 mg/day and simvastatin 20 mg/day in a randomized, double-blind, crossover study. Plasma lipids and cellular adhesion molecules were evaluated and peripheral blood flow studies with venous occlusion plethysmography were performed.

Results: Both simvastatin and raloxifene significantly reduced total and LDL cholesterol compared to baseline values ($p<0.05$) but simvastatin was more effective than raloxifene ($p<0.005$). None of the treatments had any significant effect on HDL cholesterol and triglyceride levels. Only raloxifene significantly reduced Lp(a) and ICAM-1 and VCAM-1 plasma levels compared to baseline (p=0.019, $p<0.0001$ and p=0.003, respectively). Hyperemic blood flow response on raloxifene was significantly higher compared to baseline ($p<0.05$), whereas no significant change was noted on simvastatin. Endothelium independent blood flow induced by nitroglycerine was not influenced by either active treatment.

	Baseline	Simvastatin	Raloxifene
TC (mg/dl)	267±14	176±10*#	231±12*
LDL (mg/dl)	188±12	102±6*#	153±12*
Lp(a)(mg/dl)	35±32	35±10	26±8*
ICAM-1(pg/ml)	175±10	177±11	146±9*
VCAM-1(pg/ml)	553±53	543±72	410±33*

mean±SE, *$p<0.05$ vs baseline, #$p<0.005$ vs raloxifene

Conclusion: Raloxifene administration is associated with lower ICAM-1 and VCAM-1 plasma levels as well as lower Lp(a) levels compared to simvastatin although the latter is more powerful in total and LDL cholesterol reduction. In addition, raloxifene enhances endothelium dependent dilation in the forearm circulation whereas simvastatin does not. Whether these favourable effects of raloxifene on intermediate biologic variables translate into improved clinical outcome, will only be determined when long-term studies are completed.

P2916 Differential effects of gender on large artery elasticity. A study in male to female transsexuals

C. Tsioufis, K. Tzioumis, P. Papageorgaki, M. Toutouza, M. Vitalis, C. Stefanadis, I. Kallikazaros, P. Toutouzas. *Hippokration, University of Athens, Department of Cardiology, Melissia, Greece*

Large artery stiffness has been recognized as an independent predictor for cardiovascular events. However, there are not enough data regarding the mechanical behavior of large arteries in relation to gender and particularly to male to female transsexuals.

Methods: Towards this end, we evaluated aortic and carotid elastic properties in 13 male to female transsexuals (age 44±9 years, 18±11 years after surgery) and we compared these findings with those observed in age-matched 10 premenopausal women and 10 men. Aortic and common carotid artery function indices were derived by combination of surface ultrasonographic data and simultaneous blood pressure measurements at the brachial arm. All included subjects had a negative glucose intolerance test.

Results: The three groups of men, women and male to female transsexuals were matched for age (44 vs 42 vs 43 years, respectively) body mass index (25 vs 23 vs 24 Kgr/m^2, respectively), smoking status (current smokers 45% vs 42% vs 48%, respectively), total cholesterol plasma levels (232 vs 229 vs 218 mg/dl, respectively) and office blood pressure (115/75 vs 110/75 vs 115/73 mmHg, respectively)(p=NS for all the above cases). Also, these three groups did not differ regarding the left ventricular echocardiographic data of left ventricular mass (171 vs 142 vs 158 gr, respectively), and relative wall thickness (0.41 vs 0.42 vs 0.41, respectively)(p=NS for all measurements). In contrast, both the aortic and common carotid artery distensibility were significantly lower in men compared to transsexuals (1.6 vs 2.2 dyne-1 $cm^2$10-6 and 1.1 vs 1.8 dyne-1 $cm^2$10-6, respectively, $p<0.001$ for both comparisons) while the aortic and carotid distensibility did not differ between transsexuals and women (2.2 vs 2.3 dyne-1 $cm^2$10-6 and 1.8 vs 1.9 dyne-1 $cm^2$10-6, respectively, p=NS for both comparisons)

Conclusion: These results suggest that vascular adaptations in male to female transsexuals are more closely related to those observed in premenopausal women than to those in age-matched men.

P2917 Ovariectomy changes cardiac and circulating IGF-I in hypertensive Dahl rats

M. Brink[1], J. Chrast[1], B. Mottironi[1], M. Beutler[2], F. Tosi[2], F. Eberli[2]. [1]*Medical Research Foundation, Division of Cardiology, Geneva, Switzerland;* [2]*University Hospital, Swiss Cardiovascular Center Bern, Bern, Switzerland*

Background: Multiple epidemiological studies show that heart disease is more prevalent in men than in age-matched women, and experimental studies support that 17b-estradiol (E2) has multiple effects on the cardiovascular system. However, the specific molecular mechanisms that protect women from heart disease are still poorly understood. In this study we analyzed the role of E2 in the development of cardiac hypertrophy in a rat model of hypertension. E2 modulates insulin-like growth factor-I (IGF-I) activity in various cell types, but nothing is known about its effects on the IGF-I system in cardiac cells. As IGF-I is one of the key factors determining cardiac mass, we analyzed changes in IGF-I and IGF-I receptor (R) mRNA in response to ovariectomy in normotensive and hypertensive Dahl rats.

Methods and Results: Nine week old Dahl salt-sensitive (S) and salt-resistant (R) rats were fed a high salt diet (8% NaCl). After four weeks, systolic blood pressure was increased significantly in male and female Dahl S but not in Dahl R rats (127 vs. 190 mm Hg, $P<0.001$). Male rats had higher circulating and left ventricular IGF-I levels than age-matched female rats ($P<0.01$). Hypertensive Dahl S rats have higher cardiac mass and higher cardiac IGF-I mRNA ($P<0.05$ for both), but no difference in circulating IGF-I compared to normotensive SR Dahl rats. Interestingly, ovariectomy abolished the hypertension-induced increase in cardiac IGF-I in females, and at the same time caused a significant increase in circulating IGF-I.

IGF-I in Dahl S and R after ovariectomy

	fem.		ov. fem.		male	
	R	S	R	S	R	S
LV IGF-I	2.9±0.3	5.5±0.8	3.4±0.3	3.6±0.1	8.4±1.0	14.7±3.0
LV IGF-IR	3.4±0.5	3.9±0.2	4.5±0.2	4.2±0.3	3.8±0.2	5.1±0.2
plasma IGF-I	674±22	672±28	978±12	1443±120	853±9	884±23

LV=left ventricle, IGF-IR= IGF-I receptor, ov.=ovariectomy, fem.=female, S=salt sensitive, R=salt resistant

Conclusions: The expression of IGF-I and IGF-IR differs between male and female. E2 modulates levels of cardiac and circulating IGF-I. These effects may contribute to gender-specific mechanisms of hypertrophy, leading to differences in cardiac remodeling.

P2918 Increased CRP levels in women at increased cardiovascular risk predict one year events only when associated with increased interleukin-6 levels

A. Silvestri, C. Vitale, F. Frascà, P. Galetta, C. Castiglioni, D. Onorati, M. Fini, G.M.C. Rosano. *San Raffaele, Internal Medicine, Roma, Italy*

Elevated CRP levels suggestive of heightened inflammatory state in vascular conditions are often associated with elevated Interleukin-6 (IL-6) levels. It has been suggested that CRP and IL-6 may be a predictors of unfavorable outcome in postmenopausal women (PMW) receiving hormone replacement therapy. Because of the possible metabolic effect of HRT on CRP the relative predictive importance of CRP and IL-6 levels in PMW receiving HRT remains to be elucidated. To this end we evaluated CRP and IL-6 levels before and after initiation of HRT and one year follow up in 346 consecutive PMW (mean age 66±9 years) with cardiovascular risk >20 in 10 years receiving HRT for at least one year.

Overall HRT increased CRP levels by 76% while decreased IL-6 levels by 8%. During 1 year follow up 1 patient died (non cardiac), and 4 had a major cardiovascular event.

PMW with events had elevated CRP levels compared with baseline but within the mean±1SD compared to levels obtained in all women after initiation of HRT. IL-6 levels in PMW with events were significantly higher in PMW with events than in those without events. IL-6 were predictor of future events while elevated CRP levels were associated with an unfavorable outcome only when IL-6 levels were also elevated. In a stepwise multivariate analysis IL-6 levels were a stronger predictor of outcome than CRP. CRP levels were predictors of future events only after removal of IL-6 levels and presence of cardiovascular symptoms from the analysis.

In conclusion CRP levels are increased in PMW receiving HRT. Elevated IL-6 levels may identify those PMW at increased one year risk. CRP levels predict events only when they are coupled with IL-6 levels.

P2919 Does menopausal status alter coronary flow velocity reserve in women with Syndrome X?

H. Muderrisoglu, A. Yildirir, D. Aslan-Tok, M. Ulucam, M.E. Korkmaz, B. Ozin, E. Tayfun, V. Simsek. *Ankara, Turkey*

Aim: Syndrome X term is used to describe the patients with typical anginal chest pain, ischaemic exercise tests but normal coronary angiograms. Microvascular dysfunction, measured by reduction in coronary flow velocity reserve (CFR), was speculated to be the major underlying cause. Sex predilection for women, especially around perimenopausal ages, suggests an association between hormonal status and Syndrome X. The aim of this study was to investigate effects of menopause on CFR in women with Syndrome X.

Methods: Women older than 40 years of age with anginal symptoms and positive exercise test results were evaluated with coronary angiographic examination and those with normal coronary angiograms were included in the study. After measuring baseline flow velocity with Doppler flow wire maximum hyperemia was induced by 12-18microgr intracoronary adenosine to determine CFR, defined as the ratio between hyperemic flow velocity/baseline flow velocity in all three epicardial coronary vessels. Women with uncontrolled hypertension, rest angina, hepatic/renal insufficiency, rhythm other than sinus or those using hormone replacement therapy were excluded. The lower limit of normal for CFR was accepted as 2.5.

Results: Thirty-one women with a mean age of 51.6±8.3 years were evaluated for the measurements of CFR. The incidences of CFR<2.5 were 50% for left anterior descending (LAD), 69% for circumflex (Cx) and 37% for right coronary artery (RCA) groups. The study population was subdivided into two depending on the menopausal status. Body mass index, cardiovascular risk profile and exercise capacity characteristics of postmenopausal (n=19) and premenopausal (n=12) women were similar (p>0.05). Postmenopausal women had a significantly higher incidence of angina during exercise tests compared to premenopausal women (74% vs 25%) (p=0.01). The CFR values for LAD and Cx arteries were similar in pre-and postmenopausal groups (2.8±0.6 vs 2.2±1.0, p=0.06 for LAD; 2.2±0.6 vs 2.2±0.9, p=0.5 for Cx), whereas CFR values of the RCA were significantly reduced after menopause (3.2±0.9 vs 2.3±0.5, p=0.001).

Conclusion: Women with syndrome X have an increased incidence of low CFR values, which are more pronounced after menopause, suggesting a role for low estrogen levels in the pathogenesis of this syndrome. This reduction in CFR might have a predilection for the RCA vasculature, the clinical significance of which needs to be clarified.

P2920 Effects of combined hormone replacement therapy on various sensitive systemic markers of inflammation in healthy postmenopausal women

B. Guzic Salobir[1], I. Keber[1], L. Vrabic[2], W. Koenig[3]. [1]*University Clinical Centre Ljubljana, Dpt. of Angiology, Slovenia, Slovenia;* [2]*Novo Nordisk A/S, Ljubljana, Slovenia;* [3]*University of Ulm Medical Centre, Dpt. of Internal Medicine II-Cardiolog, Ulm, Germany*

Atherosclerosis is a chronic inflammatory disease. Several large epidemiological studies suggest a cardioprotective effect of hormone replacement therapy (HRT) in postmenopausal women which might be attributed to a decrease of blood lipids, and improvement of endothelial function, the hemostatic balance and oxidant state. HRT might influence the inflammatory response also. Various trials have shown an increase in C- reactive protein (CRP) serum concentrations and no significant change or even a decrease in fibrinogen concentrations after HRT. The effects of HRT on cytokines and serum amyloid A (SAA) concentration are less well defined.

The aim of the present randomized, placebo-controlled study was to investigate the effects of continuous, combined hormone replacement therapy (HRT) on various markers of inflammation in healthy postmenopausal women.

Sixty-one healthy postmenopausal women (mean age 55.2 ± 8.8 years, duration of menopause 5.8 ± 5.5 years) were randomized to receive a combination of estradiol (2 mg) and norethisterone acetate (1 mg per day) (n=31) or placebo (n=30). Concentrations of high sensitivity CRP, SAA, fibrinogen, interleukin-6 and tumor necrosis factor-alpha (TNF-alpha) were determined before, after 3 and after 6 months of treatment with HRT.

We found a significant increase in concentration of CRP after HRT (median and interquartile range at baseline: 1.12 (0.81-2.06) mg/L; after 3 months 2.64 (1.12-5.06) mg/L and after 6 months 1.95 mg/L (1.34-3.38), all p<0.01 in comparison with baseline). There were no significant changes in the placebo group (1.41 (0.55-2.98) mg/L at baseline, 1.25 (0.66-3.46) mg/L after 3 months and 1.46 (0.54-3.09) mg/L after 6 months). No significant differences were observed for SAA, fibrinogen, interleukin-6 and TNF- alpha between the two groups during the study period.

In conclusion, 6 months of treatment with continuous, combined estradiol and norethisterone acetate increased CRP concentration without significant changes in SAA, fibrinogen, IL-6 and TNF-alpha concentrations in healthy, postmenopausal women. Further studies are needed to explore the clinical relevance of these observations.

P2921 No association between sex hormone levels and coronary artery disease (CAD) in postmenopausal women

B. Klein[1], B R. Winkelmann[1], R. Gök[1], R. Winkler[1], J. Friedrich[1], W. März[2], J. Senges[1], G. Taubert[1]. [1]*Herzzentrum Ludwigshafen, Cardiology Dpt., Ludwigshafen, Germany;* [2]*Universitätsklinikum Freiburg, Klinische Chemie, Freiburg, Germany*

Background: Sex hormones are discussed to influence cardiovascular disease. The aim of the study was to investigate sex hormones in postmenopausal women with angiographically documented CAD.

Methods: 580 postmenopausal women (age > 55 years, FSH > 30 IU/l) scheduled for coronary angiography for clinical reasons were enrolled in LURIC, a prospective cohort study to assess classic and new risk factors for CAD. A detailed history was taken and fasting blood for hormones was obtained. Sex hormones and baseline characteristics were studied for a control group (no stenoses), patients with moderate CAD (stenoses 10-50%) and patients with stenoses > 50%. Women on hormone replacement therapy and digitalis therapy were excluded.

Results: see table.

Postmenopausal women	No CAD, n=132	CAD 10-50% stenoses, n=115	CAD > 50% stenoses, n=333
age (years)	65 ± 6	68 ± 6	70 ± 7*
smoking	21%	22%	37%*
arterial hypertension	58%	74%	74%*
diabetes	19%	29%	41%*
hypercholesterolemia	48%	63%	77%*
LH (IU/l)	30 ± 13	30 ± 13	28 ± 14
FSH (IU/l)	53 ± 23	55 ± 21	49 ± 22*
17-beta-estradiol (ng/ml)	33 ± 35	30 ± 28	32 ± 25
testosterone (µg/l)	0.9 ± 0.9	0.9 ± 1.2	0.8 ± 0.5

* p < 0.005

Conclusion: In postmenopausal women there is no association between sex hormone levels and coronary artery disease. However, the classic risk factors age, smoking, arterial hypertension, diabetes mellitus and hypercholesterolemia are closely associated with presence and extension of CAD.

LIPIDS (EPIDEMIOLOGY)

P2922 Plasma coenzyme Q10 (CoQ10) concentrations in patients with coronary atherosclerosis

A. Sagcan[1], E. Kýlýnc[2], D. Kayapinar[3], H. Kultursay[1], A. Yalcin[3]. [1]*Atakalp Heart Hospital, Cardiology, Izmir;* [2]*Dept. of Analytical Chemistry, Izmir* [3]*Dept. of Biochemistry, Ege University, Fac. of Pharmacy, Izmir, Turkey*

Background: CoQ10 (Ubiquinone) is a fat-soluble vitamin-like substance present in every cell of the body and serves as a coenzyme for several of the key enzymatic steps in the production of energy within the cell. CoQ10 is an important mitochondrial electron transfer component and has been postulated to function as a powerful antioxidant protecting LDL from oxidative damage. CoQ10 as an endogenous antioxidant, packaged into the LDL+VLDL fractions of cholesterol, has been suggested as an important anti-risk factor for the development of atherosclerosis as explained by the oxidative theory. Hence, beneficial effects of supplementation with CoQ have been reported.
Aim: The purpose of this study was to assess which ratio is useful for the risk of atherogenesis in both males and females.
Methods: We performed a case-control study among 30 male and female patients (mean age:55±9) with angiographically documented coronary atherosclerosis (stable or un-stable angina pectoris) and 19 controls (mean age:53±10) free from symptomatic cardiovascular disease and atherosclerotic plaques. Subjects using HMG-CoA reductase inhibitors were excluded from the study. CoQ10 was extracted from plasma by using hexane/methanol and determined by electrochemical method of HPLC.
Plasma CoQ10 concentrations were significantly lower in patients with CAD than in controls. Also, the LDL/CoQ10 ratio was higher in patients with CAD than control. Results are shown on table.

CoQ10 levels and LDL/CoQ10 ratio

	Patients	Control	p
CoQ10 (micromol/L)	0.82±0.43	2.55±1.49	0.003
LDL/CoQ10 (micromol/ml)	169	55.6	0.001

CoQ10: coenzyme Q10, LDL: low density lipoprotein cholesterol.

The positive, significant correlations were found between the total cholesterol/CoQ10 ratio and the HDL/CoQ10 ratio (p=0.02, P=0.342, respectively). The negative correlation was determined between the patients and the controls for total lipids/CoQ10 ratio, the LDL/CoQ10 ratio and the (total cholesterol-LDL)/HDL ratio (p=-0.31, p=-0.12, P=-0.46, respectively).
Conclusion: We concluded that the lower plasma CoQ concentration and the proportion of CoQ10 in lipids available is related to risk of atherosclerosis.

P2923 PPARalpha regulates the secretion and size of VLDL by decreasing the post -ER pre-secretory proteolysis of apoB-100

D. Lindén, K. Lindberg, J. Oscarsson, L. Li, L. Asp, J. Borén, O. Wiklund, S.-O. Olofsson. *Sahlgrenska University Hospital, Wallenberg Laboratory, Göteborg, Sweden*

The atherogenicity of LDL is determined during the assembly of its pre-cursor VLDL. While large VLDL give rise to small atherogenic LDL with long half life, small VLDL results in less atherogenic LDL with shorter half life. The peroxisome proliferator activated receptor alpha (PPARalpha) has a central role in the lipid metabolism. We have therefore investigate the role of PPARalpha in the assembly and secretion of apoB containing lipoproteins. The PPARalpha agonist WY 14,643 induced an increase in the secretion of apoB-100 but not of apoB-48 in primary rat hepatocytes. The agonist also induced a substantial decrease in the rate of triglyceride biosynthesis and secretion, and a shift from large VLDL to more dens particles banding in the LDL/IDL density range. ApoB-48 VLDL disappeared and was replaced by the "HDL like particle". The PPARalpha agonist increased the co-translational (proteasomal) degradation of both apoB-100 and apoB-48, most likely by lowering the triglyceride biosynthesis. However the agonist decreased the post-ER pre-secretory proteolysis (PERPP) of apoB-100 but not of apoB-48. These results indicate that the increased secretion of apoB-100 was due to a decreased PERPP of the protein. Moreover they demonstrate that PERPP of apoB-100 is actively regulated and not only reflecting the rate of triglyceride biosynthesis. Finally the results imply that apoB-100 and apoB-48 follows different routs during the assembly of VLDL. PPARalpha agonists increased the expression and biosynthesis of liver fatty acid binding protein (LFABP). Transfection of LFABP to McARH7777 cells gave rise to an increased secretion of apoB-100 and apoB-48 and a decrease in the triglyceride biosynthesis and secretion; however the apoB containing lipoproteins remained in the VLDL density range. The increase in the LFABP also gave rise to an increase in mRNA for PPARalpha. This may suggest a mechanism by which in which LFABP and PPARalpha interact to amplify the effect of the PPARalpha agonists on the assembly of VLDL. The proposed mechanism is involved in the regulation of the size of VLDL and could explain the beneficial effects of the lipid lowering fibrates.

P2924 Lipoprotein (a) in coronary atherosclerosis: the impact of age, diabetes and smoking

C. Saely[1], S. Aczel[1], P. Langer[1], T. Marte[1], H. Drexel[2]. [1]*VIVIT-Institute, Feldkirch, Austria;* [2]*LKH-Feldkirch, Innere Medizin, Feldkirch, Austria*

Background: Lipoprotein(a) (Lp(a)) is a risk factor for coronary atherosclerosis (CA). Recently, the interactions of Lp(a) with other risk factors and its role in the elderly have attracted much interest. **Methods:** We investigated 535 consecutive patients undergoing coronary angiography. Significant CA was defined as the presence of stenoses of at least 50%. Lp(a) was measured by immunoturbidimetry from fresh serum samples. **Results:** The prevalence (prev.) of significant CA in different risk factor strata is presented in the table. Lp(a) was higher in patients with (n=314) than without (n=221) significant CA (17 vs. 12 mg/dl; p=0.003), and independently predictive of significant CA (controlled for age, gender, hypertension, smoking, triglycerides, HDL-C, LDL-C, and glucose) in multiple logistic regression analysis. Moreover, Lp(a) was lower in patients with (n=123) than without (n=358) diabetes (10 vs. 16 mg/dl; p=0.026), and in patients with (n=316) than without (n=219) a history of smoking (13 vs. 20 mg/dl; p=0.041). Among patients younger than 65 years (n=293) Lp(a) was also an independent predictor for significant CA. Among patients aged 65 years or older (n=242), Lp(a) was not significantly higher in patients with than in those without significant CA (n=147 and n=95; 19 vs. 14 mg/dl; p=0.220).

		Lp(a)	n	prev.			Lp(a)	n	prev.
Diabetes	no	=<30	221	50.2	Smoking	no	=<30	138	52.2
		>30	119	65.5*			>30	81	51.9
	yes	=<30	91	61.5		yes	=<30	219	55.3
		>30	32	71.9*			>30	97	81.4*

*statistically significant versus lowest risk factor stratum; Lp(a) in mg/dl; prevalence (prev.) in %

Conclusions: 1) Lp(a) is elevated in patients with significant CA, but this does not hold true for patients aged 65 years or older. 2) The prevalence of significant CA is highest among patients with both, the conventional risk factors smoking or diabetes and elevated Lp(a) levels. 3) Lp(a) is lower in coronary patients with diabetes or a history of smoking.

P2925 Elevated soluble tumor necrosis factor receptor levels in healthy non-obese adults with the atherogenic dyslipoproteinemia

R.S. rosenson[1], C. Tangney[2], T. Parker[3], D. Levine[3], B. Gordon[3]. [1]*Northwestern University Medical School, Preventive Cardiology Center, Chicago;* [2]*Rush University, Department of Clinical Nutrition, Chicago;* [3]*Rogosin Institute, New York, United States of America*

Background: Tumor necrosis factor a (TNF-a) expression in human adipocytes and skeletal myocytes correlates with body mass index (BMI), hyperinsulinemia and reduced lipoprotein lipase activity. TNF receptors mediate the cellular actions of TNF-a. In human adipocytes, TNFR2 is the dominant receptor involved in inhibition of insulin signaling. We examine the relationships of select inflammatory mediators in the atherogenic dyslipoproteinemia (ADL) and the effects of statin therapy on select inflammatory mediators. **Methods:** 60 non-smoking, non-obese (BMI <30 kg/m^2), normoglycemic (HbA1c <8%) subjects participating in a randomized 8 week trial comparing pravastatin 40 mg, simvastatin 20 mg, simvastatin 80 mg or placebo. Soluble TNFR1, TNFR2, IL-6 and TNF-a were measured by electroimmunoassay and hs-CRP by immunoturbidimetry. ADL (TG >1.69 mmol/L, HDL-C <1.04 mmol/L in men and <1.30 mmol/L in women, and/or small LDL (< 20.6 nm) was present in 42 subjects. **Results:** ADL subjects were younger (mean±SD; 49±8 vs 54±7 y, p=0.019) and had higher levels of both TNF-a (7.9±18.1 vs 2.1±0.5 pg/mL, p=0.013) and sTNFR2 (3.0±0.6 vs 2.7±0.5 pg/L, p=0.099) compared to the 18 non-ADL subjects. Age and gender predicted ADL (p=0.0436). After adjustment for age and gender, TNF-a, sTNFR1 and sTNFR2 best predicted ADL (Table). There were non-significant age and gender adjusted associations between ADL and IL-6 (p=0.056) and hs-CRP (p=0.093). Statin therapy reduced TNF-a levels more in ADL subjects (7.9±18.1 to 6.2±11.9 pg/mL, p=0.088) than in non-ADL subjects (2.1±0.5 pg/mL to 2.4±0.2 pg/mL, p=0.55), whereas there were no changes in sTNFR1 (p=0.82) or sTNFR2 (p=0.79) in ADL subjects.

Logistic Regression Models with ADL as Outcome	Overall Classification Accuracy (%)	Overall P-value for Model
+ BMI	65.0	0.0842
+ sTNFRS1B	70.0	0.0024
+ sTNFRS1A	61.7	0.0504
+ TNF-a	66.7	0.0471
+ sTNFRS1A + sTNFRS1B + TNF-a + IL-6 + hs-CRP	66.7	0.0372

Age and gender adjusted values.

Conclusions: High TNF-a, sTNFR1 and sTNFR2 levels are markers of the proinflammatory state in ADL. Prospective studies are needed to determine whether elevations in TNF-a, sTNFR1 and sTNFR2 contribute to the development of type 2 diabetes in ADL subjects.

P2926 Dyslipidemia in HIV-infected patients – A new population in coronary risk?

N. Bettencourt[1], P. Mateus[2], C. Dias[2], M. Mota[3], L. Simões[2], R. Vieira[3], V. Gama[2], A. Branco[3]. *[1]CHVNGaia, Cardiologia, Porto, Portugal; [2]CHVNGaia, Cardiologia, Vila Nova de Gaia, Portugal; [3]CHVNGaia, Medicina Interna, Vila Nova de Gaia, Portugal*

Introduction: Recent findings suggest that Highly Active Antiretroviral Therapy (HAART) used in HIV-infected patients may cause dyslipidemia (hypercholesterolemia and hypertriglyceridemia) in previous normolipidic patients or aggravate pre-existing hyperlipidemia. Therefore this therapy may contribute to increase the atherogenic potential of these patients and to a possible premature development of coronary disease in this population.
Objective: To compare the lipoprotein profile and the prevalence of hyperlipidemia in the HIV-infected population currently followed in our department of infectious disease (DID) against the same data in the population followed in DID before the introduction of HAART with Protease Inhibitors (PI) in the treatment of this disease.
Population and Methods: The HAART with PI began, in our hospital, after January of 1997.
We studied - as pre-HAART population (A) - every patient followed in DID in 1996 (n=81), mean age 33 years (range 19-56), 58 males. As post-HAART population (B) - were studied the patients being followed in DID by September of 2001 (n=425), mean age 35 years (range 20-77), 343 males.
We compared the mean values of total cholesterol and triglycerides of both populations and evaluated the prevalence of hypercholesterolemia and hypertriglyceridemia.
Results: The mean cholesterol level in the pre-HAART population (A) was 155,2 mg/dl and 182,5 mg/dl in B. The mean triglyceridemia was 151,9 mg/dl in A and 144,2 mg/dl in B. The prevalence of hypercholesterolemia, defined as cholesterolemia > 200 mg/dl was 18,3% (n=15) in A and 31,1% (n=132) in B (p=0,019). The prevalence of hypertriglyceridemia defined as triglyceridemia > 200 mg/dl was 22,2% (n=18) in A and 13,6% (n=58) in B (p=0,048).
Conclusions: Despite the sample limitations, a tendency to a change in the lipoprotein profile of the HIV-infected population is found. Besides the trend towards a decrease of the mean values of triglyceridemia - possibly justified by a better control of the virus (which has hypertriglyceridemic effect) - there is a clear raise of hypercholesterolemia after half-decade of HAART. As a possible consequence, we may expect a future increase of coronary disease incidence in these patients.

P2927 Association of risk factors of coronary artery disease and clot strength

R. Artang[1], E. Jensen[2], F. Petersen[3], N.J. Frandsen[4], J.D. Nielsen[5]. *[1]Coagulation Laboratory, Hellerup, Denmark; [2]Hilleroed Hospital, Clinical Chemistry, Hilleroed, Denmark; [3]Hilleroed Hospital, Internal Medicine B, Hilleroed, Denmark; [4]Gentofte University Hospital, Cardiology, Hellerup, Denmark; [5]Coagulation Laboratory, Hellerup, Denmark*

Purpose: The clot strength (the elastic shear modulus of clotting blood) is increased in patients with coronary artery disease. Elevated plasma levels of fibrinogen, C-reactive protein (CRP), homocysteine and cholesterol are also associated with increased risk of coronary artery disease. The aim of our study was to investigate the association of plasma concentrations of these risk markers with clot strength.
Methods: After obtaining informed consent, 81 subjects were included: 20 healthy volunteers, 23 with stable angina, 19 with unstable angina (UA) and 19 with myocardial infarction (MI). Upon admission, blood was drawn from the UA and MI patients before any antithrombotic treatment. Clot strength in dyne/cm^2 was measured on citrated whole blood by thrombelastography. Plasma concentrations of fibrinogen, CRP, homocysteine and total cholesterol were correlated to clot strength using Spearman's correlation coefficient.
Results: A highly significant correlation was observed between fibrinogen concentration and clot strength ($r = 0.82$, $p < 0.0001$). Clot strength was also logarithmically associated with the CRP level ($r = 0.54$, $p < 0.0001$). There was no correlation between cholesterol level and clot strength ($r = -0.12$, p ns), or homocysteine level and clot strength ($r = 0.1$, p ns).
Conclusion: Clot strength is directly correlated to the level of plasma fibrinogen, the structural component of the blood clot. The association between clot strength and CRP level follows a logarithmic pattern. The clinical application of the latter finding requires further investigation. Increased plasma levels of homocysteine and total cholesterol have no direct effect on clot strength.

P2928 Risk of coronary artery disease associated with thrombin activable fibrinolysis inhibitor (TAFI) levels

A. santamaria[1], A. Martinez[2], A. Oliver[3], I. Tirado[1], M. Borrell[1], J. Mateo[1], J.C. Souto[1], J. Fontcuberta[1]. *[1]hospital de Sant Pau, Hematology, barcelona, Spain; [2]Hospital de Sant Pau, Cardiology, Barcelona, Spain; [3]Fundación Puigvert, Hematology, Barcelona, Spain*

Introduction: Thrombin activable fibrinolysis inhibitor (TAFI) is a recently described component that potently inhibits t-PA-induced fibrinolysis. High TAFI levels may lead to an hipofibrinolytic state contributive to an increased risk of arterial thrombotic disease. To our knowledge,there is no available information about TAFI functional levels in coronary artery disease (CAD).
Aim of the study was to analyze the risk of arterial thrombosis related to TAFI.
Material and methods: TAFI antigenic (Ag) and functional (Fn) levels in plasma of 104 CAD patients were compared to those of 150 control subjects. The Ag levels were determined by an ELISA method (Hyphen, Andrésy France) whereas Fn was measured by Mosnier methodology. Thrombotic risk was calculated by logistic regression (odds ratio and confidence interval 95% CI). Cut-off points were calculated by ROC. Results are expressed as mean ± SD.
Results: All conventional cardiovascular risk factors (age, hypertension, smoking, familial history of CAD, obesity, diabetes mellitus) as well as Factor VIIIc and fibrinogen were significantly more prevalent in CAD than in controls, but heterozigous for the PT20210A and Factor V mutations were not. Furthermore, no differences in TAFI Ag levels were found between CAD patients (107%±28) and controls (106%±31). However, TAFI Fn was increased ($p<.001$) in CAD patients (116.2%±24.3) compared to controls (101%±19). To calculate the risk we compared patients with TAFIf levels higher than 120% (n=39)vs controls (n=14). Unadjusted OR was 5,8(95%CI 3-11,5)for patients with CAD compared with controls. Adjusted OR by age, sex, smoking,diabetes,hypertension, family history of arterial disease, fibrinogen, factor VIIIc and atrial fibrilation (AF), AAF, FVL and PT20210A did not change, and showed an increased risk of 5,6 (95%CI2-16,2)for CAD patients compared with controls.
Conclusions: Elevated TAFI Fn levels are associated with a higher risk of CAD. Therefore, inhibition of t-PA-induced fibrinolysis may play an important role in pathogenesis of CAD and also may have important therapeutical implications. Determination of TAFI Fn levels is, nowadays, more specific than antigenic.

P2929 Atrial fibrillation is independently associated with raised plasma von Willebrand factor in women but not men: results from the Rotterdam study

D.S.G. Conway[1], J. Heeringa[2], B.S.P. Chin[1], D.A.M. van der Kuip[2], J.C.M. Witteman[2], A. Hofman[2], G.Y.H. Lip[1]. *[1]City Hospital Birmingham, University Department of Medicine, Birmingham, United Kingdom; [2]Erasmus Medical Center, Dept of Epidemiology and Biostatistics, Rotterdam, Netherlands*

Introduction: Atrial fibrillation (AF) is associated with increased risk of stroke. Elevated prothrombotic plasma markers have been demonstrated in AF, but may be due to additional underlying cardiovascular disease, rather than AF itself. We sought to confirm the presence of independent associations between AF and three prothrombotic markers in a large, community-based study of an elderly population.
Methods: We measured plasma von Willebrand factor (vWf, a marker of endothelial damage/dysfunction), fibrinogen and soluble P-selectin (sP-sel, a marker of platelet activation) in 162 patients with AF and 324 age and sex matched paired controls participating in the Rotterdam Study.
Results: Amongst the group as a whole (51%male; mean age 77,sd8), there were no significant differences in plasma fibrinogen (p=0.8), sP-sel (p=0.6) or vWf (p=0.08) between cases and controls. However, AF was significantly associated with increased vWf amongst women (146 vs. 136iU/dl,p=0.02), but not men (142 vs. 141iU/dl,p=0.8). After adjusting for potential confounding factors using conditional logistic regression analysis, a significant independent relationship remained between vWf and AF in women (OR=1.19, 95%CI 1.02-1.40, table), with a fivefold increase in risk of AF in the upper quartile of vWf compared to the lower quartile (OR=5.0,95%CI 1.34-18.7).

Odd Ratio for Atrial Fibrillation (per 10iU/dl Increase in Plasma von Willebrand Factor Levels) Among Gender Groups

		Odds Ratio (95% confidence interval)
Whole Group (n=486)	Crude	1.06 (0.99-1.12)
	Adjusted	1.06 (0.98-1.15)
Men (n=249)	Crude	1.01 (0.93-1.10)
	Adjusted	1.00 (0.90-1.12)
Women (n=237)	Crude	1.11 (1.01-1.26)
	Adjusted	1.19 (1.02-1.40)

Conclusion: Amongst an elderly community-based population there was no significant relationship between AF and plasma fibrinogen or sP-sel levels. However, AF was independently associated with increased plasma vWf among women but not men. The relationship between AF and vWf (endothelial damage/dysfunction) deserves further investigation as a potential mechanism of the increased risk of stroke in elderly women with AF.

P2930 Generation velocity of small-sized platelet aggregates predicts thrombotic complications during percutaneous coronary interventions

T. Sakamoto, H. Ogawa, S. Miyamoto, I. Kajiwara. *Kumamoto University Hospital, Cardiovascular Medicine, Kumamoto, Japan*

Background The ischemic complications of percutaneous coronary interventions (PCI) including abrupt closure, side branch occlusion or distal embolization of platelet aggregates or thrombus deteriorate the effects of the treatment. Generation velocity of small-sized platelet aggregates monitored by a novel laser-light scattering method is a sensitive marker of platelet activation. The method is quite useful because data are obtained at bedside in about 15 min.
Methods and Results: We measured ADP-induced platelet aggregability in platelet-rich plasma obtained from the peripheral vein in patients with acute coronary syndromes (ACS) (n=60) prior to urgent PCI to predict ischemic complications during the procedures. Platelet aggregability in stable exertional angina (SEA, n=54) was also measured as control. Platelet aggregability was determined as generation velocity of small-sized platelet aggregates which contain 70-1,400 platelets by a novel platelet aggregometer with a laser-light scattering method. Small-sized platelet aggregates (counts/ 10sec) were generated more frequently in ACS than in SEA ($26.53x10^3 \pm 5.19x10^3$ vs $14.52x10^3 \pm 2.54x10^3$, $p<0.05$). There were no differences in medium- (1,000-11,000 platelets) and large-sized (11,000-33,000 platelets) aggregates between the two groups. Periprocedural ischemic complications occurred in 15 patients (EVENT group) of the 60 ACS patients underwent PCI. Generation of small-sized aggregates was elevated in the EVENT group than in non-EVENT group (n=45) ($60.46x10^3 \pm 13.16x10^3$ vs $15.22x10^3 \pm 3.58x10^3$, $p<0.0001$). Logistic regression analysis revealed that the peak velocity of the generation of small-sized aggregates predicts ischemic complications during PCI procedures ($p=0.0093$, $R=0.325$) Meanwhile other coronary risk factors, antiplatelet or anticoagulant agents used and balloon to reference vessel diameter ratio had no predictive values.
Conclusions Monitoring of platelet aggregability measured by the laser-scattering method prior to PCI is informative and useful to predict periprocedural thrombotic complications in patients with ACS.

P2931 Clotting factor VIII is a key player for plasmatic and in situ thrombosis in chronic thromboembolic pulmonary hypertension

D. Bonderman[1], P.L. Turecek[2], A. Weltermann[3], J. Jakowitsch[4], A. Adlbrecht[4], P.A. Kyrle[3], G. Maurer[1], I.M. Lang[4]. *[1]General Hospital, Cardiology, Vienna, Austria; [2]Baxter BioScience, Vienna, Austria; [3]General Hospital, Hematology, Vienna, Austria; [4]General Hospital, Cardiology, Vienna, Austria*

Background: Chronic thromboembolic pulmonary hypertension (CTEPH) may be considered as an extreme variant of recurrent thromboembolism. However, no abnormalities of coagulation and fibrinolysis have been defined that explain the clinically progressive thrombosis in the pulmonary vasculature of these patients.
Methods and Results: Because plasma factor VIII (FVIII) levels above 230IU/dl have been shown to confer a 6.6-fold increased risk for recurrent deep venous thrombosis, we measured plasma FVIII levels in CTEPH patients (n=111). FVIII in CTEPH patients (232.9±103.2%) was higher than in age and sex matched healthy controls (93.0±23.3%, $p<0.001$, n=82) and patients with non-thromboembolic pulmonary hypertension (PAH, 168.2±81.2%, p=0.009, n=77). Hemodynamic improvement after pulmonary thromboendarterectomy (PTE) did not normalize plasma FVIII levels (226.4±88% versus 212±94%, p=0.8999, n=22). To substantiate the genetic background of this observation in CTEPH patients, blood group analyses were performed. Blood group non-O was more prevalent in CTEPH patients (82%) than in PAH patients (56%) or the Middle European population (60%, p=0.0026). RT-PCR demonstrated FVIII expression in CTEPH pulmonary thrombi harvested during PTE and in freshly excised deep leg vein thrombi. In situ-hybridization showed FVIII mRNA in endothelial cells and smooth muscle cells within organized CTEPH pulmonary thromboemboli and deep leg vein thrombi, which displayed identical histological patterns.
Conclusions: The data support the concept that elevated plasma FVIII is a key player and not an epiphenomenon in the pathogenesis of CTEPH. In addition, local FVIII expression may promote thrombus organization and recurrence.

CARDIAC REHABILITATION

P2932 Diastolic augmentation is an independent predictor of improved outcome in 3536 patients following enhanced external counter pulsation (EECP)

A. Brown[1], D. Dodd[1], P. Bagger[2], A. A Louis[3], E.D Kennard[4], S. F Kelsey[4], J. H Horgan[1] on behalf of IEPR Investigators.. *[1]Beaumont Hospital, Cardiology, Dublin, Ireland; [2]Hammersmith Hospital, Cardiology, London; [3]Hull Hospital, Cardiology, Hull, UK; [4]Univ. of Pittsburgh, Pittsburgh, USA*

Background: EECP produces diastolic augmentation of coronary blood flow and has been shown to improve angina. Despite this it has only recently been used in Europe for treatment of refractory angina. We analysed the clinical characteristics, degree of diastolic augmentation and response to treatment in patients enrolled in the international EECP patient registery (IEPR) in America (US) and Europe. **Methods:** 3536 patients underwent a course of treatment consisting of 35 one-hour sessions. Canadian class (CC) of angina was carefully documented pre- and post the 7 week course. Diastolic augmentation was assessed using a finger plethysmogram. The ratio of the peak diastolic amplitude to peak systolic amplitude was calculated. **Results:** There was a significant difference in baseline characteristics between groups. The US group (3465 patients) had more diabetic (43 vs 22.9% p=<0.001), hypertensive (71.6 vs 31% p=<0.001), hyperlipidaemic (81.1 vs 64.3% p=<0.001) patients, and more patients with multi-vessel disease (76.2 vs 62.5% p= <0.05) as well as more patients in CC III/IV (86.6 VS 54.9% P=<0.01). The European group (71 patients) had more patients who had previously undergone CABG (93 VS 70.9% P=<0.001), but fewer PTCAs (23.2 vs 66.3% p= <0.001) and more male patients (91.5 vs 75% p= <0.001). Despite these differences logistic regression analysis showed no difference in outcome between the two groups. However diastolic augmentation (measured as the last peak ratio) was an independent predictor of outcome in both patients with modest angina (CC I/II, odds ratio 1.67 [1.19 - 2.34]) and patients with severe angina (CC III/IV, odds ratio 1.63,[1.38 - 1.92]). Diabetes, smoking, hypertension, prior CABG, female sex and increasing age were all associated with lower levels of diastolic augmentation and diabetes (0.68 [0.41 - 0.96]), CABG (0.54 [0.35 - 0.82]), and heart failure (0.71 [0.59 - 0.85]) with a poorer outcome. **Conclusion:** The patients in the European and US EECP registries vary in their baseline characteristics. Despite this diastolic augmentation remains an independent predictor of benefit offering a possible physiological rationale for the improvement in symptoms seen in these patients.

P2933 How to advise on return to work after myocardial infarction or heart surgery

B. Heyndrickx, J. De Sutter, N. De Cock, G. De Backer. *Ghent University, Cardiac Rehabilitation, Gent, Belgium*

Background: Current advice on return-to-work is based on stress testing and ejection fraction. Neither correlate well with prolonged work capacity. Recommendations derived from work physiology state that mean workload should not exceed 33% and peak workload should not exceed 50% of maximal aerobic power. **Objective:** To determine whether simple heart rate recording while at work combined with detailed job description is feasible and could help in advising patients on return-to-work on short and long term. **Methods:** We included 54 patients referred to our tertiary centre after an acute myocardial infarction or heart surgery to assess if they could resume work. All underwent regular bicycle stress testing. They were evaluated while at work for the duration of a full work shift. A continuous heart rate recording was performed with a Polar sports-tester and was analysed with commercially available software. Simultaneously a detailed report of the various tasks and working conditions was made. Workload was calculated using the measurements obtained during bicycle stress test and Polar recording. If the mean workload exceeded 33% and/or repeated peak loads exceeded 50% of maximal aerobic power and considering specific job requirements we advised people not to resume their previous job but to look for job adaptation or to stop working. If not, return-to-work was encouraged. One-year follow-up to inform on their current working situation was done by phone or a house call. **Results:** A total of 54 patients, (47men/7 women, mean age: 49 years), were examined. 25(46%) were advised to resume their previous job and 29(54%) were advised to look for job adaptation or to stop working. Patients for whom no objection was made to resume work had lower mean and peak workload registrations. There were no differences in age, gender, cardiac risk factors, and ejection fraction or total bicycle workload. Of those advised to resume their previous job, 20(80%) did; 14(16%) returned to work under adapted working conditions and 1(4%) stopped working claiming that it was physically to demanding. After 1 year 23(92%) of those patients were doing the same job as before the cardiac event. Of the remaining 29 patients advised to look for job adaptation or to stop working, 14(48%)obtained a job adaptation, 7(24%) stopped working and 8(28%) maintained their previous work. After 1 year 22(76%) had either adapted or stopped working. **Conclusion:** An on-the-job Polar registration in combination with extensive job description is easy-to-use and valuable in advising on return-to-work on short and long term.

P2934 Mental stress-induced ischaemia in patients after myocardial infarction

M. Bilinska, E. Tylka, J. Tylka, R. Piotrowicz. *Institute of Cardiology, Dep. of Cardiac Rehabilitation, Warsaw, Poland*

Background: Myocardial ischemia may be triggered by exercise and non-exercise stimuli.The purpose of this study was to determine the usefulness of laboratory mental stress (MS) in inducing myocardial ischemia and/or cardiac arrhythmia in patients (pts) post myocardial infarction, with stable coronary artery disease.
Methods: Sixty four men, mean age 45 ± 6 years underwent: 15 min mental stress test during 24 h Holter monitoring and exercise stress testing.
Results: Only 8 pts (13%) had positive mental stress test (MS(+)). Five of them had ST segment depression > 1.0 mm (STD), and the remaining 3 pts had cardiac arrhythmias (2 pts had nonsustained VT, 1 pt had episode of FA). All episodes were silent. MS(+) pts had higher heart rate (HR) during the mental test than those with negative stress test (MS(-)) (120/min vs 105/min, $p< 0.05$). In contrast, at least one episode of daily life ischemia (DLI) was recorded in 23 pts (36%) on Holter monitoring. In MS(+) pts average duration of DLI (17 min vs 10.5 min, $p<0.05$) and mean HR during ischemia (124/min vs 94/min, $p< 0.05$) were greater than in MS(-) pts.
Exercise – induced ischemia (STD > 1.0 mm) was observed in 29 of 64 pts (45%). However, in MS(+) pts exercise duration (708 ± 132 s vs 924 ± 174 s, $p< 0.01$), time to 1 mm STD (432 ± 108 s vs 624 ±162 s, $p< 0.01$) were significantly shorter and double product at 1mm STD (13400 ± 2913 vs 14800 ± 3321 mmHg/min, $p< 0.05$) was lower than in MS(-) pts.
MS(+) pts become less accurate during mental work in comparison to MS(-) pts. Intelligence level was comparable in both groups [43.2 in MS(+) pts vs 40.2 in MS(-) pts; NS].
Conclusion: 1. Mental stress – induced ischemia is a weak inducer of ischemia and arrhythmia in patients with stable coronary artery disease.
2. Patients with mental stress – induced ischemia are more likely to display ischemia during daily life and exercise stress testing.
3. Only subset of patients after myocardial infarction, with specific psychological profile, is prone to ischemia and arrhythmia during mental work.

P2935 Effect of physical training on quality of life and exercise tolerance in patients with chronic heart failure

M. Klocek, A. Kubinyi, B. Bacior, K. Kawecka-Jaszcz. *Jagiellonian Univ., I Cardiac Dept., Kraków, Poland*

Aim: To assess changes in quality of life (QoL) and oxygen consumption in the course of two different patterns of physical training in patients with congestive heart failure (CHF).
Material and Method: The study population consisted of 42 men, age 55.9 ± 8.1 years with ischaemic CHF (NYHA II and III), and a duration of CHF 3.1 ± 1.0 years, receiving standard pharmacotherapy. Patients were randomised into groups: A (14 men) - with constant level of workload, B (14 men) - with progressive/increasing level of workload and C (14 men) not trained and serving as controls. In groups A and B physical training was conducted for up to 6 months (60 min of training daily, 3 times a week). Mean age, BMI, duration and severity of CHF were similar in all groups. QoL was assessed three times: at the beginning of the study and at 3 and 6 months by using the Minnesota Living with Heart Failure Questionnaire (MLHF). At the start and at six months of training in all patients cardiopulmonary exercise test and echocardiography were performed.
Results: Oxygen consumption as well as exercise time and workload (in METs) improved in both trained groups ($p<0.01$). Improvement in QoL was positively correlated with peak VO2 only in group B ($r=0.47$, $p<0.05$). At baseline as well as at 6 months no significant differences between groups in left ventricular systolic and diastolic function were found. At the start of the study, the MLHF total indexes were similar in groups A and B, but lower than in group C, i.e. 65.4, 65.3 and 71.0 points respectively. In groups A and B improvement in the MLHF score was observed ($p<0.001$) at 3 and 6 months. However, overall improvement in MLHF was markedly greater in group B (39%) than in group A (29%) ($p<0.01$), as well as oxygen uptake (VO2 max in group increased B from 15.3 to 19.3 ml/kg/min and VO2 max in group A from 15.4 to 16.5 ml/kg/min, $p<0.001$).
Conclusions: Regular physical training improves QoL in men with CHF, but only progressive/increasing workload seems to markedly improve oxygen uptake.

P2936 Gender differences in physical health and psychological well-being at entry into rehabilitation after acute myocardial infarction

U. Haertel[1], J. Gehring[2], G. Klein[2], M. Schraudolph[3]. *[1]University of Munich, Human Science Centre, Munich, Germany; [2]Herz-Kreislauf-Klinik, Bernried, Germany; [3]Private Herz-Kreislauf-Klinik, Lauterbacher Mühle, Germany*

Objective: To identify gender differences at the beginning of cardiac rehabilitation that may influence the long-term outcome of myocardial infarction.
Methods: Study subjects were 309 men and 201 women, aged 30 to 75, who were admitted to a cardiac rehabilitation clinic about three weeks after first acute myocardial infarction. At baseline, all patients completed a standardized interview that included a number of questions on socio-economic factors, chronic diseases, and subjective well-being. To assess symptoms of anxiety and depression the Hospital Anxiety and Depression Scale (HADS) was introduced at the beginning and the end of the four-week clinic stay.
Results: After adjustment for age, a number of statistically significant sex differences were found. Women reported significantly more co morbid conditions such as high blood pressure, angina pectoris, gall bladder disease, kidney disease and osteoporosis. They also reported more somatic symptoms such as weakness, sleeplessness and back pain. The age-adjusted prevalence of high anxiety scores (HADS > 10) was 23% in women and 13% in men ($p < 0.05$). And about 16% of women compared to 8% of men were identified as depressed. In age-specific analyses, the gender differences were more pronounced in younger patients (under 60 years) than in older patients (60 to 75 years). Applying multivariate analyses, among men and women it was found that the prevalence of chronic somatic diseases was the best predictor for the occurrence of anxiety and symptoms of depression. After 4 weeks of in-hospital rehabilitation both men and women reported significantly less symptoms of anxiety and depression though the gender differences in anxiety remained significant.
Conclusion: The results of this study indicate that age and gender specific plans of care need to be directed at patients with coronary heart disease.

P2937 Clinical predictors of return to work in coronary artery bypass surgery patients – Data from the PERISCOP study

P. Sellier[1], G. Chatellier[2], C. Dubois[3], M.C. D'Agrosa-boiteux[4], H. Douard[5], P.C. Goepfert[6], C. Monpere[7], A. Saint-Pierre[8] on behalf of the Investigators.. *[1]Broussais-HEGP, Cardiac rehabilitation Dept., Paris, France; [2]Broussais-HEGP, Informatic Dept, Paris, France; [3]Foch Hospital, Cardiac Surgery, Suresnes, France; [4]Cardiologic Center, Durtol, France; [5]Haut Levêque Hospital, Cardiology Dept., Pessac, France; [6]Brabois Hospital, Rehabilitation Dept., Vandoeuvre les Nancy, France; [7]Bois Gibert, Cardiac Rehabilitation, Ballan Mire, France; [8]Center, Cardiology, LYON, France*

Background: PERISCOP is a prospective multicentre study aiming at the determination of prognostic factors by non invasive methods after coronary artery bypass surgery (CABG).
Aim: to analyse the predictors of return to work (RTW) in the subgroup of patients (pts.) aged less than 60 yrs, working before CABG.
Methods: Pts. with recent (20 days) CABG were prospectively included in this study (41 rehabilitation centers). Cardiac evaluation was performed at 20±10 days after CABG by exercise testing, echocardiography and 24-hour ambulatory ECG monitoring (AECG). Clinical status and RTW were evaluated by self-administered questionnaire one year after surgery. A logistic regression using RTW (yes=1) as the dependent variable was used to identify the independent predictors of work resumption.
Results: Among the 2065 pts. included in the PERISCOP study, 530 pts. (male: 95%, mean age: 50.5 ± 6 yrs) met the inclusion criteria. Among them, 26 were lost to follow up and 340 (68%) returned to work. The median delay before RTW was 3 months. The significant predictors of RTW are shown on table.

table

Variable	Increase in risk of not returning to work (CI)	p value
Age (> 51)	64% (77-45)	< 0.0001
Occupation (worker)	50% (74-5)	0.033
Region (South East)	72% (86-42)	0.0005
Angina	59% (80-15)	0.016
Dyspnea	53% (72-21)	0.0041
Exercise duration < 7min	46% (65-16)	0.0063

Conclusions: In a representative sample of French pts. experiencing recent CABG, increased age, severity of disease, low occupational category and living in the South-East of France were predictors of low rate of RTW after surgery.

P2938 Short term multidisciplinary cardiac rehabilitation program improves endothelial function

J. Klein, A. Butnaru, M. Klutstein, D. Tzivoni. *Shaare Zedek Medical Center, Cardiology Dept., Jerusalem, Israel*

Background: Individual risk factor modification, in particular lipid lowering, has been shown to improve endothelial function in CAD patients. However, little is known about the effect of comprehensive risk factor modification and lifestyle change on endothelial function.
Goals: To assess the effect of a 3 month multidisciplinary cardiac rehabilitation program (CR) on endothelial function in stable CAD patients.
Methods: 42 stable CAD pts (7%women), mean age 65y were randomized into CR group (n=21) and no-CR group (n=21), who received usual care. CR program included: exercise (EX) training, nutritional counselling, lipid lowering medication and lifestyle modification.
Endothelial-dependent brachial artery flow-mediated vasodilation (FMD) was assessed with high resolution (10MHz) ultrasound at baseline, and after 1, 2 and 3 months. Lipids and EX testing Bruce protocol were assessed at baseline and at 3 months.
Results: Baseline characteristics were similar in both groups, including FMD. Compared to no-CR group, at the end of the 3rd month, CR patients had significantly reduced TC, LDL, TG ($p<0.02$), increased EX test duration ($p=0.02$). and increased weekly EX time (4.8±0.8 hours vs 0.5±1 hours in the control group, $p<0.0001$). BMI did not change in either group. In the CR group a trend towards improved FMD (%) was detected after 2 months (8.1±7 vs 4.9±6 at baseline), which became statistically significant at the 3rd month (10.5±6, $p=0.009$ compared to baseline, and $p=0.04$ vs no CR group) (Table). No change in FMD was detected in the control group over the study period.

Endothelial Function (FMD%)

FMD (%):	Baseline	Month 1	Month 2	Month 3
CR Group	4.9±6	4.8±7	8.1±7*	10.5±6**$
no-CR group	6.2±8	3.6±9	3.5±7	5.7±8

*p=0.055 Vs. no-CR group, **p=0.009 Vs.baseline CR, $p=0.04 Vs. no-CR

Multivariate analysis revealed a non-linear association between LDL change, weekly EX and %FMD response.
Conclusions: 1) CR significantly improved lipid profile, EX duration and weekly EX. 2) Endothelial function significantly improved in the CR group at the end of 3months. 3) LDL change and weekly EX hours are associated with this improvement.

P2939 Changing clinical patterns in the cardiac rehabilitation program, the Haifa experience

E. Goldhammer, A. Tanchilevich, E.G. Abinader. *Bnei-Zion medical center, Cardiology, Haifa, Israel*

Today's cardiology patients are likely to be older, sicker, and to stay in hospital fewer days than in the past. Most of them undergo treatment modalities such as angioplasty and stenting, thus, being diagnosed, treated and discharged quickly.
To evalute the impact of changing clinical trends on cardiac rehabilitation trends we have assessed retrospectively 4159 files of patients joining rehabilitation program during the period 1.5.83-31.12.01.
Clinical & demographic data were retrospectively assessed at 3 time points, 1984, 1993, and 2001.Data reviewed included: age,gender, socio-economic status, early drop-out rates, risk factors, F.C., previous infarction, percutaneous interventions (PCI's), CABG,pacemaker or valve surgery, primary/secondary prevention.Medications were reviewed as well.
Results: mean age increased constantly, 59.4 years± 4.5, 67± 5.8 and 71.5±4.9, $p<0.01$, gender distribution did't change through the years (females 20.5%, 23.1%, and 21%, p=ns); pensioners = 27%, 43.7%,and 47.5% respectively, $p<0.01$. "Blue Collars" = 58%, 51.6%, and 44.5%, $p<0.01$).Early drop-out(less than 6weeks of participation)=20.4%, 18.7%, and 20.5%, p=ns.
Previous myocardial infarction = 91%, 72.4%, and 71%,p=0.05; previous PTCA/Stent=0%, 8.4%, and 63.1%, $p<0.01$, F.C. II-III = 2.6%, 4.5%, and 17.5%, $P<0.01$. Participation for primary prevention = 6.5%, 8.1%, and 5.9%, p=ns.Medications: Aspirin = 64.8%, 70.5%, and 92.5%, $p<0.01$, Statins = 4.6%, 30.5%, and 56.1%, $p<0.01$, Beta blockers = 21.9%, 25.4%, and 48.1%, $p<0.01$.
Conclusions = participants mean age increased consistently over the years. In 1984 most patients joined rehabilitation program following myocardial infarction while in 2001 most were patients who underwent CABG and/or percutaneous interventions. Use of Aspirin, Statins and beta blockers grew consistently. Cardiac rehabilitation constitutes a high fidelity mirror of the changing clinical trends and patterns in cardiology.

P2940 Improved physical performance and circulatory response in moderate to severe heart failure patients undergoing exercise training

D. Freimark[1], M. Motro[2], J. Leor[1], E. Schwammenthal[1], E. Elmaleh[2], Y. Adler[2]. [1]*Tel Hashomer Hospital, Cardiology, Ramat Gan, Israel;* [2]*Tel-Hashomer hospital, Cardiac Rehabilitation Institute, Ramat Gan, Israel*

Background: Determination of hemodynamic outcome in patients with congestive heart failure (CHF) undergoing cardiac rehabilitation has been difficult to assess due to lack of easily obtainable hemodynamic information in every day practice. Thoracic electrical bioimpedance (TEB) relies on the proportional change in the conduction of alternating current applied across the thorax as a function of blood volume in the heart and great vessels. Using this technique cardiac index (CI) can easily be determined. The aim of our study was to assess the functional responses and immediate post peak exercise CI obtained non-invasively using TEB in patients with moderate to severe CHF before and after participating in cardiac rehabilitation program.
Methods: Between 01/2000 and 08/2001 57 consecutive patients with moderate to severe CHF (FC III) who were referred to a cardiac rehabilitation program were studied. Among those, 44 patients, mean EF=24±5% (exercise group) participated in the exercise program, and 13 patients, mean EF=21±7%, did not (control group). Six minute walk test, Modified Bruce exercise test duration and immediate post peak exercise CI, obtained by TEB, were measured before and after 18 weeks physical training.
Results: The 2 groups did not differ in age, gender, risk factors, prevalence of ischemic etiology and treatment. No differences were found between exercise and control in all measured parameters before physical training: six minute walk test, Modified Bruce exercise test duration and immediate post peak exercise CI (310±87 vs. 306±108meter, 5.8±.6 vs. 4.4±3.6 minutes, and 4.1±1.2 vs. 4.4±1.3 L/min/m^2, respectively).Significant differences were found between groups after 18 weeks of physical training in all parameters: six minute walk test, Modified Bruce exercise test duration and immediate post peak exercise CI (444±84 vs. 281±127 meters, $p<0.001$, 9.8±3.0 vs. 4.1±3.7 minutes, $p<0.001$, and 4.8±1.0 vs. 3.6±1.3L/min/m^2, $p=0.0053$, respectively)
Conclusions: Exercise training improves immediate post peak exercise cardiac index, detected by thoracic electrical bioimpedance, in moderate to severe heart failure patients (FC III). This improvement can partially contribute to the better physical performance detected in these patients after physical training.

BRAIN NATRIURETIC PEPTIDE IN HEART FAILURE MANAGEMENT

P2941 N-terminal pro-brain natriuretic peptide accurately predicts heart failure in general population. A population study

M. Rivera[1], R. Talens[1], V. Miro[2], F. Garcia de Burgos[3], V. Bertomeu[4], R. Paya[5], A. Salvador[6], V. Climent[5] on behalf of Grupo Disfuncion VI, Comunidad Valenciana. [1]*Hospital La Fe, Research Unit, Valencia;* [2]*Valencia, Spain;* [3]*Hospital Elche, Cardiologia, Elche;* [4]*Hospital S Juan, Cardiologia, Alicante;* [5]*Hospital General, Cardiologia, Valencia;* [6]*Hospital Peset, Cardiologia, Valencia, Spain*

Background: Plasma levels of N-terminal pro-brain natriuretic peptide (NT-proBNP) are raised in left ventricular dysfunction (LVD). Population studies looking to predict heart failure (HF) were performed using BNP however NT-proBNP was never used in a multicenter study. In this multicenter population study we compared NT-proBNP in high NYHA class subjects with NYHA class I.
Methods: We studied 215 subjects (119 F, 96 M), age 66±9, (45-86), obtained from a random sample of 432 people from the Valencian Community, (Alicante, Castellon, Valencia), that in a previous questionnaire declared to suffer from some degree of dyspnea. These 432 subjects were referred to their local hospital (10 hospitals involved in the study) where blood samples were taken, an echo-Doppler study was performed, a specific questionnaire was completed and were classified according to NYHA functional classes. All blood samples were sent to the same hospital and NT-proBNP was measured. Out of the 432 subjects we got a positive answer from 215.
Results: NT-proBNP was significantly lower, 53 (0-1860) pg/ml in NYHA I than in NYHA>1, 132 (13-2585), $p<0.0001$. Receiver operator characteristic (ROC) curves which plot sensitivity vs 1-specificity of the ability of NT-proBNP to separate NYHA I from NYHA>I, had an area under the curve (AUC) of 0.74. At a cut-point of 85 pg/ml there was a 73% sensitivity, 66% specificity in detecting the presence of NYHA>I. When we compared gender groups (male, M; female, F) we found an AUC in F of 0.74. At a cut-point of 85 pg/ml there was a 74% sensitivity, 60% specificity in detecting the presence of NYHA>I, when compared with ROC curve in M, AUC 0.8, 71% sensitivity, 75% specificity at a cut-point of 88 pg/ml in detecting the presence of NYHA>I.
Conclusions: This multicenter population study shows that an easy, rapid test can predict HF. We believe that NT-proBNP may be a good screening tool for detecting HF in general population.

P2942 B-type natriuretic peptide predicts sudden death in patients with chronic heart failure: a selection mode for ICD implantation?

R. Berger[1], M. Huelsmann[1], K. Strecker[1], A. Bojic[2], B. Stanek[1], R. Pacher[1].
[1]University of Vienna, General Hospital, Dept. of Cardiology, Vienna; [2]Ludwig Boltzmann Institute, Cardiovascular Research, Vienna, Austria

Background: Given the high incidence of sudden death in patients with chronic heart failure (CHF) and the efficacy of implantible cardioverter defibrillators, an appropriate tool for prediction of sudden death is desirable. B-type natriuretic peptide (BNP) has prognostic significance in CHF and the stimuli for its production also cause electrophysiological abnormalities. This study tests BNP levels as predictor of sudden death.
Methods: BNP levels, in addition to other neurohormonal, clinical and hemodynamic variables, were obtained from 452 patients with LVEF <35%. For prediction of sudden death only survivors without HTx or mechanical assist device and patients who died sudden were analysed.
Results: Up to 3 years 293 patients survived without HTx or mechanical assist device, 89 patients died and 65 patients unterwent HTx. Mode of death was sudden in 44 patients (49%), pump failure in 31 patients (35%), 14 patients (16%) died from other causes. Univariate risk factors of sudden death were log BNP (x2=12, p=0.0005), log N-ANP (x2=9, p=0.003), LVEF (x2=8, p=0.005), log N-BNP (x2=8, p=0.006), systolic blood pressure (x2=6, p=0.01), big endothelin (x2=5, p=0.03), NYHA class (x2=4, p=0.04) and diastolic blood pressure (x2=4, p<0.05). In the multivariate model log BNP levels were the only independent predictor of sudden death (x2=12, p=0.0005). Using a cutpoint of log BNP <2.11 (=130 fmol/ml) Kaplan Meier sudden death free survival rates were significantly higher in patients below (99%) compared to patients above this cutpoint (81%) (p=0.0001).
Conclusion: BNP levels are a strong independent predictor of sudden death in patients with CHF.

P2943 Brain natriuretic peptide kinetics during dynamic exercise in patients with chronic heart failure

S. Krüger[1], J. Graf[1], U. Janssens[1], T. Stickel[1], D. Kunz[2], P. Hanrath[1].
[1]University clinic, Medical Clinic I, Aachen, Germany; [2]Clinical chemistry, University clinic, Aachen, Germany

Background: Plasma levels of brain natriuretic peptide (BNP) are increased in patients (pts) with chronic heart failure (CHF) and left ventricular dysfunction. Previous reports demonstrated that dynamic exercise stimulates BNP secretion in CHF. However, little is known about the kinetics of BNP secretion during dynamic exercise and the following recovery phase in a larger cohort of CHF pts.
Methods: We prospectively studied 37 pts with CHF (60 ± 10 years, 9 women, LVEF 26 ± 6%) and 20 healthy controls (58 ± 11 years, 6 women, LVEF 60 ± 3%). All CHF pts had a LVEF < 35%. Cardiopulmonary exercise testing was performed in all CHF pts and controls. BNP (pg/ml; immunoassay, Biosite Diagnostics, San Diego, USA) was obtained prior to symptom-limited bicycle exercise, at peak exercise and at 1 and 5 minutes of recovery time.
Results: Peak VO2 was significantly higher in controls than in CHF pts (19.8 ± 4.1 vs. 15.0 ± 3.6 ml/min/kg, p < 0.01). BNP concentrations were significantly higher in CHF pts compared to controls at rest, peak exercise and at 1 and 5 minutes of recovery. In controls BNP-levels were not significantly different at rest (25 ± 20 pg/ml), peak exercise (35 ± 31 pg/ml, n.s.) or in the recovery phase (41 ± 40 and 38 ± 36 pg/ml, n.s.). In CHF there was an increase of BNP from rest (428 ± 421 pg/ml) to peak exercise (507 ± 450 pg/ml, n.s.), 1 minute (560 ± 460 pg/ml, n.s.) and 5 minutes recovery (526 ± 424 pg/ml, n.s.). Interestingly, six of 37 CHF pts (16%) showed a decrease in BNP at exercise compared to rest but none of the controls. These CHF pts with a decrease in BNP showed no difference in peakVO2, LVEF and BNP at rest, but a significant difference in BNP at peak exercise (202 ± 241 vs. 555 ± 465 pg/ml, p < 0.05) when compared to pts with an BNP increase at exercise.
Conclusions: During dynamic exercise BNP levels rise from rest to a maximum at 1 minute recovery phase. However, BNP levels at peak exercise and at recovery are not significantly different compared to BNP at rest. This is due to the fact that in contrast to controls there are some CHF patients with a decrease in BNP at exercise. The reason for this phenomenon deserves further study.

P2944 Comparison of a near patient NT-ANP test with plasma NT-ANP and BNP for the detection of left ventricular systolic dysfunction in suspected heart failure

A. Hannah[1], S. Clements[2], J.J. Morton[2], T.A. McDonagh[3], H.J. Dargie[2].
[1]aberdeen royal infirmary, Cardiology, Aberdeen, United Kingdom; [2]Western Infirmary, Cardiology, Glasgow, United Kingdom; [3]Glasgow Royal Infirmary, Cardiology, Glasgow, United Kingdom

Background: The natriuretic peptides BNP (brain natriuretic peptide) and NT-ANP (atrial) are useful in the evaluation of patients with suspected LV systolic dysfunction (LVSD). Near patient natriuretic peptide tests would allow a more rapid and convenient assessment of the breathless patient, particularly in primary care.
Methods: We evaluated a near patient spot-test for NT-ANP in 53 patients with suspected heart failure, comparing with plasma BNP (direct IRMA) and NT-ANP (RIA). Echocardiography was performed and wall motion score calculated (9 segment). Sensitivity, specificity, negative and positive predictive values were calculated for the detection of moderate-severe LVSD (WMSI less than 1.3) and milder LVSD (WMSI less than 1.6).
Results:

WMSI13	sensitivity(%)	specificity (%)	PPV (%)	NPV (%)
ANP spot-test	83.3	35.3	27.8	87.6
ANP 4.0ng/ml	91.7	41.2	31.8	94.3
BNP 50pg/ml	100	37.3	32.3	100
WMSI16				
ANP spot-test	87.5	37.9	53.5	78.1
ANP 4.0ng/ml	83.3	51	58.1	78.6
BNP 50pg/ml	93.7	44.8	58	90.0

BNP, NT-ANP and the spot-test were all significantly higher (p<0.05) in patients with LVSD. BNP correlated most strongly with WMSI (r = -0.404). 16 of 17 false positive spot-tests had elevated BNPs. 10 of these had another echo abnormality present: significant valve dysfunction, LVH or right heart dilatation.
Conclusions: Near patient testing of NT-ANP is feasible and of similar diagnostic value as plasma NT-ANP in patients with suspected heart failure. BNP is superior to both in terms of ability to exclude the presence of LVSD.

P2945 A comparison of BNP and NT-proBNP as markers of mild forms of left ventricular dysfunction

A. Hammerer-Lercher[1], W. Ludwig[1], S. Müller[2], E. Neubauer[2], B. Puschendorf[1], O. Pachinger[2], J. Mair[2]. [1]Med. Chemistry and Biochemistry, Innsbruck, Austria; [2]Cardiology, Innsbruck, Austria

Introduction: It has been shown that among all hormones secreted upon ventricular stretch, B-type natriuretic peptide (BNP) has emerged as the best biochemical diagnostic marker for heart failure (HF). However, NT-proBNP appears to be a useful new marker. We therefore tested, whether NT-proBNP can effectively diagnose mild heart failure.
Methods: After giving informed consent 86 consecutive patients (31-83 years) with clinically suspected mild HF who were referred for coronary angiography were enrolled in this study. BNP was measured within 2 hours from blood collection in EDTA-whole blood samples by a POCT immunoassay (TRIAGE®, Biosite Diagnostics, La Jolla, CA). For NT-proBNP plasma samples were stored at -20 °C until batch measurement by an enzymeimmunoassay (Biomedica, Vienna, Austria). 47 persons showed to have a normal LVEF and were referred as controls. 19 patients presented with mild systolic heart failure, and 20 patients suffered from isolated left ventricular diastolic dysfunction.
Results: NT-proBNP concentration was significantly increased in patients with mild heart failure (p=0.002, median: 425.95 fmol/ml) compared to control persons (median: 217.5 fmol/ml), but there was no significant difference between controls and patients with isolated diastolic heart failure. BNP concentrations were significantly increased in patients with mild heart failure (p=0.00) or isolated diastolic dysfunction (p=0.018). Receiver-operating characteristic (ROC) plot analysis showed an equal performance for BNP and NT-proBNP in the discrimination between controls and patients with mild heart failure. The area under curve (AUC) was 0.78 ± 0.065 for BNP and 0.75 ± 0.076 for NT-proBNP. A BNP of <46 pg/ml or a NT-proBNP of <249 fmol/ml ruled out mild heart failure with a negative predictive value of 0.9 or 0.83, respectively. However, BNP was the better diagnosic marker to determine patients with isolated diastolic dysfunction with an AUC of 0.7 ± 0.065 vs. the AUC of NT-proBNP of 0.49 ± 0.079. Moreover, the inverse correlation with angiographically determined LVEF was better for BNP (r=-0.395, p<0.01) than for NT-proBNP (r=-0.273, p<0.05).
Conclusion: The diagnostic performance to correctly select patients with isolated diastolic dysfunction was significantly increased with BNP. However, NT-proBNP may be an equal useful biochemical marker as BNP for the diagnosis of mild heart failure.

P2946 BNP variations under diuretic treatment predicts short term mortality in acute or decompensated heart failure

P. Jourdain[1], F. funck[1], M. bellorini[1], N. guillard[1], J. loiret[1], B. thebault[1], D. duboc[2], M. desnos[3]. [1]*René Dubos Hospital, Cardiology Dept., Pontoise, France;* [2]*cochin, cardiology, paris, France;* [3]*Hopital G. Pompidou, Cardiology Dept., Paris, France*

Hospitalisations for decompensated heart failure are linked with bad outcome. We wanted to determine if BNP plasma level at the admission or the variations of BNP plasma levels in the first 24 hours of treatment could help to determine the immediate outcome of the patients and could help to monitor the effects of the diuretic treatment.

Background Treatment of decompensated heart failure is currently based on clinical criteria. BNP is an hormone correlated to left ventricular end diastolic pressure. We hypothesize that measuring BNP levels might be useful in assessing short term outcome in patients hospitalised for decompensated heart failure.

Methods We have included 120 consecutive patients hospitalised for decompensated heart failure and we have measured BNP levels at the admission and 24 Hours later.

Results A BNP plasma level at the admission > to 1200 pg/ml is linked with an in hospital mortality of 70%. All the patients with a good outcome despite initial BNP > 1200 pg/ml showed a dramatic decrease of their BNP levels in the first 24 hours of treatment.

Conclusions In patients admitted for decompensated CHF, Initial BNP plasma level and changes in the first 24 hours are very strong predictors of in hospital mortality.

P2947 Is the viral infection influencing the cardiac BNP concentration in DCM patients?

S. Heringer-Walther. *UKBF, Cardiology Dept., Berlin, Germany*

Dilated cardiomyopathy (DCM) is one of the most frequent causes of heart failure however its pathogenesis is not well understood. There is growing body of evidence suggesting that viral infection and autoimmunologic mechanisms may also play an important role in the pathogenesis of both DCM and a predisposing condition, acute myocarditis (MC). Thus, identifying the factors that regulate these processes is of prime importance in understanding the etiology of these diseases.

Brain natriuretic peptide (BNP) is secreted in an endocrine fashion mainly from the heart in response to ventricular stretch, and produces several biological effects. Although, increased BNP levels are used as a prognostic marker in patients with heart failure and acute coronary disease, the molecular mechanisms that lead to abnormal regulation of BNP remain unknown. Thus, the aim of the study was to evaluate the pattern of cardiac BNP concentrations in different groups of DCM and their diagnostic and/or predictive potency. The study was performed in the following group of patients: 1- Control (EF>50%), n=11; 2- DCM, virus negative, without inflammation, n=9; 3- DCM, virus negative, inflammation positive, n=9; 4- DCM, virus positive, without inflammation, n=10; 5- DCM, virus positive, inflammation positive, n= 9; 6- No DCM, no MC, virus negative, without inflammation, EF<50%, n=10. Endomyocardial biopsies were taken from the right ventricular septum with a cordis bioptome. The samples were homogenised and extracts assayed for BNP levels in duplicate by immunoradiometric assay (IRMA; Schering, Germany).

We observed an increase in BNP concentration in biopsies of all patients groups compared to the control group (group1: 30 ± 11; group 2: 235 ± 140; group 3: 234 ± 86;. group 4: 119 ± 57; group 5: 48 ± 13; group 6: 74 ± 42 pg/mg protein). However, these increases were more pronounced in groups without the virus (group 2 and 3) compared to the groups with virus (group 4 and 5)

To our knowledge, this is the first report demonstrating the measurement of BNP concentrations in single endomyocardial biopsies with a wet weight of 3 to 5 mg. Surprisingly, the BNP concentrations are significantly reduced in DCM with viral infection and/or inflammation compared to virus and inflammation negative DCM. Whereas a direct viral control on BNP seems to be unlikely, the possible explanation for this observation is that inflammatory cells and factors released by viral infection could influence BNP generation and release.

P2948 N-terminal pro brain natriuretic peptide as a prognostic marker in the general population

B.A. Groenning[1], I. Raymond[1], P.R. Hildebrandt[1], J.C. Nilsson[1], M. Baumann[2], J. Trawinski[2], F. Pedersen[1]. [1]*Copenhagen Univ. Hosp. Frederiksberg, Dept. of Cardiology and Endocrinology, Frederiksberg, Denmark;* [2]*F. Hoffmann-La Roche Ltd, IHCS Dept., Basel, Switzerland*

Background: The purpose of the study was to evaluate N-terminal pro brain natriuretic peptide (NT-proBNP) as a marker for cardiac morbidity and all-cause mortality in the general population.

Methods: Randomly selected subjects (382 women & 290 men) in 4 age groups (50-59 (n=174); 60-69 (n=204); 70-79 (n=174); >80 years (n=120)) from four Copenhagen general practitioners filled in a heart failure questionnaire, were examined clinically, and by ECG, echocardiography and NT-proBNP measurements.

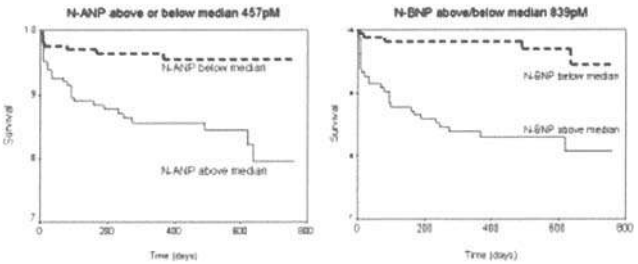
Results: Median (range) follow-up was 805 (60-1171) days. In Cox proportional hazards analyses, age, gender, history of hypertension, history of ischaemic heart disease, diabetes, dyspnea, ankle edema, heart rate, systolic and diastolic blood pressures, abnormal ECG, left ventricular ejection fraction (LVEF) and NT-proBNP were evaluated as potential prognostic markers for mortality, congestive heart failure (CHF) admissions and other cardiac admissions. Log10(NT-proBNP) (hazard ratio (HR)=5.70, p<0.0001) and male gender (HR=3.10, p=0.004) were independent markers for mortality. Log10(NT-proBNP) (HR=13.8, p<0.0001), dyspnea (HR=1.45, p=0.003) and male gender (HR=2.71, p=0.03) were independent markers for CHF admissions, and log10(NT-proBNP) (HR=3.69, p<0.0001), abnormal ECG (HR=2.56, p=0.003) and history of ischaemic heart disease (HR=1.90, p=0.03) were independent markers for other cardiac admissions. All-cause mortality (26 vs 6 deaths, p=0.0003), first CHF admissions (18 vs 2, p=0.0002), and first admissions from other cardiac causes (44 vs 13, p=0.0001) were significantly higher in subjects with NT-proBNP>32.5pmol/l (study median) than in subjects with NT-proBNP<32.5pmol/l.

Conclusion: In this large sample of the general population, NT-proBNP was identified as the single most powerful prognostic marker for all-cause mortality as well as for cardiac morbidity. The results point towards an increased role for NT-proBNP analysis in the evaluation of patients suspected of heart failure.

P2949 Comparison of NT-proBNP and NT-proANP in the prediction of mortality and heart failure after acute myocardial infarction

R J. O'Brien, B. Demme, I. Squire, J E. Davies, L L. Ng. *University of Leicester, Dept of Medicine &Therapeutics, Leicester, United Kingdom*

The N-terminal fragments of both B-type (N-BNP) and atrial(N-ANP) natriuretic peptide are useful in the prediction of LV function and mortality after acute MI(AMI).Few studies have directly compared the prognostic utility of N-ANP with N-BNP.Plasma N-ANP and N-BNP were measured on day three in 327 unselected patients following AMI (152 anterior; 245 male,median age 65[range 32-95]). During a follow up of median 472 days(range 5-764),33(10.1%) patients died, 70 were hospitalised with an ACS(21.4%),19(5.8%) with LVF,and 43(13.1%) suffered outpatient LVF. Median N-ANP and N-BNP were higher in patients with any of previous MI, angina, LVF or diabetes (all p<0.05). N-BNP was higher in anterior AMI (1252 v 708 pM,p=0.004). Both peptides increased with worsening Killip class (p=0.0005),and with the degree of LV dysfunction (p<=0.001) assessed by echo.In univariate analyses, both N-ANP and N-BNP were higher in those dying, readmitted with heart failure or developing outpatient LVF (all p=0.0005).Factors significant in univariate analysis (previous MI,angina,age,N-ANP,N-BNP,1/creatinine and Killip Class for death) were entered into multivariate regression models. Only N-BNP remained independently predictive of all three endpoints (odds ratios: death 3.6[1.4- 9.3], admission with LVF 11.0[2.1-56.7] and outpatient LVF 2.4[1.0-5.5]. N-ANP failed to have additional predictive value over N-BNP. Survival was lower in those with N-ANP(p=0.0004) or N-BNP(p=0.0001) above the median (see Fig 1).



Cox proportional hazards models for death showed significant ratios for only N-BNP(5.0[CI 2.0-12.9]). A single measure of N-BNP following AMI independently predicts death and heart failure, and is superior to N-ANP in this respect.

P2950 Automated measurement of N-terminal proBNP for biochemical detection of left ventricular dysfunction

A. Luchner[1], C. Hengstenberg[1], H. Loewel[2], G. Riegger[1], H. Schunkert[1], S. Holmer[1]. [1]*Klinikum der Universität, Innere Medizin II, Regensburg, Germany;* [2]*Institut für Epidemiologie, GSF Forschungszentrum, München, Germany*

N-terminal pro-brain natriuretic peptide (proBNP), the amino-terminal signal peptide of the second cardiac natriuretic peptide BNP has been found a promising biochemical marker of left ventricular (LV) dysfunction and heart failure (CHF).
In the current study, we aimed to assess for the first time the usefulness of fully automated measurement of proBNP (Elecsys®proBNP, Roche Diagnostics). A total of 467 subjects late after myocardial infarction (MI, MONICA MI register Augsburg; elapsed time after MI 1-10 years, mean 5.6) as well as 458 siblings without MI were studied. All study subjects were characterized with respect to hemodynamic and anthropometric parameters and renal function (glomerular filtration rate, GFR) and underwent echocardiography with respect to LV ejection fraction (EF, Simpson method) and mass (Devereux method). In subjects with MI, proBNP was significantly increased (299.3±29.1 pg/mL vs. no MI 84.9±7.7, $p<0.01$), particularly in the presence of LV dysfunction (515.5±142.8 pg/mL, $p<0.01$ vs. no MI), LV hypertrophy (447.9±73.0 pg/mL vs. MI without hypertrophy 264.2±31.9, $p<0.03$), renal dysfunction (456.3±72.1 pg/mL vs. MI without renal dysfunction 221.5±13.3, $p<0.01$), and CHF (340.9±36.2 pg/mL, $p<0.01$ vs. no MI). In uni- and multivariate analyses, a significant correlation was present between proBNP and EF (r: -0.20, $p<0.001$), LV mass index (r: 0.27, $p<0.001$), and GFR (r: -0.27, $p<0.001$) in addition to age (r: 0.14, $p<0.001$) and gender (β-coefficient 70.3±33.2, $p<0.04$ multivariate). Patients with LV dysfunction (EF<35%) were detected by proBNP with a sensitivity of 91% and specificity of 75% at an optimal cutpoint of 188pg/mL and an area under the ROC curve of 0.85.
ProBNP represents a novel diagnostic tool for the detection of LV dysfunction in patients at risk. Automated measurement of this marker is now feasible and may provide clinical benefit. In addition to LV dysfunction, increased LV mass, female gender, and renal dysfunction should be considered as important confounders of increased proBNP concentrations.

P2951 BNP and risk stratification in patients with congestive heart failure

A B. Scardovi, A. Chiera, N. Aspromonte, E. Cerquetani, F. Lumia, M. Romano, V. Ceci. *S.Spirito, Cardiology, Rome, Italy*

We sought to determine the possible relationship among brain natriuretic peptide (BNP) and cardiopulmonary parameters commonly used for risk stratification in patients suffering from congestive heart failure (CHF-PTS).
Fourty, II and III NYHA class, consecutive CHF-PTS of various etiology were enrolled; mean age was 70,9 ± 11.6; the mean ejection fraction (EF) was 32,9% ± 8.3.
BNP plasma level was measured by means of the triage system (Biosite Diagnostics, Triage BNP test) before cardiopulmonary test (CPx). CPx parameters were: VO2 peak (PVO2), anaerobic threshold (AT), ventilation and carbon dioxide production ratio (VE/VCO2), ventilation and breathed out oxygen ratio (VE/VO2)and percent of maximum predicted PVO2 (%PVO2). The measured parameters are shown in the the table.

BNP	263.6 ± 258.9
AT	9.56 ± 2.2
PVO2	12.35 ± 4.3
% PVO2	60.1 ± 20.3
VE/VO2	47.85 ± 11.9
VE/VCO2	38.14 ± 8.2

A reverse statistically significant correlation among BNP level, AT (r=-0.82), PVO2 (r=-0.80) and % PVO2 (r=-0.60) was observed.
Although PVO2 is an important measurement in predicting survival from heart failure, CPx is not a simple technique and is not widely available. Our preliminary data suggest that bedside BNP measurement can be considered an useful substitute of a complex test as the CPx for risk stratification.

P2952 N-terminal pro-brain natriuretic peptide: relationship to peak oxygen consumption and cardiac power output in patients with chronic heart failure

S.G. Williams[1], D.J. Wright[1], R. O'Brien[2], L.L. Ng[2], L.B. Tan[1]. [1]*Leeds General Infirmary, Institute For Cardiovascular Research, Leeds, United Kingdom;* [2]*University of Leicester, Medicine and Therapeutics, Leicester, United Kingdom*

N-Terminal pro-Brain Natriuretic Peptide (N-BNP), the 76 amino acid residue amino terminal portion of pro-BNP, has previously been shown to independently predict left ventricular function and 2 year survival in patients with CHF. N-BNP also provides a strong correlation with reduced left ventricular wall motion index on echocardiography. We examined the relationship between N-BNP and other indicators of left ventricular dysfunction determined by exercise testing in patients with CHF.
We recruited 86 patients with CHF (mean age 56 years, 84% male, mean LVEF 36.8±2%) and 10 healthy controls (mean age 52 years, 90% male) to undergo cardiopulmonary exercise testing with measurement of peak oxygen consumption (VO2) and haemodynamic variables such as peak cardiac power output (CPO), an independent predictor of prognosis. A venous blood sample was taken and plasma N-BNP was measured using an in-house non-competitive two site immunoluminometric assay for full length N-BNP.
We demonstrated significantly higher N-BNP (expressed as mean±SEM) levels in the CHF group (905±173 fmol/ml) compared with the control group (26.7±12 fmol/ml, $p<0.0001$). There was a significant negative correlation of log N-BNP with both peak VO2 ($r = -0.5$, $p<0.0001$) and peak CPO ($r = -0.572$, $p<0.005$) in the group with CHF. N-BNP and exercise parameters did not show any significant relationship in healthy controls.
We have shown plasma levels of N-BNP to significantly correlate with peak VO2 and peak CPO, both strong predictors of prognosis in CHF.

P2953 The efficacy of new interventional programmes depends on the stage of heart failure, evaluated by BNP plasma concentration

R. Pacher[1], K. Schenk[2], D. Sponer[1], R. Berger[1], P. Moser[2], M. Huelsmann[1]. [1]*University of Vienna, Internal Med II, Cardiology, Vienna, Austria;* [2]*Ludwig Boltzmann Institute, Cardiovascular Research, Vienna, Austria*

Background: Interventional programmes, including heart failure (HF) outpatient clinics and HF nurse specialists improve life quality, reduce readmission rates and decrease costs. Little is known in which stage of disease such interventions are most effective. Therefore, we evaluated the impact of severity of HF, determined by BNP plasma levels, on the efficacy of special outpatient care ("SOPC") in comparison with conventional outpatient care ("COPC").
Methods: 112 HF patients (mean age: 68±12 years, 63% males) who were hospitalized 3 months prior to study entrance were randomized to SOPC (n=48) or COPC (n=64). In all patients an individual prescription of RAAS antagonists and additional betablockade including an uptitration schedule according to the ESC guidelines was performed by a cardiologist at the first visit in the HF outpatient clinic. Diuretic regimes and additional therapies (digitalis, anticoagulants, antiarrhythmics) were prescribed as clinical appropriate. In the SOPC group regular home visits by a nurse specialist were arranged after 3, 6 and 12 months as well as in case of worsening HF to controll the precribed therapeutic regimen, body weight, heart rate, blood pressure and signs and symptoms of HF.
Results: In the SOPC group a significant reduction of the event rate (readmission rate and all cause mortality) was achieved (17% vs. 33%; p=0.04). BNP plasma levels were comparable in both groups (314±272 vs. 369±369 pg/ml; p=n.s.). Patients with BNP values <260 pg/ml had a comparable 1 year event-rate, with and without SOPC (0% vs. 3%; p=n.s.). Patients with BNP values >260 pg/ml, treated with SOPC had more events compared to patients with BNP values <260 pg/ml treated with COPC (32% vs. 3%; p=0.002). Patients with BNP values >260 pg/ml had fever events with SOPC than with COPC (32% vs. 75%; p=0.003).
Conclusion: The efficacy of SOPC depends on the severity of disease evaluated by BNP levels. BNP determination might be helpful in selecting patients for novel care programmes, especially when resources are limited.

P2954 Influence of additional restrictive filling patterns on N-terminal pro-brain natriuretic peptide in patients with systolic dysfunction

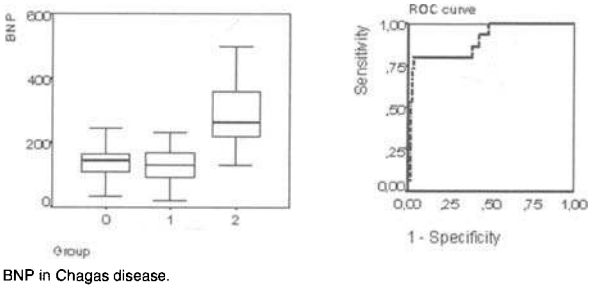
R M. Kell, D. Lossnitzer, F. Meister, J. Backs, C. Zugck, C. Krueger, M. Haass.
University of Heidelberg, Dep. of Cardiology, Heidelberg, Germany

Background: In patients with congestive heart failure (CHF) natriuretic peptides have been reported to improve risk assessment. The aim of the present study was to investigate whether in CHF patients with a systolic dysfunction (LVEF < 40%) an additional restrictive diastolic left ventricular dysfunction affects N-terminal pro-brain natriuretic peptide (NT-proBNP) concentrations.
Methods: Plasma concentrations of NT-proBNP were measured by ELISA in 296 CHF patients (age 59 ± 11 years, 84% male, n = 82 ischemic, n = 214 dilated cardiomyopathy, n = 37 NYHA functional class I, n = 120 class II, n = 139 class III, LVEF 22 ± 10% and peak oxygen uptake 14.7 ± 5.5 ml/min/kg). Doppler echocardiographic transmitral flow patterns revealed additional restrictive (E/A > 2 or E/A 1-2 and DT < 140 ms) filling patterns in 177 patients. Non-restrictive patterns were defined as E/A < 1 or E/A = 1-2 with DT > 140 ms.
Results: In patients with additional restrictive filling patterns (RF) plasma levels of NT-proBNP were twice as high (524 ± 555 vs. 216 ± 263 pmol/l; p < 0.001) than in patients with non-restrictive filling patterns (NRF). During a follow-up period of 31 ± 18 months 79 patients were admitted to hospital due to cardiac decompensation, 87 patients died due to cardiac causes. Compared to patients without cardiac event, patients with cardiac decompensation had significantly higher NT-proBNP concentrations (312 ± 446 vs. 473 ± 453 pmol/l; p = 0.009). There were also significant differences between survivors and non-survivors (320 ± 413 vs. 614 ± 626 pmol/l; p = 0.003).
Even after stratification into two groups (patients with non-restrictive filling patterns (NRF) and patients with additional restrictive filling patterns (NRF)) significant differences between the groups of patients without cardiac event and patients with cardiac decompensation (NRF: 178 ± 244 vs. 488 ± 576 pmol/l, p < 0.001; RF: 321 ± 291 vs. 586 ± 520 pmol/l, p = 0.009) and between the groups of survivors and non-survivors (NRF: 178 ± 211 vs. 388 ± 386 pmol/l, p < 0.001; RF: 301 ± 320 vs. 590 ± 622 pmol/l, p = 0.001) could still be detected.
Conclusion: Patients with systolic dysfunction and additional restrictive filling patterns have significantly increased concentrations of NT-proBNP compared to patients with non-restrictive diastolic dysfunction. However, even within each subgroup NT-proBNP predicted cardiac decompensation and cardiac death, indicating that its predictive value is not simply explained by discriminating restrictive and nonrestrictive diastolic dysfunction.

P2955 Brain natriuretic peptide in the diagnosis of systolic left ventricular dysfunction in Chagas disease

A.L. Ribeiro[1], A.M. Reis[2], M.V. Barros[3], M.R. Sousa[2], A.A. Perez[2], A.L. Rocha[2], F.S. Machado[3], M.O. Rocha[2]. [1]*Federal University of Minas Gerais, Belo Horizonte, Brazil;* [2]*Federal University of Minas Gerais, Belo Horizonte, Brazil;* [3]*Ecoar - Medicina Diagnostica, Belo Horizonte, Brazil*

Background: Left ventricular (LV) dysfunction is the main predictor of mortality in Chagas disease,a major health challenge in Latin America. It would be desirable to develop screening methods to indicate which patients should be submitted to complete echocardiographic LV evaluation.
Objective: To describe the behavior of brain natriuretic peptide (BNP) in a cohort of Chagas disease patients in order to establish its diagnostic value in the detection of LV global systolic dysfunction.
Methods: Chagas disease patients and healthy controls without other diseases were submitted to a standardized protocol, including ECG and echocardiography. They were divided into three groups according to serological status and LV ejection fraction (LVEF): group 0 (controls, n = 26), group 1 (Chagas disease, LVEF > 0.40, n = 136) and group 2 (Chagas disease, LVEF < 0.41, n = 15). BNP plasma concentrations were measured using radioimmunoassay. The diagnostic performance of the BNP values in the diagnosis of LV systolic dysfunction in the Chagas disease population was evaluated using the ROC curve.
Results: BNP concentrations were significantly elevated in group 2 when compared to group 1 and controls and are correlated with LVEF (rs: - 0.46, P < 0.01). The area under the ROC curve for various concentrations of BNP in the diagnosis of LV dysfunction was 0.89 ± 0.04. An elevated BNP (>210 pg/dl) has a sensitivity of 80%, specificity of 93.2%, positive predictive value of 52.2% and negative predictive value of 98.1%.
Conclusion: This study discloses a hitherto unrecognized elevation of BNP values in Chagas disease patients with global LV systolic dysfunction. BNP measurement can be an accurate test in the screening of patients who are at high risk of heart failure and death.



BNP in Chagas disease.

P2956 Does left ventricular geometry influence the concentration of plasma brain natriuretic peptide in patients with congestive heart failure?

R. Isnard[1], F. Pousset[1], O. Chafirovskaia[1], A. Gackowski[1], A. Carayon[2], D. Thomas[1], M. Komajda[1]. [1]*Pitié-Salpetrière Hospital, Cardiology Dept., Paris, France;* [2]*Pitié-Salpetrière Hospital, Biochemistry Dept., Paris, France*

A restrictive pattern of the transmitral flow which is a marker of increased left ventricular (LV) filling pressure has been shown to be associated with elevated plasma brain natriuretic peptide (BNP) in patients with congestive heart failure. However, little is known about the implication of LV geometry in this setting. We hypothetized that LV dilation should also contribute to increased plasma BNP levels through an increased in LV mass and LV stress.
We studied 187 heart failure patients with LV systolic dysfunction (LV ejection fraction < 45%), who underwent a complete echocardiographic study and a plasma BNP measurement (RIA). Patients were divided in subgroups according to the presence of a restrictive (R: E/A ratio > 2 or 1<E/A ratio < 2 and deceleration time of E < 130 ms) or non restrictive (nR: E/A ratio < 1 or 1<E/A ratio < 2 and deceleration time of E > 130 ms) pattern of the transmitral flow and to the degree of LV dilation (LV end diastolic diameter, LVEDD > or < median value, 67 mm).
The highest plasma BNP concentration was found in the subgroup of patients with both restrictive pattern and LV dilation (table).

	A: nR and LVEDD < 67 mm, n=59	B: nR and LVEDD > 67 mm, n=39	C: R and LVEDD < 67 mm, n=45	D: R and LVEDD > 67 mm, n=44
Plasma BNP (pg/ml)	94±112	159±180	165±192	281±190

Group A, B, C: NS, A versus D, p = 0.00002, B versus D, p= 0.013; C versus D, p = 0.015

Multiple regression analysis shows that LVEDD (beta 0.18), E/A ratio (beta 0.31) and LV ejection fraction (beta -0.32) were independently associated with plasma BNP.
We conclude that LV geometry independently influences the increase of plasma BNP in patients with chronic heart failure.

P2957 N-terminal pro-brain natriuretic peptide and hypertension. Its importance in the diagnosis of heart failure

M. Rivera[1], R. Talens[1], F. Garcia de Burgos[2], V. Climent[3], I. Roldan[4], G. Grau[5], J.L. Diago[6], V. Bertomeu[7] on behalf of Grupo Disfuncion VI, Comunidad Valenciana. [1]*Hospital La Fe, Research Unit, Valencia, Spain;* [2]*Hospital Elche, Cardiologia, Elche, Spain;* [3]*Hospital General, Cardiologia, Alicante, Spain;* [4]*Hospital Peset, Cardiologia, Valencia, Spain;* [5]*Hospital Alcoy, Cardiologia, Alcoy, Spain;* [6]*Hospital Castellon, Cardiologia, Castellon, Spain;* [7]*Hospital S Juan, Cardiologia, Alicante, Spain*

Background: Plasma N-terminal pro-brain natriuretic peptide (NT-proBNP) may be useful in the diagnosis of heart failure (CHF) and asymptomatic ventricular dysfunction (LVD) and its increase has a relationship with wall stress (WS). A frequent cause of the increase in WS is hypertension (HT). In a population study we compared NT-proBNP levels in subjects with and without the diagnosis of HT.
Methods: We studied 215 subjects (119 F, 96 M), age 66±9, (45-86), obtained from a random sample of 432 people from the Valencian Community (Alicante, Castellon, Valencia), who in a previous questionnaire declared to suffer from some degree of dyspnea. These 432 subjects were referred to their local hospital (10 hospitals were involved in the study) where blood samples were taken, an echo-Doppler study was performed, a specific questionnaire was completed which included the question asking if they had been previously diagnosed with HT. Blood samples were all measured independently at the same hospital. Out of the 432 subjects we got a positive answer from 215 and this study was complete in 202. Seventy two subjects declared that they had been previously diagnosed with HT and 130 had not been diagnosed with HT. NT-proBNP levels are in pg/ml and mitral flow propagation velocity (Vp) in cm/s.
Results: For the whole population NT-proBNP was 88 (0-2585). When we compared HT subjects, LV mass index 126±44 gr/m^2, Vp=57±19, with no HT, LV mass index 106±46 gr/m^2, Vp=60±19, we found higher NT-proBNP levels in HT, n=72, 123 (0-2184) when compared with no HT, n=130, 77 (0-2585), $p<0.01$. When we excluded systolic LVD we found 118 (0-2184) in HT and 72 (0-997) in those without HT, $p<0.01$. When we also excluded diastolic LVD we found 101 (0-430) in HT and 69 (0-997) in those without HT, $p<0.05$.
Conclusion: This population study shows that hypertension must be take into account when using NT-proBNP for CHF diagnostic with and without systolic LVD and independently from the detection or non-detection of diastolic LVD. This should be confirmed in new studies for its potential importance in clinical practice.

P2958 Brain natriuretic peptide for the evaluation of dyspnoeic patients in the emergency department

F. Post[1], D. Peetz[2], P. Knoess[1], D. Mertens[1]. [1]*Johannes Gutenberg-Universität, Klinik, II. Medizinische Klinik, Mainz, Germany;* [2]*Clinical Chemistry, Johannes Gutenberg Universität, Mainz, Germany*

Dyspnea is a common symptom in a general emergency department. While some dyspnoeic patients should quickly be referred to a cardiologist, others show diseases that are non-cardiac. Brain natriuretic peptide (BNP) is a well known serologic marker for determination left ventricular dysfunction. Thus, we examined wether by determination of BNP Patients with cardiac diseases can be divided from Patients with non-cardiac diseases.
Method: We measured BNP in 100 patients with dyspnea as leading symptom in the emergency department. Treating physicians were blinded to BNP measurements. Afterwards all patients were divided into "cardiac" and "non-cardiac" patients by a panel blinded to BNP results. This was done on the basis of all findings gathered during the patient's hospital stay. The severity of dyspnoea was evaluated by a standardized Scoring system. Groups were compared
Results: The table shows the results.

	BNP	Dyspnoea-Score
Cardiac (n= 57)	905,0 fmol/l	87,5
Non-cardiac (n= 43)	83,5 fmol/l	84
p-value	<0,0001	n.s.

Conclusion: BNP proves to be an excellent marker in the emergency department. Dyspnoe related to ventricular dysfunction can be divided from "non-cardiac"-dyspnea within 20 minutes. Measurements of BNP should be incorporated of the diagnostic work-up of dyspnea in the emergency department.

P2959 What are the N-terminal pro-brain natriuretic peptide values in normal subjects? A community-based study

M. Rivera[1], F. Garcia de Burgos[2], V. Bertomeu[3], A. Salvador[4], J. Cosin[5], J.L. Diago[6], R. Paya[7], V. Miro[8], F. Sogorb[9], J. Valencia[9] on behalf of Grupo Disfuncion VI, Comunidad Valenciana. [1]*Hospital La Fe, Research Unit, Valencia, Spain;* [2]*Hospital Elche, Cardiologia, Elche, Spain;* [3]*Hospital S Juan, Cardiologia, Alicante, Spain;* [4]*Hospital Peset, Cardiologia, Valencia, Spain;* [5]*Centro Investigacion La Fe, Cardiologia, Valencia, Spain;* [6]*Hospital Castellon, Cardiologia, Castellon, Spain;* [7]*Hospital General, Cardiologia, Valencia, Spain;* [8]*Valencia, Spain;* [9]*Hospital General, Cardiologia, Alicante, Spain*

Background: Plasma N-terminal pro-brain natriuretic peptide (NT-proBNP) may be useful in de diagnosis of heart failure (CHF) and asymptomatic ventricular (LV) dysfunction. However the range of NT-proBNP observed in subjects without cardiovascular (CV) disease or LV dysfunction are poorly defined and may be age specific.
Methods: We studied 215 subjects (119 F, 96 M), age 66±9, (45-86), obtained from a random sample of 432 people from the Valencian Community, Spain (Alicante, Castellon, Valencia), who in a previous questionnaire declared to suffer from some degree of dyspnea. These 432 subjects were referred to their local hospital (10 hospitals were involved in the study) where blood samples were taken, an echo-Doppler study was performed, a specific questionnaire was completed and subjects were classified according to NYHA functional classes. Tapes were all measured independently at the same hospital. Out of the 432 subjects we got a positive answer from 215. From this population, we identified subjects in sinus rhythm without CV, renal or pulmonary disease or diabetes, they were not on any CV medications, and they all had a normal systolic, diastolic and valvular function on Echo (n=88). NT-proBNP levels are in pg/ml.
Results: For the whole population values of NT-proBNP were 47 (0-318). When we compared age groups (50-60, AI; 60-70, AII and 70-80, AIII) we found $p<0.001$. We found a higher NT-proBNP in AII subjects, 69 (0-291), when compared with NT-proBNP in AI subjects, 27 (0-127), $p<0.05$. NT-proBNP was also higher in AIII subjects, 81 (16-318), $p<0.0001$.
Conclusion: This multicenter population study shows that in absence of disease or abnormal cardiac structure or function, the effect of age on NT-proBNP values may need to be taken into consideration when using NT-proBNP in clinical practice.

P2960 Brain natriuretic peptide levels in assessment of left ventricular dysfunction in type 2 asymptomatic diabetic patients

J.C. Charniot[1], J.P. Albertini[2], R. Cohen[3], F. Ferriere[2]. [1]*Hôpital Avicenne, Service de Cardiologie, Bobigny cedex, France;* [2]*Avicenne Hospital, Biochemistry, Bobigny, France;* [3]*Avicenne Hospital, Endocrinoly, Bobigny, France*

Background: Diabetes is associated with an increased risk for cardiovascular disease including increased left ventricular mass and wall thickness, reduced left ventricular systolic chamber. Echocardiography is the basis for diagnosis of left ventricular (LV) dysfunction, but its cost and availability limits its use for routine screening. As Brain Natriuretic Peptide (BNP) accurately reflects early LV dysfunction, we hypothesized that BNP might be useful as a prospective screening tool in asymptomatic diabetic patients to evaluate LV function prior to perform echocardiography.
Methods and Results: Among 121 type 2 asymptomatic diabetic patients, consecutively hospitalized for the assessment of diabetic status, 81 patients having both BNP and complete echocardiography were studied. BNP was measured in EDTA-whole blood by a point-of-care immunoassay (Triage®, Biosite Diagnostic, BMD, France). The results were blinded to the cardiologist making the assessment of LV diastolic dysfunction or LV systolic dysfunction. According to echographic data, patients were divided into normal, diastolic dysfunction and systolic dysfunction. In the 25 patients with a normal LV function, BNP levels averaged 14±4 pg/mL, and were lower than in those with abnormal cardiac function (71.8±13.3 pg/ml $p<0.0001$), in abnormal group, BNP levels were lower in those with either diastolic dysfunction (n=29, BNP=68±14 pg/mL, $P<0.0001$) or systolic dysfunction (n=9, BNP=224±41 pg/mL, $P<0.0001$). Well-controlled patients (n = 18) receiving cardiac drugs had abnormal diastolic LV function but similar BNP levels to those of patients with normal LV function (BNP=21±7 vs. 14±4 pg/mL, P=0.34). ROC analysis revealed an AUC of 0.88 for the detection of LV diastolic or systolic dysfunction and an AUC of 0.91 for the detection of systolic dysfunction. The best cut-off of BNP levels to detect LV dysfunction was 33 pg/mL (accuracy=80%, sensitivity of 84%, specificity of 76% positive and negative predictive values (PPV, NPV) of 88% and 69%, respectively). For the detection of LV systolic dysfunction, the best cut-off was 120 pg/mL (accuracy=82%, sensitivity of 83%, specificity of 78% and PPV=78% and NPV=83%, respectively). Age, LV mass index, LVEDD and LVESD were significantly and independently correlated with BNP (multivariate r=0.80, P=0.0002, 0.03, 0.002 and 0.01, respectively).
Conclusions: In asymptomatic diabetic patients, BNP levels could accurately predict LV dysfunction and may be helpful for monitoring therapy. A level <33 pg/mL may preclude the need for expensive echocardiography.

P2961 NT-pro Brain natriuretic peptide as marker for severity and prognosis of left ventricular dysfunction

B. Pieske[1], D. von Lewinski[1], C.H. Herrmann-Lingen[2], J. Sander[1], W. Schenker[1], T. Yksel[1], G. Hess[3], L. Binder[1]. [1]*University Hospital Göttingen, Cardiology and Pneumology, Göttingen, Germany;* [2]*University of Göttingen, Psychosomatics and Psychotherapy, Göttingen, Germany;* [3]*Roche Diagnostics, Tutzingen, Germany*

Brain natriuretic peptide (BNP) is secreted from the ventricles upon stretch, and BNP plasma levels are elevated in congestive heart failure. We determined the value of plasma levels of NT-pro BNP, the inactive N-terminal cleavage product during activation of BNP, for diagnosis of inapperent left ventricular dysfunction and assessement of prognosis in patients with overt heart failure.

Methods: Clinical evaluation of 30 healthy controls, 196 asymptomatic patients with cardiovascular risk profile (hypertension, diabetes, hyperlipidemia), but no known ventricular dysfunction (risk patients, RP), and 98 patients with echocardiographically demonstrated reduced left ventricular function (EF <40%; LV-Dys). Correlation of clinical parameters with NT-proBNP plasma levels (Elecsys, Roche Diagnostics, Tutzing, Germany).

Results: NTproBNP plasma levels were 36±4 pg/ml in controls, 251±62 pg/ml in RP ($p<0.01$ vs. controls), and 4716±695 pg/ml in LV-Dys ($p<0.001$ vs controls or RP). In RP, NT-proBNP plasma levels were positively correlated with systolic hypertension ($p<001$), pathological echocardiographic findings (LV hypertrophy, pathological E/A ratio, EF, LVEDD; p=0.037) and proANP plasma levels ($p<0.01$). In LV-Dys, NT-proBNP levels increased significantly with increasing NYHA class (NYHA I: 1759±855; NYHA II: 3027±605; NYHA III: 4271±733; NYHA IV: 10816±2623 pg/ml). There was a direct correlation between NT-proBNP levels and NYHA class (r=0.544; $p<0.001$), EF (r=-0.234; p=0.034), or age (r=0.249; p=0.041). In patients with normal kreatinine values (n=44), the correlation with NYHA class (r=0.621; $p<0.001$) or EF (r=0.417; p=0.006) was even better. After 1 year, 20 of 109 patients in LV-Dys (18.3%) had died. In these patients, the initial NT-proBNP levels (29.004 pg/ml) were significantly ($p<0.001$) higher than in survivors

P2962 Value of cardiopulmonary exercise testing and brain natriuretic peptide to predict prognosis of patients with chronic heart failure

S. Krüger, U. Janssens, J. Graf, T. Stickel, P. Hanrath. *University clinic, Medical Clinic I, Aachen, Germany*

Background: Cardiopulmonary exercise testing (CPX) and determination of brain natriuretic peptide (BNP) are used to estimate survival in patients (pts) with chronic heart failure (CHF). No data, however, exists comparing the prognostic value of both methods in a cohort of pts with moderate to severe CHF simultaneously.

Methods: We prospectively studied 85 consecutive CHF pts (59 ± 13 y., 63 men, LVEF 26 ± 6%, NYHA II-III, 34 ischemic heart disease, 51 dilated cardiomyopathy) with regard to the incidence of cardiac decompensation and/or cardiovascular mortality. At study entry all pts underwent a symptom-limited CPX with determination of peak VO2 and resting BNP plasma level.

Results: During the study period of 273 ± 142 days, 2 pts (2.4%) were lost to follow-up, 4 pts (4.8%) died from cardiac disease, and 10 pts (12.2%) suffered from cardiac decompensation. Kaplan-Meier estimates of freedom from cardiac decompensation/death differed significantly both for pts above and below the median values of BNP and peak VO2. The event-free survival rate was 95% in pts with a plasma BNP < 292 pg/ml (median value) compared to only 76% in pts with a BNP > 292 pg/ml ($p < 0.05$). CPX resulted in comparable findings with an event-free survival rate of 95% in pts with a peak VO2 > 15.3 ml/min/kg (median value) compared to only 76% *in* pts with a peak VO2 < 15.3 ml/min/kg ($p < 0.05$).

Conclusions: Plasma BNP seems to be a valuable tool for risk stratification in pts with moderate to severe CHF. BNP was comparable to the prognostic power of peak VO2. Thus BNP might help to reduce the need for more expensive and time consuming cardiac tests like CPX in the management of CHF.

P2963 Determination of a prognostic threshold for bedside B type natriuretic peptide in chronic heart failure

P. Jourdain[1], F. funck[1], M. bellorini[1], N. guillard[1], J. loiret[1], B. thebault[1], M. desnos[2]. [1]*René Dubos Hospital, Cardiology Dept., Pontoise, France;* [2]*Hopital G. Pompidou, Cardiology Dept., Paris, France*

NYHA classification and left ventricular ejection fraction are the major prognostic factors used in routine in chronic heart failure. BNP is a peptide secreted by the myocytes. We thus wanted to determine the interest of measuring bedside BNP compared to the traditional prognostic factors

Methods BNP plasmatic level was determined by bedside ultra fast "triage" immuno-fluorescent assay (Biosite laboratories). Left ventricular ejection fraction was determined by echocardiography.

Results We included 171 consecutive patients. The follow-up was 6 months. The patients were separate in two groups at the end of the follow-up. Group A included patients alive and the group B the patients deceased of heart failure during the follow-up. The group B presented a higher NYHA class (respectively 3,75±0,44 versus 2,28±1,05 $p<0,001$), a lower LVEF (28,5%±8,21 versus 37,7±8,8 $p< 0,001$) and a much higher BNP level (1208±166 versus 295±54,3 pg/ml $p< 0,001$) than group A. In univaried analysis, LVEF and BNP level can predict mortality (respectively $p< 0,04$ and $p<0,001$). In multivariate analysis, only BNP level is an independent prognostic factor ($p<0,001$).

Mortality is null in the group of the patients presenting a left ventricular ejection fraction < 35% having normal BNP and is about 47% at the end of the follow-up in the group of the patients with a left ventricular ejection fraction < 35% and a BNP > 300 pg/ml Mortality is related to the BNP level more than to the LVEF and NYHA class. In ROC curves, 800 pg/ml of BNP seems to be the best threshold to predict mortality at 6 month.

Conclusions the plasmatic BNP level obtained in routine is a very good prognostic marker in chronic heart failure. Patients with a BNP < 300 pg/ml have a good prognosis regardless to LVEF or NYHA classification. It allows to determine the prognosis of patients suffering from chronic heart failure in a finer way than the LVEF or NYHA class.

P2964 N-terminal brain natriuretic peptide (N-BNP) and atrial natriuretic peptide (N-ANP) in healthy neonates: marked and rapid increase after birth

T.S. Mir[1], R. Laux[2], B. Liedke[2], C. Heinze[2], S. Läer[3], J. Weil[4]. [1]*University Hospital Eppendorf, Paediatric Cardiology, Hamburg, Germany;* [2]*AK Barmbek, Neonatology, Hamburg, Germany;* [3]*Pharmakology, University Hospital Eppendorf, Hamburg, Germany;* [4]*Paediatric Cardiology, University Hospital Eppendorf, Hamburg, Germany*

The purpose of the study was to examine possible variances in the expression of N-BNP and N-ANP during the developmental circulatory changes after birth in healthy term neonates. Reference values for N-BNP and N-ANP in neonates are not known.

Methods: N-BNP and N-NP plasma concentrations were measured in peripheral venous (n=116) and umbilical cord blood (n=37) in 153 healthy term neonates (5.1,0 – 30 days) using a validated enzyme immunoassay. For comparison the newborns were divided into eight different age groups from birth to 30 days of age.

Results: The plasma N-BNP and N-ANP concentrations were the highest at 1 day of age (600, 254-893 and 110350; 10000 - 436000 fmol/ml) and were found significantly higher compared to 0 days of age (201, 58-430 and 5680 - 16900; $p<0.0001$). After this marked increase N-BNP and N-ANP levels decrease regularly and become stable at the fifth day of life.

Conclusion: The N-BNP and N-ANP plasma concentrations in healthy neonates showed a marked and preferential increase during the first days of age, suggesting that these natriuretic peptides have a physiological role in the perinatal change from fetal to neonatal circulation.

EXERCISE TRAINING IN HEART FAILURE

P2965 Assessment of ventilatory response to exercise in patients with chronic heart failure

R. Zymlinski, J. Petruk-Kowalczyk, W. Banasiak, P. Ponikowski. *Clinical Military Hospital, Cardiology, Wroclaw, Poland*

In chronic heart failure (CHF), cardiopulmonary exercise testing (CPX) is useful in monitoring clinical severity of the disease, determining the optimal timing of heart transplantation and for risk stratification. The aim of this study was to assess the practical value of newly described parameter derived from CPX i.e. the ventilatory response to exercise in unselected population of CHF pts.

Material and methods: We investigated 80 consecutive, stable CHF pts (61 men, age: 61 yrs, NYHA class I/II/III: 9/39/32, left ventricular ejection fraction [LVEF]: 33%) and 20 age- and sex-matched healthy controls that underwent CPX. The regression slope of minute ventilation against carbon dioxide production (VE/VCO2 slope) was used as an index of ventilatory response to exercise. In addition, peak oxygen uptake (peak VO2) and anaerobic threshold (AT) were measured.

Results: When compared to the control group CHF patients had lower peak VO2 (17.9±4.1 vs 32.4±7.1 ml/kg/min) and higher VE/VCO2 slope (34.8±10.1 vs 23.9±4.1, CHF vs controls respectively, $p<0.001$ for both comparisons). VE/VCO2 correlated neither with age nor with indices of left ventricular function (ejection fraction, diastolic and systolic diameters)($r<0.2$, $p>0.1$ in all analyses). However, we found correlation between VE/VCO2 and peak VO2 ($r=-0.51$, $p<0.001$), NYHA class (NYHA I-II vs III, $p<0.001$) and quality of live as assessed by the Minnesota questionnaire ($r=0.39$, $p<0.05$). To investigate reproducibility of VE/VCO2 slope 14 CHF pts and 10 controls underwent a second CPX within 10-18 days. In both groups VE/VCO2 slope had acceptable reproducibility (coefficient of variance of 14% in CHF and 11% in controls). During the follow-up (average 11 months) 10 (13%) CHF pts died. Augmented VE/VCO2 was related to poor prognosis independently of peak VO2, NYHA class and impaired left ventricular function ($p<0.05$).

Conclusions: In a broad, unselected population of CHF patients, increased exercise ventilation (VE/VCO2 slope) correlates with the objective and subjective indices of exercise intolerance, and may per se have a prognostic value. The assessment of VE/VCO2 could be used as an additional, simple and reproducible CPX-derived parameter in patients with CHF.

P2966 Improvement of regional myocardial function following exercise training in left ventricular dysfunction measured by Doppler myocardial imaging

M. Deljanin Ilic[1], S. Ilic[2], Lj. Nikolic[1], D. Djordjevic[1], V. Stoickov[1], V. Skakic[2]. *[1]Institute of Cardiology, Echo Lab, Niska Banja, Yugoslavia; [2]Institute of Cardiology, Clinical Cardiology, Niska Banja, Yugoslavia*

The aim of the study was a quantitative assessment of the effects of exercise training on regional systolic and diastolic myocardial function in patients (pts) with left ventricular (LV) dysfunction, using pulsed wave Doppler myocardial imaging (PW-DMI).

Method: In the group of 51 male pts (mean age 56.7 ± 8.7 years) with ejection fraction (EF) < 40%, at baseline and after four weeks echocardiography studies were performed.

Regional myocardial function, was obtained from apical approach, with PW-DMI sample volume within any LV segment at basal and medium level. In each adequately visualized segment we calculated m.v. of systolic (S), early (E) and late (A) diastolic waves and their ratio E/A - index of regional diastolic function. After the initial study, pts were randomized to trained (T, n=32) and control (C, n=19) groups. Patients in T group exercise daily about 40 minutes in the 10 to 15 minutes intervals over a period of four weeks at a residential rehabilitation center while pts in C group received usual community care.

Results: After four weeks, in the T group regional diastolic function of basal and medium LV segment significantly improved (E/A from 0.88 ± 0.39 to 0.98 ± 0.41, $P<0.05$ and E/A from 0.82 ± 0.37 to 0.95 ± 0.42, $P<0.01$) as well as regional systolic function (S from 7.2 ± 3.1 to 8.0 ± 3.3 cm/s, $P<0.05$ and S from 6.7 ± 3.3 to 7.5 ± 3.5 cm/s, $P<0.05$). In the C group evaluation of regional diastolic function of basal and medium LV segments showed slightly changes (E/A from 0.89 ± 0.36 to 0.93 ± 0.39, NS and E/A from 0.86 ± 0.35 to 0.89 ± 0.38, NS) as well as regional systolic function (S from 6.8 ± 3.1 to 7.1 ± 3.5 cm/s, NS and S from 6.0 ± 2.9 to 6.4 ± 3.3 cm/s, NS). EF increased slightly in the T group but was not changed in the C group.

Conclusion: In LV dysfunction exercise training significantly improved regional systolic and diastolic myocardial function which can be estimated by PW-DMI, even before significant changes in LV EF occurred.

P2967 Exercise training decreases biventricular oxidative metabolism and improves left ventricular efficiency in patients with dilated cardiomyopathy

K. Stolen[1], J. Kemppainen[1], H. Ukkonen[1], K. Kalliokoski[1], M. Luotolahti[2], J. Airaksinen[3], P. Nuutila[1], J. Knuuti[1]. *[1]University of Turku, Turku PET Centre, Turku, Finland; [2]Turku University Central Hospital, Department of Clinical Physiology, Turku, Finland; [3]Turku University Central Hospital, Department of Internal Medicine, Turku, Finland*

The effect of exercise training on myocardial oxidative metabolism and efficiency was studied in 16 clinically stable patients with dilated cardiomyopathy (NYHA class I-II) using positron emission tomography (PET) techniques. Nine of these patients participated in a 5 month endurance and strength training program at an intensity of 70% of peak oxygen consumption (VO2), while 7 patients served as control subjects. Measurements of left ventricular function were assessed using two-dimensional echocardiography. Basal oxidative metabolism in both the left (LV) and right (RV) ventricle were measured using the monoexponential clearance rate of [11C]acetate (kmono). An estimation of myocardial work per gram of tissue was calculated as (systolic blood pressure x stroke volume x heart rate)/LV mass. Myocardial efficiency was calculated as myocardial work/LVkmono. The patient groups were comparable at baseline in terms of LVkmono, LV work, and LV efficiency, however baseline RVkmono values were slightly lower in the training group compared to the control group. Peak VO2 increased by 27% in the training group (19.4±4.1 to 24.6±5.2 ml/kg/min; $P<0.001$) where no change was observed in the control group (20.6±4.2 to 21.2±2.9 ml/kg/min; P=NS). An improvement in ejection fraction was also observed in the training group (33±8 to 39±9%; P=0.004) compared to the control group (35±7 to 37±6%; P=NS). Biventricular oxidative metabolism along with LV work and efficiency results are shown in the table.

	Training group		Control group	
	Baseline	Follow-up	Baseline	Follow-up
RVkmono (/min)	0.047±0.006#	0.0421±0.007*	0.056±0.006#	0.0570±0.009
LVkmono (/min)	0.065±0.014	0.059±0.016*	0.073±0.012	0.074±0.014
LV work (mmHgxml/g)	1.88±0.74	2.02±0.63	2.46±0.55	2.54±0.59
LV efficiency (mmHgxml/g/min)	28.8±9.8	34.4±7.9*	33.6±6.9	34.2±5.4

*P<0.05 (Baseline vs. Follow-up); #P<0.05 (between groups).

Exercise training improved LV function and exercise tolerance while biventricular oxidative metabolism decreased. This decrease resulted in an enhanced LV efficiency. Therefore, we conclude that exercise training is an energetically favorable way to improve myocardial function and exercise tolerance in patients with dilated cardiomyopathy and mild heart failure.

P2968 Augmented plasma adenosine response to exercise and reduced exercise ammonia in heart failure: a possible alteration of purine degradation

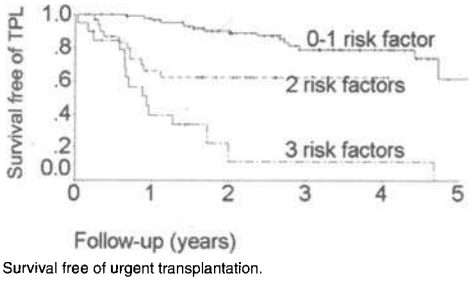
T. Kinugawa, S. Osaki, K. Ogino, M. Kato, Y. Tomikura, O. Igawa, I. Hisatome, C. Shigemasa. *Tottori University Faculty of Medicine, Div of Cardiology/1st Dept Int Med, Yonago, Japan*

Background: During strenuous muscle exercise, purine nucleotide degradation occurs and adenosine monophosphate (AMP) is metabolized into two pathways. One is deamination by AMP deaminase, an enzyme responsible for ammonia production, and other is dephosphorylation by 5'-nucleotidase, an enzyme responsible for adenosine production. Recently, it has been reported that inheritance of the mutant AMP deaminase 1 allele is associated with good prognosis in patients with chronic heart failure (CHF). Such patients have reduced AMP deaminase activity in their skeletal muscle and might have enhanced adenosine production with relative activation of 5'-nucleotidase. This study determined whether plasma adenosine response to exercise is augmented in patients with CHF.
Methods: Maximal ergometer exercise tests with expired gas analysis were performed in 51 patients with CHF (age=61±2 years, left ventricular ejection fraction=38±1%, peak VO2=18.0±0.7 ml/min/kg, NYHA class I/II/III=19/18/14) and 20 normal controls. Serial changes in plasma ammonia and adenosine were determined. The exercise response was assessed by the ratio for the change (delta) in each metabolite to peak work rate.
Results: Peak work rate decreased as CHF worsened (Control, NYHA I, II, III: 155±11, 141±10, 97±8, 72±7 watts, $p<0.0001$). Resting plasma adenosine, but not ammonia, were higher in class III CHF (22±5, 17±4, 31±7, 46±13 nmol/L, $p<0.05$). The changes in plasma ammonia by exercise were smaller as CHF worsened. The ratio for delta-ammonia to peak work rate was smaller in class III CHF (0.59±0.13, 0.41±0.06, 0.37±0.10, 0.22±0.11 μg/dL.watts, $p<0.05$). Plasma adenosine response to exercise tended to be augmented in class III CHF, and the ratio for delta-adenosine to peak work rate was significantly augmented in class III CHF (0.90±0.20, 0.86±0.14, 1.11±0.27, 2.92±0.67 nmol/L.watts, $p<0.001$).
Conclusions: Plasma adenosine levels were significantly higher, and adenosine response to exercise normalized with the peak work rate was augmented in patients with severe heart failure. On the other hand, plasma ammonia response was attenuated. These results suggest that there may be an altered adenine nucleotide metabolism with shunting of ATP catabolic pathway from AMP deamination to adenosine production. Given the physiological actions, the enhanced adenosine production at rest and during exercise may have cardioprotective effects in patients with CHF.

P2969 Combination of submaximal and maximal exercise testing for improvement of prognostic assessment in heart failure

H.P. Brunner-La Rocca[1], M. Brehm[1], D. Weilenmann[2], H. Rickli[3], C. Schalcher[3], E. Oechslin[1], W. Kiowski[1]. [1]*University Hospital, Cardiology, Zurich, Switzerland;* [2]*Kantonsspital, Cardiology, Basel, Switzerland;* [3]*Kantonsspital, Cardiology, St.Gallen, Switzerland*

Peak exercise testing has been used for long to assess prognosis in congestive heart failure (CHF). More recently, there has been an increasing interest in submaximal exercise testing, trying to substitute maximal exercise testing. However, maximal and submaximal exercise testing may not test the same. Thus, combining the 2 tests may augment the predictive value of exercise testing.
Methods: Ergospirometry was performed in 146 patients with CHF (EF 27±13%), using a 2-step treadmill protocol (first 6 minutes 1mph, 6% elevation, followed by a ramp protocol 0.15W/kg/min). The mean response time (MRT=O2-deficit/DVO2) of VO2 during initiation of exercise and peak oxygen consumption (VO2max) were measured. DVO2=difference of VO2 from rest to steady state. Cardiac death and urgent transplantation were considered as endpoints (follow-up 27±17months).
Results: Thirty-two patients (22%) died and 11 (8%) were urgently transplanted. In multivariate Cox-regression analysis, MRT (hazard ratio (HR) for combined endpoint: 1.68 per 10s, $p<0.0001$), VO2max expressed as % of normal value (HR=0.62 per 10%, $p<0.0001$), and resting systolic blood pressure (SBP; HR=0.71 per 10mmHg, $p=0.003$) were independently related to prognosis. The following cut-off points were used (combined endpoint, all $p<0.001$): MRT>50s (HR=4.47), VO2max<50% (HR=4.67), resting SBP<105mmHg (HR=3.11). Patients with all 3 risk factors (n=20) had a very bad prognosis (mortality/combined endpoint: 1 year: 49%/60%; 2 years: 83%/89%), while patients with no or only one factor (n=94) were not at particular risk (1 year: 3%/3%; 2 years: 10%/11%; figure).
Conclusion: The combined use of parameters of submaximal and maximal exercise testing provides a more complete picture for risk assessment in CHF.

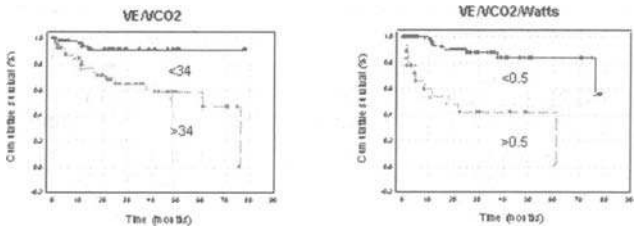


Survival free of urgent transplantation.

P2970 VE/VCO_2 slope normalized for the achieved exercise workload (Watts) better predicts prognosis than the VE/VCO_2 slope in heart failure

M. Guazzi[1], S. De Vita[1], G. Reina[2], M.D. Guazzi[1]. [1]*University of Milan, Institute of Cardiology, Milan, Italy;* [2]*Institute of Statistics, University of Milan, Milan, Italy*

Background: The level of physical activity is tightly related to prognosis in chronic heart failure (CHF). The slope of the VE/VCO2 relationship during exercise is a strong predictor of survival in CHF. Nevertheless, this parameter does not account for endurance and intensity of exercise.
Aim of the present study was to assess whether normalization for the achieved exercise workload (Watts) strengthens the prognostic power of the VE/VCO2 slope in CHF.
Methods: For this purpose, we enrolled in a prospective study 100 patients (78 men, 22 women), mean age 60±9 years, NYHA class II-III, with mean ejection fraction of 35±10% in stable haemodynamic conditions and optimized pharmachological therapy. Patients underwent maximal cardiopulmonary testing by cycloergometer (personalized ramp test).
Results: The mean value of oxygen consumption at peak exercise (peak VO2) was 16.2±4.3 ml/kg/min and the averages of VE/VCO2 slope and VE/VCO2/W were 34±8 and 0.39±0.2, respectively. The mean follow-up of the study was 26.5±2 months.
The survival curves analysis by Cox regression hazard method showed that long term prognosis is better predicted by the VE/VCO2/W, than the VE/VCO2 ($p<0.0001$ vs $p<0.03$). Figures show Kaplan Meier curves for VE/VCO2 slope (cut-off: 34) and VE/VCO2/W ratio (cut-off: 0.5).



Kaplan Meier survival curves.

Conclusions: These results document that both VE/VCO2 and VE/VCO2/W are related with mortality. Nevertheless, normalization of VE/VCO2 slope for the achieved exercise workload strengthens the prognostic power of this relevant clinical indicator.

P2971 Lower prognostic value of peak VO_2 compared with the exercise ventilatory response in the patients with heart failure on beta-blocker therapy

M. Metra[1], S. Nodari[1], E. Vizzardi[1], N. Pezzali[1], E. Trussardi[1], G. Parinello[2], C. Giovanelli[1], L. Dei Cas[1]. [1]*Chair of Cardiology, University of Brescia, Brescia, Italy;* [2]*Unit of Medical Statistics, University of Brescia, Brescia, Italy*

Long-term beta-blocker (BB) administration to the patients with chronic heart failure (HF) is associated with a significant improvement in left ventricular ejection fraction (LVEF) and hemodynamics with only small changes in maximal functional capacity. We thus hypothesised that the prognostic value of these parameters could be influenced by BB therapy. One-hundred eighty-four patients with HF (LVEF, 20±7%; peak VO2, 14.3±4.5 ml/k/min) were assessed by MUGA and cardiopulmonary exercise (ex) testing with invasive hemodynamic monitoring before and, in the 164 patients (89%) who survived, after 9-12 months of maintenance therapy with carvedilol (n=102; 41±17 mg/day) or metoprolol tartrate (n=62; 106±45 mg/day). During the 29±20 months of follow-up after the reassessment on BB therapy, 28 of the 164 patients (18%) died and 16 underwent heart transplantation (Tx). Among the parameters assessed before the initiation of BB therapy, Cox multivariate regression analysis selected peak VO2 (HR, 0.83; 95%CI, 0.75-0.91; p=0.0002) and serum creatinine (p=0.002) as significant predictors of total mortality and, similarly, serum creatinine (p=0.007), peak VO2 (p=0.002) and NYHA class (p=0.004) as predictors of mortality and Tx. In contrast, when the data obtained during BB therapy were used, the variables selected were serum creatinine (p=0.005), VE/VCO2 slope (HR, 1.06; 95%CI, 1.01-1.10, p=0.009), age (p=0.027) and resting PWP (p=0.035). Six, 12, 24 and 36 months cumulative survival was of 97%, 96%, 94% and 94% respectively, in the patients with peak VO2 > 14 ml/kg/min, 98%, 90% and 83% and 77% in the patients with peak VO2 < 14 and > 10 ml/kg/min and 74%, 64%, 59% and 51% in the patients with peak VO2 < 10 ml/kg/min (p<0.001 at log-rank tests). Six, 12, 24 and 36 months survival was 98%, 96%, 92% and 88% in the 65 patients with a normal, <35, VE/VCO2 slope and 91%, 83%, 79% and 76% in the other 99 patients with a VE/VCO2 slope > 35 (p<0.001). Peak VO2 was highly related to peak ex heart rate (HR), CI, stroke volume index (SVI), mean pulmonary artery pressure (PAP) and PWP (r= 0.44, 0.77, 0.61, -0.37 and -0.34, respectively; all p<0.001) while VE/VCO2 slope was less related to peak ex HR (r=-0.15), CI (r=-0.53) and SVI (r=-0.51). Thus, maximal functional capacity remains useful for the prognostic assessment of the HF patients on BB therapy. The lower prognostic value of peak VO2 may be related to its greater dependence on the HR and CI response to ex which may be influenced by BB therapy independent from its beneficial effects on LV function.

P2972 Effect of exercise training on skeletal muscle metabolism in patients with dilated cardiomyopathy

J. Kemppainen[1], K. Stolen[2], K. Kalliokoski[2], T. Salo[2], J. Airaksinen[2], P. Nuutila[2], J. Knuuti[2]. [1]*University of Turku, Turku PET Centre, Turku, Finland;* [2]*University of Turku, Turku PET Centre, Turku, Finland*

Most training studies related to chronic heart failure involve a combination of patients with an etiology of ischemic and idiopathic cardiomyopathy. Due to limited data available regarding on effect of exercise training on skeletal muscle metabolism in patients with idiopathic dilated cardiomyopathy (DCM) we aimed to determine the adaptive peripheral changes in perfusion and metabolism in DCM after combined aerobic and resistance training.

Fifteen, NYHA I-II, DCM patients on stable medical therapy were studied. The subjects were prospectly selected to either a training group (n=8, LVEF=34±8%) or a non-training group (n=7, LVEF=36±6%) based on residence. The training program lasted for five months, 3 days/week at an intenisty of 65-70% of VO2max. Also, 2 days/week home training was included into program. Training consisted of both strength and endurance training components. Muscle blood flow, oxygen consumption, and glucose uptake was quantified using [15O]-water, [15O]-oxygen, [18F]-FDG, and positron emission tomography (PET). Subjects performed one-legged isometric exercise at an intensity of 10% of maximal isometric force during scanning. The measurements were done during euglycemic hyperinsulinemic clamp before and after exercise training or equal control period.

Attendance in the training program was 88%. Average improvement in exercise capacity was 27% in training group, p<0.001. Training improved whole body glucose uptake (23%, p<0.05), resting (53%, p=0.08) and exercise stimulated glucose uptake (55%, p<0.05). Changes in resting or exercise stimulated blood flow or oxygen uptake were not observed after training. Measured variables remained unchanged in control group.

Training was safe and it improved exercise capacity efficiently in this patient group. Insulin sensitivity was improved along with insulin and exercise stimulated skeletal muscle glucose uptake by training. Therefore, regular exercise with combined strength and endurance training was beneficial for these patients and counteracts the metabolic disturbaces caused by DCM.

DIAGNOSIS AND MONITORING OF HEART FAILURE

P2973 Elevation of biochemical markers of myocardial injury associated with pulmonary embolism

M D. Stewart[1], H H. Gray[2]. [1]*Southampton General Hospital, Wessex Cardiac Unit, Southampton, United Kingdom;* [2]*Southampton General Hospital, Wessex Cardiac Unit, Southampton, United Kingdom*

The introduction of cardiac specific troponin estimation has improved the recognition and management of patients with acute coronary syndromes (ACS). However, conditions other than ACS may also present as emergencies with acute chest pain and dyspnoea, such as acute pulmonary embolism (PE). The tendency to assume that elevation of these biochemical markers always indicates coronary artery disease may potentially result in incorrect diagnosis and inappropriate investigation. We present results from an epidemiology study into the investigation and management of confirmed pulmonary embolism in Southampton, UK (population 430,408).

Over a one-year period in Southampton University Trust Hospitals 219 cases of pulmonary embolism were confirmed by ventilation perfusion lung scan or helical computerised tomographic pulmonary angiography. Due to diagnostic uncertainty at presentation, biochemical markers of myocardial injury (creatinine kinase [CK] and troponin) were requested by clinicians in 71 cases (38 had creatinine kinase levels only, 10 troponin had levels only, and 23 had both CK and troponin measured). 3 patients had troponin levels >1.5ug/L, 2 of whom also had CK levels >250IU/L. 8 further patients had troponin levels between 0.15 -1.5ug/L without CK elevation, 5 patients had an elevation of CK >250IU/l without troponin measurement and 4 patients had troponin levels 0.15 -1.5ug/L without CK measurement. Thus, 20 of 71 (28.1%)of patients with confirmed PE had elevation of either CK or troponin levels.

An elevated troponin or CK may be found in acute pulmonary embolism and therefore the detection of a raised biochemical marker of myocardial injury does not necessarily indicate ACS or exclude a clinically suspected acute PE. The mechanisms by which these markers are raised in acute PE may be multifactorial but will include myocardial ischaemia induced by acute right heart strain or haemodynamic compromise due to massive PE. Further research is required to determine whether elevation of these markers is related to prognosis or if they may be used to indicate potential benefit from thrombolysis therapy in acute PE.

P2974 Coronary angiography in CHF patients with no history of ischaemic heart disease. A clinical study

A. Mortara, P. Delfino, C. Auguadro, C. Cavalotti, D. Poggio, S. Saccaggi, M. Manfredi, G. Specchia. *Policlinico di Monza, Cardiology, Monza (MI), Italy*

The aim of the present study was to verify the clinical usefulness of coronary angiography (CA) in a consecutive series of CHF patients admitted to our heart failure clinic. Indication to CA was proposed following the recent European guidelines in order to elucidate the cause of CHF and to assess prognosis. Among 112 patients with history of heart failure and LVEF < 40% who underwent CA, 51 subjects (mean age 63±10 yrs, LVEF 32±6%, NYHA cl. II-III) were studied for uncertain aetiology of the disease. When not contraindicated an effort test or Echo-dobutamine test were performed before CA in all these patients. Diabetes, hypertension and dislipidemia were present respectively in 20%, 41% and 20% of the 51 patients, while none suffered of previous myocardial infarction or angina.

After non invasive procedures an ischemic aetiology was suggested in 6 patients, all affected by diabetes plus an other risk factor. CA showed normal coronary arteries in 42, one vessel in 4, two vessels in 4 and three vessels in 1 subject. Four out of 5 patients with two or three vessels disease were treated with PTCA or CABG. In the absence of diabetes and a positive non-invasive test, CA showed normal coronary arteries in 100% of the patients.

Conclusion: In those CHF patients who: i) do not present positive history of ischemic heart disease, ii) have no angina or diabetes, iii) can be submitted to a valid functional test which results negative, coronary angiography does no give further clinical information and may be avoided. This approach will allow to significantly reduce the high costs of treatment of heart failure with undetermined aetiology.

P2975 Circadian distribution of onset of acute pulmonary oedema in 206 consecutive patients with or without coronary artery disease

C. Pena-Gil, J. Figueras, J. Guerra, J. Rodriguez, J. Soler-Soler. *Hospital Vall d'Hebron, Cardiology, Barcelona, Spain*

In 206 consecutive patients admitted within 12 hours of onset of an acute cardiogenic pulmonary edema (APE) the clinical and echocardiographic characteristics were prospectively investigated, with especial emphasis in the time of onset of respiratory symptoms. Patients with chronic heart failure or those with progressive heart failure over a period of >12 hours were excluded. In 176 (85%) a diagnosis of coronary artery disease (CAD) was based on a history of myocardial infarction, presence of angina with ECG changes during APE, coronary estenosis >70% in =>1 main vessel or clear scintigraphic evidence of reversible ischemia. Of the remaining 30 patients,10 presented isolated valvular heart disease (5%), 10 hypertensive cardiomyopathy (5%) and 11 had other cardiac disease (5%).

The mean interval between onset of APE and hospital admission was 3.3±2.7 hours. Circadian presentation was distributed in 3 intervals of 8 hours: 05-12 (a), 13-20 (b) and 21-04 (c). Overall, 109 (53%) patients presented APE in c, 58 (28%) in a and 39 (19%) in b ($p<0.001$). Patients with CAD showed a similar distribution: 91 (50%) in c, 51 (28%) in a, and 33 (18%) in b ($p<0.001$) than those without CAD: 16 (55%) in c, 7 (24%) in a and 6 (21%) in b ($p<0.05$). Moreover, among patients with rapid atrial fibrillation (>130 beats/min) as trigger of APE (n:29), 21 with CAD and 8 without, the circadian distribution (c: 16 (53%), a: 5 (17%) and b 8(27%)($p<0.04$)) was also similar (p: ns) than in those without rapid atrial fibrillation (c:93 (53%), a:53 (30%), and b 31 (17%)($p<0.001$)).

Conclusion: In >50% of patients with APE onset of sypmtoms occurs from 21-04 hours and in only <20% it occurs from 13-20 hours. This nocturnal predominance appears to be independent of the underlying kind of heart disease or trigger of this event.

P2976 Myocardial damage detected by troponin T in heart failure is associated with low functional capacity in the 6-minute walk test

E.R. Perna, N. Augier, S.M. Macin, J.P. Cimbaro Canella, D.A. Moratorio, E.F. Farias, J.R. Cialzeta, P. Liva. *Instituto de Cardiologia J. F. Cabral, Heart Failure Clinic, Corrientes, Argentina*

Background: Six minute walk test offers an objective measures of functional capacity (FC) and yields prognostic information in patients (pts) with chronic heart failure (CHF). Ongoing myofibrilar degradation has been detected by troponin T (cTnT) in CHF. We hypothesize that myocardial damage could be associated with a low FC in pts with CHF.

Methods: Between 01/2001 and 03/2001, 153 outpatients from a Heart Failure Program were prospectively included. Patient's evaluation included clinical examination, ECG, echocardiography and biochemical test. Baseline cTnT of 3° generation >=0.02 ng/mL was considered abnormal. Low functional capacity was defined as a walked distance <300 mts and was present in 33 pts (21.5%)(Group 1).

Results: Mean age of group 1 was 70±9 vs. 60±11 years in pts without low FC (Group 2)($p<0.001$), and women were 54.5% vs. 27%, respectively ($p=0.002$). Intermittent claudication was more frequent in group 1(18 vs. 5%, $p=0.01$) and NYHA functional class was higher (2.81±0.5 vs 2.14±0.9). Ischemic etiology was similar between groups, but hypertensive etiology was more prevalent in group 1 (36 vs 16%, $p=0.009$). cTnT >=0.02 ng/mL was detected in 45% of group 1 and 20% of group 2 ($p=0.003$). In a multiple regression analysis, independent variables associated with a low FC were: age (OR=1.09, CI=1.03-1.16, $p=0.002$), functional class (OR=2.9, IC=1.3-6.4, $p=0.009$), female gender (OR=4.7, IC=1.7-13.3, $p=0.003$), hepatomegaly (OR=10.9, IC=1.1-103, $p=0.03$) and myocardial damage (OR=3.3, IC=1.2-9.4, $p= 0.02$).

Conclusion: Low FC in a walk test was present in a quarter of patients with CHF and it was associated with clinical characteristics such as age, female gender and NYHA class as well as increased level of cTnT. The biochemical evidence of ongoing myocardial injury in CHF stable patient was a strong predictor of low performance in 6-minute walk test.

P2977 Endocardial acceleration based implantable system for monitoring acute ventricular failure

G. Plicchi[1], E. Marcelli[1], T. Bombardini[1], G. Gaggini[2]. [1]*S.Orsola-Malpighi Hospital, Biomedical Technology Unit, Bologna, Italy;* [2]*Sorin Biomedica Cardio, Saluggia (VC), Italy*

Acute volume overloading leading to acute heart failure and possibly to death is not a rare event in clinical practice and no implantable systems able to alert such dramatic events are currently available. Peak endocardial acceleration during isovolumic contraction phase (PEA I) is determined by left ventricle (LV) dP/dtmax changes and during isovolumic relaxation (PEA II) by both aortic pressure and LVdP/dtmin.

Aims of this study: 1) to test the capability of an implantable endocardial acceleration (EA) sensor to immediately detect systolic and diastolic impairment during LV acute volume overload, as documented by LV end diastolic pressure (LVEDP).

Methods: in 6 anesthetized sheep (63 ± 4Kg) an EA sensor, housed in the tip of a standard pacing lead (Best, Sorin), was screwed in the apex of the right ventricle. A Millar catheter was positioned in the LV to monitor LVdP/dtmax, LVdP/dtmin and LVEDP; external ECG was recorded. Once basal data were acquired 2L liters of glucose solution (10%) were acutely infused through the jugular vein in 10 min.

Results: at 1L volume overload PEAI suddenly increased from 0.57±0.24 g to 0.93±0.40g, strictly related to LVdP/dtmax variation from 798±373 mmHg/s to 1021±280 mmHg/s at 1L and to LVEDP increase from 12.7±0.5 mmHg to 21.2±4.5 mmHg.

After an initial phase of increase of PEAII (from 0.22±0.10 to 0.28±0.09 g), extremely sensitive to LVEDP increase, a drop of both PEA II and LVdP/dtmin occurred at 2L volume overload, when LVEDP reached values (31±4mmHg) indicative of LV dilation and lung edema.

Conclusions: The EA sensor was able to detect 1L acute volume when acute recruitment of LV function through the Starling mechanism occurred. A PEA I and PEA II based survey system for hemodynamically instable pts can promptly alert life threatening events of acute volume overload and acute diastolic failure. This implantable EA based system opens a new window in early and effective alert systems for patients that risk acute volume overloading.

P2978 Clinical and etiological features, management and outcomes of acute heart failure: the EFICA cohort study

F. Zannad[1], A. Cohen Solal[2], M. Desnos[2], L. Guize[2], Y. Juillière[3], A. Mebazaa[4], P. Rougé[5], K. Samii[4] on behalf of the EFICA investigators, France. [1]*INSERM-CHU, Centre d'investigation clinique (CIC), Nancy, France;* [2]*AP-HP, cardiology, Paris, France;* [3]*CHU, Cardiology Dept., Nancy, France;* [4]*AP-HP, Emergency and ICU, Paris, France;* [5]*CHU, Emergency and ICU, Toulouse, France*

Introduction: Acute heart failure (AHF) accounts for 14,000 hospitalisations per year in France which is twice as many as hospitalisation for acute MI. Yet, no recent observational study of AHF is available for reference. Furthermore, compared to chronic HF, AHF has been the subject of very few clinical trials.

Methods: EFICA (Etude d'observation Francaise de l'Insuffisance Cardiaque Aiguë) is an observational cohort study with prospective case ascertainment of patients admitted consecutively from May to December 2001 to 60 representative CCUs and ICUs in France, with the diagnosis of AHF.

Results: A total of 599 patients were enrolled. They were aged 73 [25-98], and had the following characteristics: aged above 80: 31%; male 58%; admitted through an emergency unit: 54%; previously diagnosed with CHF: 65%; previously admitted for AHF: 35%. AHF most frequent causes were ischemic heart disease 60%, dilated cardiomyopathy 28%, valvular disease 25% and hypertension 21%. The most frequent precipitating factors were acute myocardial ischemia 36%, arrhythmia 26%, infection 18%. On admission 82% had pulmonary oedema and 29% had cardiogenic shock. Echocardiography was performed on admission in 400 pts. Median LVEF (measured in 322 pts) was 35%. LVEF was >45% in 26% of pts. On admission 52% of pts were receiving diuretics, 42% ACE inhibitors and 23% betablockers. CKMB was measured in 240 pts among which 37% had abnormal levels. Troponine I, measured in 337 pts was high in 46%. Serum creatinine was elevated in 51%. During hospitalisation, 60% received ventilatory assistance, 4% circulatory assistance 53% inotropic support (82% dobutamine) and 3 pts heart transplant. Median length of stay (LOS) at ICU was 4 days [1-79] and total LOS was 12 days[1-113]. In-hospital mortality was 29% among which 76% was related to cardiogenic shock, 25% acute MI and 12% ventricular arrhythmia deaths. Sudden death accounted for 18% of total deaths.. Six month outcome data and prognostic analyses are currently being performed and will be presented at the meeting.

Conclusion: EFICA provides an up-to-date database on clinical and etiological features, management and outcomes of AHF which are critical for designing new management strategies and clinical trials specific to this deadly condition.

PULMONARY CIRCULATION

P2979 NT-pro brain natriuretic peptide as novel marker for diagnosis and prognosis of acute pulmonary embolism

B. Pieske[1], L. Binder[2], C.H. Herrmann-Lingen[3], N. Hruska[1], G. Hess[4], S. Konstantinides[1]. [1]*University Hospital Göttingen, Cardiology and Pneumology, Göttingen;* [2]*Clinical Chemistry,* [3]*Psychosomatics and Psychotherapy, University of Göttingen, Göttingen;* [4]*Roche Diagnostics, Tutzingen, Germany*

Plasma levels of brain natriuretic peptide (BNP) are increased in heart failure, but no data are available for changes in BNP levels during acute pulmonary embolism. We tested plasma levels of NT-proBNP (pBNP), the N-terminal cleavage product during activation of BNP, in patients admitted with acute pulmonary embolism (PE).
Methods: 31 patients with acute PE; diagnosis by clinical signs + echocardiography + spiral CT or ventilation/perfusion scintigraphy. Determination of NT-proBNP plasma levels (Elecsys, Roche Diagnostics) upon admittance and after 4,8, and 12 hours.
Results: pBNP was massively elevated in PE upon admittance, as compared to control persons (5118±1985 vs. 36±4 pg/ml, $p<0.05$). pBNP levels further increased to 5669, 5934, and 6352 pg/ml after 4,8, and 12 hours, respectively. In patients with right ventricular dilatation (RV-dil) on echocardiography (n=6), pBNP was significantly higher as compared to patients without RV-dil (20059 vs. 1706 pg/ml, $p<0.05$). We observed a close correlation between RVEDD (in mm) and pBNP levels ($r=0.651$; $p<0.001$). In patients with RV-dil, pBNP markedly increased during the first 12 hours (to maximally 29941 pg/ml after 4 hours; $p<0.001$), but did not change in patients without RV-dil. Patients with clinical complications (iv catecholamines, intubation, resuscitation or death; n=7) had significantly higher pBNP levels upon admittance as compared to patients with uncomplicated clinical course (32428 vs. 1706 pg/ml, $p<0.001$).
Conclusion: NT-proBNP plasma levels markedly increase during acute pulmonary embolism. This increase correlates with RV dilatation and clinical complications. NT-proBNP could be a novel marker for differential diagnosis and prognosis of pulmonary embolism.

P2980 CTnI as the leading parameter for therapy in patients with acute pulmonary embolism in Goldhabers group II

K. Conradi[1], O. Gunkel[2], P.C. Schulze[1], S. Conradi[3], E. Boudriot[1], B. Lauer[2], G. Schuler[1]. [1]*University Leipzig - Heart Center, Department of Cardiology, Leipzig, Germany;* [2]*Zentralklinik Bad Berka, Department of Cardiology, Bad Berka, Germany;* [3]*University Leipzig - Heart Center, Department of Radiology, Leipzig, Germany*

Introductions: In patients with acute pulmonary embolism (PE), impairment of right ventricular function is correlated to the extent of the embolic process. Mortality is increased in patients (pts) with massive PE. However, simple serologic markers for the extent of PE are still lacking. The aim of this study was to investigate the clinical and prognostic significance of sensitive and specific serum parameter of (right ventricular) myocardial damage cardiac troponin I (cTnI) in pts with acute PE. Threshold value indicating myocardial damage was 0.4ng/ml for cTnI.
Method: We prospectively investigated 40 pts with acute PE confirmed by positive d-dimer and computed tomography. Venous blood samples were drawn initially and after 6,12, 36, 24, 30, 36, 42 and 48 hours following admission for the investigation of serum parameters measured by routine laboratory methods. Right ventricular function was assessed by echocardiography (echo). Exclusion criteria were duration since the last acute event of embolism more than 48 hours, outdoor resuscitation, high grade coronary artery disease (>50% diameter stenosis), recent myocardial infarction, suspected chronic thromboembolic pulmonary hypertension or renal insufficiency with creatinine above 2.0 mg/dl.
Results: All pts were classified for the extend of PE in regard to the Goldhaber-Classification, 8 pts (20.%) were normotensive without signs of RV-dysfunction according to Goldhaber grade I (all pts cTnI neg), 21 pts (52.5%) were normotensiv without catecholamines but had RV-dysfunction on echo according to Goldhaber II (5 pts cTnI neg., 16 pts cTnI pos), 11 pts (27.5%) presented hemodynamic unstable with hypotension and need for inotropic support according to Goldhaber grade III (all pts cTnI pos). CTnI is correlated to an impaired RV function in patients with acute PE as assessed by echo (RVEDD in pos. cTnI 41.41mm ± 1.3 vs. 36.41mm ± 1.38 in cTnI neg. pts, $p<0.05$). 30-days-mortality was significantly increased in pts with acute PE and positive cTnI (37.04%) whereas non of the cTnI negative pts died ($p<0.02$). Thrombolysis and/or surgical embolectomy ($p<0.01$) as well as inotropic support ($p=0.035$) were significantly more often performed in cTnI-positive pts compared to cTnI-negative pts.
Conclusions: CTnI is qualified for the early discrimination of severity and a good predictor of mortality in PE. Especially under the consideration that non of the patients with negative cTnI died it seems to be a good screening parameter, e.g. patients of Goldhaber group II with negative cTnI don't need thrombolysis or embolectomy.

P2981 Troponin I elevation as a marker of right ventricular dysfunction and severity in pulmonary embolism

S. Amorim, P. Dias, R. Rodrigues, F. Macedo, M.J. Maciel. *Hospital de S. João, Cardiology Department, Oporto, Portugal*

Background: Cardiac troponin I (Ti) is a specific marker which allows the detection of minor myocardial cell damage. In patients (pts) with severe pulmonary embolism (PE), the rise in pulmonary artery pressure can lead to a progressive right ventricular dysfunction (RVD) and clinical studies demonstrated the presence of ischemia and even right ventricular infarction. **Aims:** Our aims were to determine the prevalence and diagnostic utility of Ti in identifying pts with RVD and ascertain if it correlates with the severity of PE. **Methods:** We studied 77 pts with PE diagnosed by pulmonary angiography, ventilation-perfusion lung scan, spiral computed tomography scan or by a combination of abnormal echocardiogram with clinical presentation suggestive of PE or with positive subsidiary exams (d-dimers, venous doppler of the lower limbs, EKG, blood gas analysis). We further classified the PE in severity levels, according to the European Society of Cardiology, being the PE: 1- massive, if there was shock and/or hypotension, 2- submassive, if we found right ventricular hypokinesis on the echocardiogram, and 3- non-massive, in the remaining cases. We considered the highest Ti serum value since the admission until 24 hours and a normal value of <0.10 ng/ml. **Results:** Among the 60 pts with Ti measurements, 42 had elevated values of Ti. Among the pts with RVD, 26 (81.3%) had increased Ti levels and only 14 pts (35%) with elevated Ti values didn't have RVD, indicating that positive Ti tests were significantly associated with RVD ($p=0.038$). The pts with positive Ti tests had an earlier beginning of symptoms (92.5 ± 152.79 vs 234.4 ± 232.47 hours, $p=0.02$) and a higher prevalence of emboli in proximal vessels (pulmonary trunk and right or left main pulmonary arteries) (92.0% vs 50.0%, $p=0.012$) than those with normal Ti tests. The mean level of Ti among pts with severe PE (1.65±4.27 ng/ml) was significantly higher than in those with submassive PE (1.06±0.97 ng/ml), which in turn was higher than in those with non-massive PE (0.53±0.74 ng/ml) ($p=0.045$). This gradual relationship didn't exist with the levels of d-dimers nor with the levels of systolic pressure of the pulmonary artery.
Conclusions: Around 55% of pts with PE have elevated Ti values and this test is significantly associated with RVD. Ti measurements provide additional information in the evaluation of pts with PE by the identification of pts of greater severity and at increased risk of hemodynamic deterioration, which can benefit of more aggressive therapeutical strategies.

P2982 Haemostatic and inflammatory markers in atherothrombosis of central pumonary arteries

A. Russo[1], C. Vigna[1], M. Margaglione[2], V. De Rito[1], A. Massaro[1], R. Fanelli[1], G. Di Minno[2], F. Loperfido[3]. [1]*Cardiology,* [2]*Atherosclerosis Unit, Casa Sollievo Sofferenza, San Giovanni Rotondo (FG), Italy;* [3]*Complesso Integrato Columbus, Cardiology, Catholic University, Roma, Italy*

Some patients (pts) with chronic obstructive pulmonary disease (COPD) show at transesophageal echocardiography (TEE) stratified atherothrombotic lesions (AL) within central pulmonary arteries (CPA) in the absence of previous pulmonary embolism (PE) or significant increase in pulmonary artery systolic pressure (PAPS). We investigated the relation between TEE evidence of CPA AL and a thrombogenic or inflammatory substrate in 40 consecutive pulmonary or cardiac patients (20 with COPD, 14 with nonischemic dilated cardiomyopathy [DCM], and 6 with mitral valve disease [MVD]; mean age: 69±9 yrs), without a history of PE and showing PAPS <45mmHg at transthoracic Doppler echocardiography. Pts with venous thrombosis, neoplastic, hematologic, acute or chronic inflammatory disease, ischemic heart disease, carotid or peripheral arteries disease, or actually smoking were excluded. There were 14 pts with CPA AL (35%)(8 with COPD, 4 with DCM, and 3 with MVD) and 26 without (75%). There were no differences in age (69 vs 70 yrs), gender (60% vs 73% male), PAPS (36±8 vs 38±7mmHg), systolic blood pressure (131±16 vs 126±15mmHg), total cholesterol (C) (195 vs 191mg/dl), LDL-C (134 vs 139mg/dl), HDL-C (48 vs 49mg/dl), triglycerides (165 vs 162mg/dl), prevalence of atrial fibrillation (50% vs 34%), diabetes (28% vs 23%) and hypertension (43% vs 32%) between pts with and without CPA AL. Also, there were no differences in platelets and white-cell counts, hematocrit (38% vs 41%), antithrombin III (97±12% vs 94±14%), protein C (91±28% vs 90±37%) and protein S (89±28% vs 81±22%) activity, prevalence of factor V Leiden (3.8% vs 3.8%) and protrombin gene 20210A mutation (7.1% vs 3.8%), and plasma levels of fibrinogen (353±135 vs 363±75mg/dl) and homocysteine (10.6±3.7 vs 10.7±4.6μmol/l). Nephelometric C-reactive protein concentration was however significantly higher in pts with CPA AL (1.44±1.2mg/dl) than in those without (0.68±0.61mg/dl) ($p<0.05$). Conclusions: 1) CPA AL are a relatively frequent TEE finding in pts with pulmonary or cardiac disease presenting without severe pulmonary hypertension; 2) in these patients, CPA AL may be related to an inflammatory substrate.

P2983 Efficiency of plasma D-dimer ELISA depends on localisation of pulmonary embolism

N. Mansencal, T. Joseph, P. Lacombe, O. Dubourg. *Hôpital Ambroise Paré, Service de Cardiologie, Boulogne Cedex, France*

Background: The diagnosis of pulmonary embolism (PE) remains difficult despite new imaging and non-imaging techniques. An abnormally elevated level of plasma D-dimer ELISA has more than 90 per cent sensitivity for identifying patients with PE The aim of this study was to determine if plasma D-dimer ELISA has the same efficiency whatever the localisation of PE.
Methods and Results: We studied 42 patients (mean age 57 ± 16 years, 43% women) presenting with PE quantified by angiographic Miller index (MI). The measurement of plasma D-dimer ELISA was performed for all patients. The localisation of PE was proximal in 9 patients (21%), lobar in 21 patients (50%) or distal (12 patients, 29%). Mean MI was 43 ± 4%. Plasma D-dimer ELISA was elevated (> 500 ng/ml) in 39 patients (93%). Only 3 patients had normal D-dimer (< 500 ng/ml). For these 3 patients, mean MI was 22 ± 11% with exclusive distal PE localisation. All patients with proximal or lobar PE had elevated plasma D-dimer ELISA even when in patients with distal PE, 25% had normal D-dimer (p = 0.004).
Conclusion: Our data suggest that plasma D-dimer ELISA fails to detect 25% of distal PE.

P2984 Evidence of pulmonary vascular dysfunction from cardiopulmonary exercise testing in experimental hyperhomocystinaemia

C. O'Dochartaigh[1], H Y. Ong[1], S. Lovell[1], C. Hanratty[1], M.P. Frenneaux[2], I. Young[3], D.P. Nicholls[3]. *[1]Belfast, United Kingdom; [2]University of Wales, Cardiff, United Kingdom; [3]Queen's University, Belfast, United Kingdom*

RATIONALE: We have shown that elevated plasma levels of homocysteine induced by methionine loading cause endothelial dysfunction in the systemic vasculature. We hypothesized that a similar effect would occur in the pulmonary vascular bed, increasing physiological dead space. Such an effect would be detectable by non-invasive cardiopulmonary exercise testing.
Methods: Ten men aged 22-31 years took part in a randomized, placebo-controlled, operator-blinded crossover study. Methionine 100 mg/kg or placebo was administered orally on two occasions a mean of 16 days apart. Blood was drawn before, and 4 hours after administration, for total Homocysteine (tHcy) levels. Subjects then carried out a maximal cardiopulmonary exercise test on a bicycle ergometer, starting at a workrate(WR) of 30Watts(W) and increasing by 20W/min. Standard cardiopulmonary parameters were measured.
Results: tHcy rose from 11.8 ± 3.1 (mean ± Std Dev) to 31.2 ± 10.3 μmol/ml ($p<0.0001$) after methionine administration, and did not rise with placebo. Exercise time, Peak oxygen consumption(PVO2), VO2/WR slope, O2pulse, Tidal volume(VT) and Minute Ventilation(VE) at peak exercise were similar in the two tests. Carbon dioxide production (VCO2), Respiratory exchange ratio(R), Endtidal CO2(PetCO2) were lower and VE/VCO2 higher at peak exercise in the Methionine-loaded tests.

Table 1: Peak Exercise gas exchange data

Test	VO2(ml/min)	VCO2(ml/min)	R	PetCO2(mmHg)	VE/VCO2
Placebo	3267 (607)	3904 (667)*	1.20 (0.05)**	37 (3)**	29.9 (2.8)*
Methionine	3152(450)	3571 (462)*	1.13 (0.05)**	34 (4)**	32.2 (4.6)*

Data shown as Mean (Std Dev). *$p<0.05$, **$p<0.01$ by paired Student T-Test

Conclusions: The differences in VE/VCO2 between the two tests, while small, are significant and are consistent with either hyperventilation, or a degree of Ventilation/Perfusion mismatch with methionine. The lower R and VCO2 are against hyperventilation. These data suggest that experimental hyperhomocystinaemia impairs pulmonary vascular function.

P2985 Prognostic value of echocardiography in massive and submassive pulmonary embolism: a retrospective study of 624 patients

G. Pacouret, E. Hamel, D. Djeffal Vincentelli, O. Fichaux, B. Charbonnier. *Trousseau Hospital, Cardiology A, Tours, France*

Right ventricular dilation induced by massive and submassive pulmonary embolism (PE) can be easily detected, at bedside, by echocardiography (EC). To test the prognostic value of this parameter, we retrospectively analyzed a population of 624 consecutive patients admitted to our institution for acute massive or submassive PE, and who were evaluated by EC at baseline.
Results: Right ventricle/left ventricle end diastolic diameter ratio (RV/LV) was calculated from the long axis parasternal view, the subcostal view or the apical 4 chamber view. 23 pts died during the index hospitalization (3.7%). Univariate analysis revealed that among 8 parameters, only the signs of shock, the perfusion lung scan (LS) defect and RV/LV were significantly associated with the risk of death (see table).

Univariate analysis of risk factors

	Death	Alive	p
	n=23	n=601	
Age (95% CI)	72 (65-78)	71 (69-72)	0.37
Gender (M/F) (n)	8/15	263/338	0.39
Previous TE (n)	7	228	0.46
CI to thrombolysis (n)	11	211	0.21
Thrombolysis (n)	9	136	0.07
RV/LV (95% CI)	0.99 (0.79-1.20)	0.70 (0.68-0.72)	< 0.0001
LS defect % (95% CI)	50 (45-55)	39 (38-40)	0.001
Shock (n)	8	53	0.0001

(CI = contra-indication, TE = thromboembolism)

After adjustement to shock, LS defect and thrombolysis, RV/LV appeared as an independent predictor of death (p=0.04) in multivariate analysis.
Conclusion: the results of this study indicate that an aggressive therapy should be considered in patients suffering from acute PE when RV/LV >= 0.8, even in the absence of signs of shock.

P2986 Nitric oxide inhalation modulates circulating endothelin-1 after left ventricular assist device implantation

F. Wagner[1], S. Buz[1], R. Hetzer[1], B. Hocher[2]. *[1]Deutsches Herzzentrum Berlin, Cardiothoracic and vascular surgery, Berlin, Germany; [2]Charité, Humboldt Universtät, Nephrology, Berlin, Germany*

Nitric oxide inhalation is an established therapy in the treatment of secondary pulmonary hypertension after left ventricular assist device (LVAD) implantation. As a selective pulmonary vasodilator inhaled nitric oxide (iNO) decreases right ventricular afterload without systemic hypotension. Endothelin-1 (ET-1) as a potent endogenous vasoconstrictor contributes to pulmonary hypertension and NO modulates the ET-1 synthesis in vitro. The effects of iNO on circulating ET-1 and big endothelin (big ET-1) in LVAD-patients were investigated.
Methods: On weaning from cardiopulmonary bypass (CPB) 15 patients with right ventricular dysfunction were treated with iNO. Plasma ET-1 and big ET-1 concentrations were measured preoperatively, on CPB prior to iNO, 12, 24, and 48 hrs. postoperatively, as well as 72 hrs after cessation of iNO.
Results: Mean initial iNO dose was 33 ppm. NO therapy was weaned in all patients without a rebound phenomenon. ET-1 and big ET-1 were increased preoperatively (1.22±0.17 and 3.64±0.71 fmol/ml, respectively). ET-1 concentrations were highest on cardiopulmonary bypass (1.40±0.18 fmol/ml).
ET-1 and big ET-1 decreased significantly during iNO therapy and were lowest 72 hrs after cessation of iNO (Table). The iNO dose and plasma ET-1 levels correlated significantly ($p<0.001$). A significant correlation was also found between ET-1, PA-pressures and PVR, but not with CI and SVR.

Plasma concentration-time profile

	12h	24h	48h	72h post NO
ET-1 (fmol/L)	1.17±0.17	0.94±0.2	0.72±0.14	0.48±0.09
big ET-1 (fmol/L)	5.49±1.13	3.64±0.49	4.12±0.93	2.18±0.23

Conclusion: Since it is known, that ET-1 mediates pulmonary hypertension, we suggest a two-fold effect of iNO therapy: first a selective vasodilation of the pulmonary vasculature and second NO-mediated inhibition of one of the most potent vasoconstrictors of pulmonary vessels: ET-1.

P2987 Serotonin receptor blockade improves monocrotaline-induced pulmonary hypertension and prolongs survival in rats

M. Hongo[1], E. Hironaka[2], S. Hayashi[1], Y. Yazaki[1], M. Owa[1], K. Kubo[1].
[1]Shinshu University, Department of Medicine, Matsumoto, Japan; [2]Shinshu University Hospital, Department of Laboratory Medicine, Matsumoto, Japan

It has been reported that platelet activity is enhanced with increased plasma levels of serotonin and P-selectin in pulmonary arterial hypertension. The present study was designed to assess the effects of serotonin receptor blockade on monocrotaline (MCT)-induced pulmonary hypertension (PH) and survival in rats. Rats were randomized to receive MCT (40mg/kg, SC) followed by placebo (group A) or sarpogrelate, a serotonin receptor blocker (50mg/kg, IP) (group B) for 3 weeks. Immunohistochemical staining for P-selectin, CD45, endothelial nitric oxide synthase (eNOS), and proliferating cell nuclear antigen (PCNA) were performed. In group A, there were marked expression of P-selection and CD45-positive leukocytes adhered to the P-selectin-expressing cells and platelets on the endothelial cells of pulmonary arterioles and venules in association with severe pulmonary hypertension, muscularization of the pulmonary arteries, and right ventricular hypertrophy. In addition, expression of eNOS on the pulmonary arteries was significantly decreased and the number of PCNA-positive cells was increased in group A compared with those of the normal control animals. These inflammatory processes, endothelial injury with impaired NO/O2- balance, and functional and structural abnormalities of the pulmonary vessels were markedly suppressed in group B. At 3 weeks after treatment, survival rate in group B was 87% compared with 40% in group A ($p < 0.05$). In conclusion, serotonin receptor blockade with sarpogrelate improves MCT-induced PH and prolongs survival in rats, which was mediated by suppression of endothelial injury, enhanced platelet activity, inflammatory responses, and proliferation of the pulmonary vascular smooth muscle cells and improved NO expression of the pulmonary vessels in this model.

P2988 Prognostic significance of cardiac pulmonary exercise testing in pulmonary arterial hypertension

J. Tongers[1], E.M. Horn[2], A.M. Yoney[2], A. Widlitz[2], G. Gates[2], R. Garofano[2], R. Goldsmith[2], R.J. Barst[2]. *[1]Hannover Medical School, Hannover, Germany; [2]Columbia University, New York, United States of America*

Cardiopulmonary exercise testing (CPET) is a useful noninvasive tool to assess functional capacity and the physiological changes associated with exercise. Patients (pts) with pulmonary arterial hypertension (PAH) have a unique response due to the combined manifestations of cardiac, pulmonary and peripheral limitations characterized by this disease. Although the prognostic significance of CPET in CHF pts is known, the objective of this study was to assess the usefulness of CPET in PAH pts. Hence, 90 consecutive patients underwent testing at baseline and after one year of treatment with chronic intravenous prostacyclin (PGI2).

To address the question of CPET as a useful surrogate endpoint, we analyzed the effects at baseline, at 1 year follow-up (f/u) and change from baseline to 1 yr. f/u (delta) of VO2, Ve/VCO2, 6-minute walk and PAPm on survival data utilizing a proportional hazard regression.

Data showed: 1) PGI2 therapy was associated with a significant improvement ($p<0.05$)in all exercise and hemodynamic parameters (table). 2) Both f/u and delta VO2 are good predictors of survival. 3) Baseline and f/u 6-minute walk are independently good predictors of survival. 4) Baseline and f/u Ve/VCO2 but not delta are independently good predictors of survival. 5) Both f/u and delta PAPm values are independently good predictors of survival.

Parameters at baseline and follow up

	Baseline	Follow up (1 yr.) on PGI2	p value
VO2 (ml/kg/min)	13.1 ± 0.6	16.9 ± 0.6	<.0005
Workload (watts)	38.0 ± 2.3	55.5 ± 3.1	<.0005
Ve/VCO2	55.7 ± 2.1	46.7 ± 1.3	<.0005
6-minute walk (m)	394.9 ± 14.6	472.4 ± 11.3	<.0005
PAPm (mm Hg)	65.4 ± 1.7	50.5 ± 1.7	<.0005

paired t-test (mean ± SEM)

Conclusion: Both 1 yr. f/u and delta VO2 and PAPm, which likely best represent treatment effects, predict survival. Baseline and 1 yr. f/u 6-min. walk and Ve/VCO2 are good predictors of survival but possibly are less sensitive to treatment effects. Thus, CPET is useful to predict survival in PAH.

P2989 Non-invasive assessment of mean and systolic pulmonary artery pression in athletes: a stress-echo study

G. Galanti, M. Rizzo, P. Manetti, M.C.R. Vono, L. Toncelli, V. Di Tante, C. Rostagno. *University of Florence, Non-Invasive Cardiac Laboratory, Florence, Italy*

Background: Doppler transtoracic echocardiography (TTE) has been validated for estimation of mean and systolic pulmonary artery pressure (PAP). Mean PAP can be evaluated in all subjects from time to peak velocity in pulmonary artery. Systolic PAP can be estimated in subjects with tricuspid regurgitation (TR) by Doppler evaluation of TR peak velocity (TRV). Rest TRV <2,5 has been reported as the upper limit in normals. At present, the whoole range of rest and exercise TRV and mean PAP in athletes is not yet completly defined.
Objectives: The aim of the study was to estabilish, in athletes, a reference range for mean pulmonary artery pression and tricuspid regurgitation velocity at rest and during exercise.
Materials and Methods: Doppler echocardiographic study was obteined in 428 conditioned athletes (mean age: 38,5±19,1) and 233 healthy sedentary subjects (mean age: 33±12) both at rest and during standardized recumbent bicycle exercise. Mean PAP was estimated in all subjects, both at rest and during stress test. TRV and systolic PAP were evaluated in a subgroup of subjects, randomized within those with detectable TR (70 athletes and 70 controls).
Results: Left ventricular dimensions and mass were significant greater in athletes than in controls; no significant differences were found in rigth atrium and ventricular dimensions between the two groups. Rest mean PAP was significantly lower in athletes than in controls (16,3±3,8 mmHg in athletes; 17,2±4,2 mmHg in controls); no significant differences were found in exercise mean PAP between athletes and controls. No significant differences were found in rest and exercise TRV between athletes and controls (2,1±0,4 -2,8±0,4 in athletes; 2,1±0,4 -2,7±0,6 in controls), that is that no differences were found in rest and exercise systolic PAP in the two study groups (28,3±6- 41,9± 10,1 mmHg in athletes; 29,3±7,3 - 38,9± 14,5 in controls).
Conclusions: This study indicates the normal range of TRV, systolic and mean PAP in a large athletes' population.

P2990 Assessment of dynamic changes in perfusion lung scintigrams in patients with CTEPH

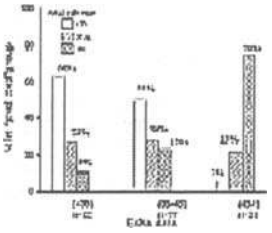
N. skoro-sajer[1], A. Becherer[2], W. Klepetko[3], M. Kneussl[4], I.M. Lang[1]. *[1]General Hospital, Cardiology, Wien, Austria; [2]Nuclear Medicine, General Hospital, Vienna, Austria; [3]Cardiothoracic Surgery, Vienna, Austria; [4]Pulmology, Vienna, Austria*

Background: Chronic thromboembolic pulmonary hypertension (CTEPH) is the result of single or recurrent pulmonary thromboemboli arising from sites of venous thrombosis. Over time thrombi become organized obstructions that are thought to expand by recurrent embolisation and in situ thrombosis. We performed a quantitative evaluation of ventilation and perfusion scintigrams (V/Q scan) in patients with inoperable CTEPH in order to assess the natural history of thrombus expansion.
Methods: We prospectively studied 11 CTEPH patients (52±11years, 7 females, 4 males) over a period of 28 months. The baseline V/Q scan was obtained at the time of diagnosis. Ventilation imaging used [99mTc] DTPA aerosol and perfusion imaging was performed with intravenous [99mTc]-labeled human albumin macroaggregates. Planar images were reconstructed in eight standard projections. The right lung (RL) and the left lung (LL) were subdivided into an upper, middle and lower region of interest (ROI). The ratio of the mean count per pixel in the ROI to the count over the heart was calculated as the Lung/Heart index (L/H). The RL and LL variation coefficient (Vc), i.e. the ratio of the count standard deviation and the average count of the ROI were evaluated from the same planar scintigrams. Student's paired t-test was used to analyze baseline and follow up data.
Results: During the observation period, mean pulmonary artery pressure increased from 48.4±14.6 to 54.7±8.1mm Hg, PVR increased from 9.8±4.6 to 10.9±4.0 Wood Units. All L/H indices increased over time. For example, baseline right middle ROI was 6.9±2.1 compared with follow up right middle ROI of 9.4±2.5 (P=0.0024), and the baseline right upper ROI was 4.2±1.5 compared with right upper ROI at follow up of 6.5±2.4 (P=0.0083). The baseline Vc was 51.7±8.0 (LL), 58.5±7.4 (RL). The follow-up Vc was 44.4±8.4 (LL) and 45.5±8.2 (RL, p=0.0017).
Conclusions: In parallel with hemodynamic deterioration,lung perfusion scintigrams in patients with inoperable CTEPH show a decrease of segmental flow abnormalities. We speculate that, over time, secondary vascular changes determine the course of CTEPH and ultimately lead into the scintigraphic pattern of nonthromboembolic pulmonary hypertension.

P2991 Screening for early pulmonary hypertension in patients with systemic sclerosis: is an aggressive invasive approach required?

D. mukerjee[1], J. Davar[2], C. Black[1], J.G. Coghlan[2]. [1]royal free hospital, rheumatology, london, United Kingdom; [2]Royal Free Hospital, Cardiology, London, United Kingdom

Aim: To document the accuracy of echo to identify early PHT in a high-risk SSc cohort.
Background: From 950 patients under regular follow-up, dyspnoeic patients with a echo-estimated tricuspid gradient (TG)>35 mmHg/those with TG<35 mmHg with dyspnoea unexplained by the presence of pulmonary fibrosis/ and those with DLCO<50% predicted were catheterised
Method: Echo and catheter measured TGs were correlated. A linear regression was derived to predict catheter-measured mean Pulmonary Artery Pressures(mPAPs)from echo estimated TGs.
Results: Out of the 140 patients studied (F: M≈119:21),mean age=56±7 years. Haemodynamics: mPA Sys=47mmHg, mPA diastolic=18 mmHg, mPAP=34 mmHg, mRAP=4 mmHg, mean echo estimated TG=42 mmHg.
Echo-estimated TG showed a positive correlation with catheter-measured TGs(r2=0.44, p<0.005).
By linear regression(figure),echo was sufficiently accurate at moderate/ high pressures (echo TG>45 mmHg) identifying>80% of patients correctly.At lower pressures where early diagnosis is critical, echo was less discriminatory- it both under/over-estimated the catheter-measured mPAPs in 30% of cases.This may lead to over-diagnosis of PHT in unaffected patients.



Cath. mPAP versus echo TG.

Conclusions Though echo accurately identified a poor prognostic group(mPAP>35 mmHg on cardiac catheter), reliance on echo to accurately identify early PHT in "at risk" SSc patients is inadequate. In its current form, echo-estimated TGs demonstrate a tendency to both under and over-estimation at the lower end of the spectrum - with the subsequent risk of exposing a patient with either no or mildly elevated pulmonary pressures to over-investigation. This latter finding is particularly relevant when applied to low prevalence PHT populations where the false positive rates are proportionately higher.

MYOCARDIAL ISCHAEMIA/INFARCTION

P2992 Value of right derivation records in treadmill test taken simultaneously with standard left derivations in the diagnosis ischaemia

Z. Yigit, N. Atinc, G. Binici, M. Ersanli, H. Akdur, H. Yuksel, D. Guzelsoy. *Institue of cardiology, Istanbul, Turkey*

Treadmill test is a common test used in the diagnosis of ischemic heart disease with a diagnostic sensitivity of 65-70%. We have evaluated the sensibility and diagnostic value of right derivations records taken simultaneously with standard left derivartions in this study.
Methods: 74 consecutive patients (30 women, 44 men, mean age 54.6±10.2 years) who were referred to our nuclear cardiology laboratory for the evaluation of chest pain were included in our study. Our exclusion criteria were previous revascularization procedure (ACBG, PTCA), bundle branch block or left ventricular hypertrophy. All patients were evaluated by exercise myocardial perfusion scintigraphy (MPS) and coronary angiograms (CA). 3 right precordial derivations (V3R, V4R, V5R) were recorded simultaneously with the standard 12 derivations during exercise. Ischemia was diagnosed as 1 mm ST depression. Sensitivity, specivity, (+) and (-) predictive value and accuracy of the tests using both standard and right derivations were estimated. Positive results were taken as a temporary perfusion defect on MPS or a coronary artery lesion greater than 70% detected by CA. 32 pts had coronary artery disease detected by MPS or CA.
Results: 30 pts had ischemic changes during exercise when evaluated by standard exercise test. In 21 of these pts, coronary artery disease was detected by MPS or CA. 11 out of 44 pts without ischemia had coronary artery disease detected by MPS or CA. Sensitivity, specivity, (+) and (-) predictive value and accuracy were calculated as 66%, 79%, 70%, 75% and 73% respectively. When right derivations were taken with the standard derivations, 21 pts had coronary artery disease out of 36 pts who had ischemia on exercise test. Only 8 pts out of 38 pts without ischemia had a perfusion defect on MPS and CA. Sensitivity, specivity, (+) and (-) predictive value and accuracy were calculated as 88, 81, 80, 90 and 84 respectively. Addition of right derivations to standard derivations has resulted in statistically significant increase in the sensitivity of the test (p=0.037) whereas specivity did not change.
Conclusion: Addition of right derivations to standard derivations during exercise test increases the sensitivity of the test in the diagnosis of ischemia.

P2993 Acute renal failure complicating first myocardial infarction: the impact on infarct course and in-hospital mortality

Z. Madzar, L. Zaputovic, Z. Cubranic, R. Miskulin, D. Marinovic, Z. Plazonic, M. Padovan. *Clinical Hospital Center Rijeka, Department of Internal Medicine, Rijeka, Croatia*

Aim: Acute renal failure (ARF) is a major cause of in-hospital morbidity and mortality, usually indicating the serious nature of the underlying disease. ARF complicates approximately 5% of hospital admissions and up to 30% of admissions to intensive care units. The aim of this study was to investigate the incidence of ARF in patients with first acute myocardial infarction (AMI), reveal the influencing factors and assess it's impact on infarct course and final outcome.
Methods: We analyzed renal function in 583 patients with first AMI (363 or 62.3% male, mean age 66.7±12.9 years), admitted to our Coronary Care Unit from January 1, 2000 to June 30, 2001. Diagnosis of ARF was based on serum creatinine levels, i.e. acute increase in creatinine from normal to above 180 μmol/L, or it's rise from baseline values for 50% or more in patients with previous mild to moderate renal failure.
Results: In 58 (9.9%) patients (34 male, 24 female, mean age 74.9±8.1 years) AMI was complicated with ARF. The causes of ARF were acute heart failure (31 pts, 53.5%), adverse drug effects (7 pts, 12.1%), transient hypotension due to volume depletion (5 pts, 8.6%), or combination of the previous causes (15 pts, 25.8%). ARF occurred more frequently in patients over 65 years (13.6% vs. 3.3%, p<0.05), diabetics (36.5% vs. 13.6%, p<0,05), hypertensive patients (12.9% vs. 4.5%, p<0.05) and those with acute heart failure (22.1% vs. 4.7%, p<0.05). Patients with ARF complicating first AMI had longer hospitalisation (19±12 vs. 12±5 days, p<0.05) and higher mortality rate (50.0% vs. 11.2%, p<0.05). Significant difference in mean maximal serum creatinine existed between 25 oliguric (43%) and 33 non-oliguric (57%) ARF patients (283±87 vs. 205±45 μmol/L, p<0.05). When compared to non-oliguric group, oliguric patients recovered renal function to baseline creatinine levels less frequently (8.0% vs. 57.6%, p<0.05), and had the highest mortality rate (76.0% vs. 30.3%, p<0.05).
Conclusion: The results indicate that ARF in first AMI occurs more frequently in older population, patients with acute heart failure, diabetes mellitus and hypertension. AMI patients with ARF need prolonged hospital stay, have more serious infarct course and significantly higher mortality, specially those oliguric.

P2994 Clinical characteristics of systemic embolization in acute myocardial infarction

C. Toth[1], I. Edes[2]. [1]*County Hospital, Department of Cardiology, Eger, Hungary*; [2]*University of Debrecen, Department of Cardiology, Debrecen, Hungary*

The frequency, risk factors and prognostic significance of systemic embolism (SE) were studied in acute myocardial infarction (AMI). Data on 1833 patients with Q-wave AMI treated at the County Hospital, Eger, during a 10-year period were analyzed. During the hospital treatment, 53 patients (2.9%) developed SE, localized as follows: 38 cerebral, 7 extremital, 3 renal and 5 multiple. The diagnosis of SE was based on the clinical symptoms, pathological findings and/or radiological examinations. The embolic events occurred most frequently (70%) in the first 72 hours of AMI. In 5 cases the SE was the first clinical manifestation of the AMI. The characteristics of the different clinical groups (AMI+SE vs. AMI alone) are summarized in the table.

	AMI+SE (n=53)	AMI without SE (n=1780)	p value
Age (years)	70.1	63.9	<0.001
Men (%)	57	64	NS
Smoking (%)	26	34	NS
Diabetes (%)	25	21	NS
Hypertension (%)	60	60	NS
Hypercholesterolemia (%)	38	45	NS
Previous MI (%)	9	12	NS
Anterior MI (%)	58	41	=0.02
Atrial fibrillation (%)	15	10	NS
Thrombolytic therapy (%)	6	22	<0.01
LV aneurysm (%)	17	8	<0.05
LV dilatation (Dd>60 mm; %)	33	20	NS
LV ejection fraction<40% (%)	25	17	NS
LV thrombus	36	7	<0.001
Hospital mortality	30	9	<0.001

Conclusions: SE is a rare and severe complication of AMI. The patients in whom SE developed were older and thrombolytic therapy was administered less frequently. On the other hand, an anterior AMI, a left ventricular aneurysm and thrombus formation were significantly more frequent in the AMI+SE group.

P2995 Predictors of new onset atrial fibrillation in patients presenting with acute coronary syndromes and their in-hospital outcomes

R.H. Mehta[1], O. Dabbous[2], P. Kuznetsova[2], E. Kline-Rogers[1], J. Gore[2], R. Goldberg[2], K.A. Eagle[1] on behalf of the Global Registry of Acute Coronary Events (GRACE) investigators. [1]*University of Michigan, Cardiology Dept., Ann Arbor, United States of America*; [2]*University of Massachussets, Department of Medicine, Worcester, United States of America*

Background: Predictors of new onset atrial fibrillation (AF) in unselected patients with acute coronary syndromes (ACS) and their outcomes have not been studied.

Methods: Accordingly, we evaluated 14,556 patients with ACS enrolled in the Global Registry of Acute Coronary Events (GRACE) between 1997 and 2000.

Results: New onset AF occurred in 908/14556 (6.2%) of ACS patients. Multivariable logistic regression analysis identified older age (per 10 year increase Odds ratio [OR] 1.65, 95% confidence interval [CI] 1.55-1.75), female gender (OR 1.20, 95% CI 1.03-1.40), heart rate (per 30 beats/minute increase, OR 1.79, 95% CI 1.65-1.96), ST elevation MI (referent unstable angina, OR 2.18, 95% CI 1.79-2.66), Non-ST elevation MI (referent unstable angina, OR 2.08, 95% CI 1.71-2.54) and cardiac arrest on presentation (OR 1.77, 95% CI 1.20-2.61) to be associated with an increased risk of AF. In contrast, prior revascularization (OR 0.74, 95% CI 0.60-0.90) and higher systolic blood pressure (per 20 mm Hg increment, OR 0.87, 95% CI 0.83-0.91) were associated with a lower risk of AF (Model c-statistics 0.75, Hosmer and Lemeshow Goodness-of-Fit p=0.14). Most comorbid conditions occurred with an increased frequency among ACS patients with AF. However, even after adjustment for the differences in baseline clinical characteristics, AF remained an important predictor of most adverse in-hospital events (table).

Odds ratio for in-hospital events

Outcome	Odds ratio-Adjusted	95% confidence interval	p value
Death	3.16	2.01, 4.95	<0.0001
Re-infarction	2.07	1.01, 4.27	0.048
Cardiogenic shock	3.61	2.24, 5.82	<0.0001
Pulmonary edema	3.95	2.54, 6.13	<0.0001
Cardiac arrest	3.21	2.01, 5.14	<0.0001
Stroke	0.61	0.13, 2.76	0.519
Major bleeding	1.78	1.06, 2.98	0.029

Conclusions: Our study helps identification of ACS patients at risk for AF who may benefit from early aggressive strategies to modify the increased risk of adverse in-hospital events observed among these patients.

P2996 Atrial fibrillation in high risk patients with acute myocardial infarction: data from the MISTRAL study

M. Marini, G. Fabbri, F. Chiarella, F. Mauri, G.M. Santoro, D. Lucci, G. Steffenino, A.P. Maggioni on behalf of MISTRAL Investigators. *ANMCO Research Center, Florence, Italy*

Background: Atrial fibrillation (AF) is a common complication of acute myocardial infarction (AMI). We observed the prevalence, clinical factors associated with its presentation and association with patient outcome in high risk (HR) pts with AMI in a community setting.

Methods and Results: 2227 pts with ST elevation AMI <12 h were recruited having >=1 of the following characteristics identifying HR: female >70 y (17.8%), diabetic >70 y (9%), Killip class >1 (23.7%), systolic blood pressure (SBP) <100 mmHg and heart rate >100 b/m (2.7%), >4 leads with ST elevation or depression (81.9%), previous Q-wave MI in another location (11.4%), contraindication to TT (10.2%).

AF was documented in 272 pts (12.2%). Pts with AF were significantly older (>70 yrs, 64% vs 32%, p<0.001), more likely to be female (43% vs 26%, p<0.001), with a higher Killip class at entry (Killip >1, 37% vs 22%, p<0.001), incidence of heart failure or cardiogenic shock during hospitalization (44% vs 23%, p<0.001) and probability to not receive reperfusion therapy (31% vs 17%, p<0.001).

At univariate analysis AF patients had higher in-hospital mortality (18.4% vs 9.1%, p<0.001) and a more frequent in-hospital combined end-point (in-hospital death, non fatal re-AMI and stroke) (21% vs 11%, p<0.001). At 1 year follow up both total mortality and 1-year combined end-point were more frequent in pts with AF than those without AF (29.8% vs 14.9%, p<0.001; 38.9% vs 19.6%, p<0.001, respectively).

Multivariate analysis indicated the most significant predictors of the development of AF were advanced age (OR 1.07, 95%CI 1.05 -1.09) and Killip class >1 (OR 1.44, 95%CI 1.06-1.95).

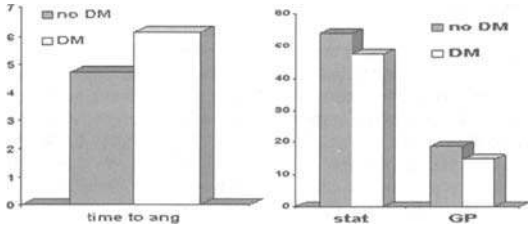
At multivariate analysis, after adjustment for clinical and demographic factors, the association between AF and in-hospital and 1-year mortality was no longer statistically significant (OR 1.02, 95%CI 0.67-1.54; OR 1.41, 95%CI 1.06-1.88, respectively). Similarly, the association between AF and in-hospital and 1-year combined end-point disappeared (OR 1.06, 95%CI 0.73-1.56; OR 1.32, 95%CI 0.95-1.83, respectively).

Conclusions: In HR pts with AMI the most significant predictors of the development of AF were advanced age and clinical severity of AMI. Differently from other studies, in this class of pts AF was not an independent predictor of mortality.

P2997 Underuse of new treatment modalities in diabetics with non-ST-segment elevation acute coronary syndrome

S. Vikman[1], J.E.K. Airaksinen[2], K. Niemelä[1] on behalf of FinACS group.
[1]*Tampere University hospital, Cardiology, Tampere, Finland;* [2]*Turku University hospital, Cardiology, Turku, Finland*

In last years our knowledge about risk stratification and treatment strategies of patients with acute coronary syndrome(ACS) without ST-elevation has increased rapidly and new guidelines have been published. It is not clear how these new guidelines have been implementated into clinical practice.
We prospectively collected all ACS patients without ST-elevation admitted in 9 hospitals in Finland during 1-3/2001, followed practice patterns and outcomes during hospitalization and at 6 months follow-up.
A total of 501 patients were entered into the survey, from which 143 (28.5%) had diabetes. Diabetics were older 71±10 vs 67±12;p<0.0001, had more treated hypertension 66% vs 48%;p<0.0001 and more peripheral vascular disease 30% vs 9%;p<0.0001 when compared to nondiabetics. Diabetics had higher risk profile than nondiabetics; ST-depression 57% vs 38%;p<0.0001, elevated troponin levels 66% vs 56%;p<0.05. Despite that the rate of in-hospital angiography was lower in diabetics than nondiabetics (32% vs 45%;p<0.05). Diabetics also waited more days for in-hospital angiography than nondiabetics(figure). In-hospital use of glykoprotein IIb/IIIa(GP) inhibitors and statins(stat) were lower in diabetics than nondiabetics (figure). At 6 months the rates of death were 16% and 7.6%;p<0.01 in diabetics and nondiabetics respectively. For the combination of death, myocardial infarction, refractory angina or readmission for unstable angina, rates of events were 38.5% vs 20%;p<0.0001, respectively.



Diabetics had higher risk profile than nondiabetics. Despite that the use of in-hospital angiography, statins and GP inhibitors were lower in diabetics than nondiabetics. Further education is needed to implementate the new guidelines into the clinical practice.

P2998 Early revascularisation for non-ST-segment elevation acute coronary syndromes: an estimation of demand in the UK

G A. Large[1], D. Gray[2], R G. Wilcox[2], J R. Hampton[2]. [1]*University Hospital Nottingham, Department of Cardiovascular Medicine, Nottingham, United Kingdom;* [2]*University Hospital Nottingham, Department of Cardiovascular Medicine, Nottingham, United Kingdom*

Background: The current ESC guidelines for the management of non-ST-elevation acute coronary syndrome (NSTEACS), recommend that patients at high risk of an adverse outcome should undergo coronary angiography and, where possible, revascularisation during their initial hospitalisation. We performed a prospective observational study to determine the likely size of the demand for early revascularisation therapy for NSTEACS in a large UK teaching hospital.
Methods: All emergency admissions to our hospital because of suspected unstable angina or myocardial infarction during the year 2000 were identified at presentation, using 'hot pursuit' methodology. Patients were excluded if their initial electrocardiograms showed persistent ST segment elevation or if they had already been included in the study. For each patient data were recorded on demography, clinical presentation and risk factors, ECG appearances, serum biomarkers levels and outcomes. The study population was then risk stratified according to ECS recommendations and an estimate made of the likely need for early revascularisation.
Results: 2098 patients were included in the study. 891 (42.5%) satisfied ESC criteria for high-risk status. Of these, 659 (74.0%) had elevated troponin levels, 199 (22.3%) developed recurrent ischaemia and 160 (18.0%) had unstable angina soon after a recent myocardial infarction.
Discussion: If the ESC recommendations on the management of NSTEACS are applied to a typical unselected population of patients admitted to a large UK hospital, the demand for early revascularisation will far exceed current service provision. The same is likely to be true for other UK hospitals.

P2999 Emergency electrocardiogram analysis during the acute phase of coronary syndromes: to be improved?

A. Berger[1], J.M. Meier[1], J.C. Stauffer[1], P.H. Eckert[2], J. Schlaepfer[1], E. Eeckhout[1], L. Kappenberger[1], J.B. Wasserfallen[3]. [1]*University hospital, Cardiology, Lausanne, Switzerland;* [2]*University Hospital, Intensive Care Division, Lausanne, Switzerland;* [3]*University Hospital, Internal Medecine, Lausanne, Switzerland*

Background: ECG analysis is essential in the management of patients with acute coronary syndrome (ACS) without persistent ST segment elevation. However, little is known about the quality of this analysis in the emergency room (ER). Our study was performed to specifically answer this question.
Methods: We prospectively compared the ECG analysis performed in the ER during the acute phase of ACS with a blind assessment by an intensivist and an interventional cardiologist; discordances were then resolved by an ECG specialist. Analysis focused on the ischemic modifications (ST segment elevation and depression, negative T-waves) of the ECG.
Results: In total, 627 ECG were included. The experts assessment wasn't fully concordant (kappa 0.8 and 0.9) with the ECG specialist. Analysis in the ER were concordant with those of the experts in only 423 ECG (67%; kappa 0.4). The details are summarized in the following table:

	No modification	ST elevation	ST depression 0.5-1	ST depression >1mm	Negative T-waves
No modification	352	18	10	2	34
ST elevation	18	21	4	3	7
ST depression 0.5-1mm	43	5	15	5	8
ST depression >1mm	12	6	4	13	1
Negative T-waves	19	2	1	2	22

X: emergency phycisians interpretation; Y: experts interpretation

Conclusion: Our study demonstrates that ECG analysis in the ER during the early management of ACS is not accurate. A better ECG analysis should allow better risk stratification and management of the patients, but the impact of these discrepancies need further study.

P3000 Acute coronary syndromes in 15 young AIDS patients receiving HIV-protease inhibitors. A 3-year follow-up study

F. Boccara[1], N. Adda[2], L. Djaouti[1], C. Smadja[1], O. Belliard[1], W. Rozenbaum[2], A. Cohen[1]. [1]*Saint Antoine, Cardiology, Paris, France;* [2]*Rothschild, Infectious disease, Paris, France*

Acute coronary syndrome (ACS) is an emerging complication in HIV-infected patients treated with highly active antiretroviral therapy (HAART) due to increase in life expectancy. HAART has been involved in metabolic disorders (MD) such as hypertriglyceridaemia (HTG), hyercholesterolemia (HCT), insulin resistance, diabetes mellitus and a syndrome of peripheral lipodystrophy. We report 15 cases of ACS (12 AMI, 3 UA) in young HIV-men associated with HAART followed during a 3 years period.

Characteristics patients		Acute phase (n=15)	
Male gender	14 (93%)	Anterior AMI	6 (40%)
Prior MI	0	Inferior AMI	7 (47%)
Age, y	42±6	Lateral AMI	2 (13%)
Current smoker	12 (80%)	3VD	4 (27%)
HCT/HTG	7 (47%)/13 (87%)	2VD	2 (13%)
HTN	2 (13%)	1VD	9 (60%)
Diabetes	0	LV thrombus	2 (13%)
Duration of HIV, y	8±4	LVEF, %	56±12
Duration PI, m	20±12	PCI	7 (47%)
CD4/mm^3	370±140	Mean FU, m	35±15
Median viral load	9300±2370	Death, AMI	1, 0
Lipodysthrophy	6 (40%)	UA, PCI, CABG	4, 3, 2

h: hours, m: months, y: years, c: copies/mL, VD: vessel disease, LVEF: left ventricular ejection fraction, PCI: percutaneous coronary intervention, CABG: coronary artery bypass graft, FU: follow-up.

Conclusion: Physicians should take aware of CV risks factors before initiating HAART in AIDS patients. Prospective studies of patients under HAART are needed to clarify the link between HAART and CV complications.Table

P3001 Metabolic protection with glucose-insulin-potassium infusion in patients with acute myocardial infarction. Results of the REVIVAL trial

J. Pache[1], A. Kastrati[2], J. Mehilli[2], J. Dirschinger[1], A. Rosskopf[2], M. Schwaiger[1], A. Schömig[2], D. Kitzbichler[2]. [1]*Klinikum rechts der Isar, 1. Medizinische Klinik, Munich, Germany;* [2]*Deutsches Herzzentrum, Munich, Germany*

Background: Intravenous glucose-insulin-potassium solution (GIK) may have a positive metabolic influence in patients with acute myocardial infarction (AMI). However, previous clinical studies have shown conflicting results with this therapy. This may have been the result of the infrequent use of reperfusion therapies in those studies. In fact, there is some data suggesting that patients with AMI who receive reperfusion therapy might have a greater benefit from GIK. The objective of this randomized trial was to assess for the first time whether GIK improves myocardial salvage in patients with AMI.
Methods: We randomized 312 patients with AMI to receive either a GIK infusion for 24 hours (GIK group, n=155) or no GIK (control group, n=157). The primary endpoint of the study was salvage index (proportion of myocardium at risk salvaged by therapy) as measured by technetium Tc 99m sestamibi scintigraphic studies performed before and 7-10 days after therapy. Secondary endpoint was the composite clinical event rate of death, recurrent MI and stroke within 30 days.
Results: Primary percutaneous intervention (PCI) was the predominant reperfusion strategy (90% of the cases). There were no significant differences in the baseline characteristics of the patients of the 2 groups, including initial perfusion defect in scintigraphy. Median [25th, 75th percentiles] of final infarct size was 9.0% [2%, 20%] of the left ventricle in the GIK group and 8.5% [3%, 21%] of the left ventricle in the control group (P=0.7). The primary endpoint of salvage index was 0.50 [0.18, 0.87] in the GIK group and 0.48 [0.18, 0.87] in the control group (P=1.0). Mortality within 30-days was 4.5% in the GIK group and 3.2% in the control group (P=0.5). The combined 30-day rate of death, recurrent MI and stroke was 5.8% in the GIK and 5.1% in the control group (P=0.8).
Conclusions: GIK does not further enhance myocardial salvage in patients with acute myocardial infarction treated predominantly with PCI. This may explain the lack of clinical benefit observed in this and previous studies with GIK.

P3002 Continuous ST-segment monitoring identifies patients with acute coronary syndromes who most benefit from early myocardial revascularization

C. Aguiar, J. Ferreira, M. Almeida, R. Teles, D. Cavaco, P. Gonçalves, R. Seabra-Gomes. *Hospital Santa Cruz, Cardiology Dept., Carnaxide, Portugal*

Background: In patients with non-ST-elevation acute coronary syndromes, early risk stratification is essential for guiding cost-effective management. Continuous ST-segment monitoring adequately reflects the dynamic nature of myocardial ischemia and coronary thrombosis, and provides important prognostic information in such patients. We investigated whether continuous ST-segment monitoring may be useful for early identification of those who most benefit from myocardial revascularization.
Methods: We studied 304 patients (22% female, age 65 ± 11 years) admitted to the CCU due to chest pain at rest (at least one episode of chest pain at rest in the previous 24 hours lasting at least 20 minutes) suggestive of an acute coronary syndrome without ST segment elevation on the admission ECG. Patients whose ECG was not interpretable for ischemia were excluded. ST segment monitoring was performed continuously for 24 hours after admission. An ST episode was defined as a transient deviation of at least 0.1 mV in any lead lasting at least 1 min. In-hospital myocardial revascularization was performed at the discretion of the attending physician. The endpoint was death or nonfatal (re) myocardial infarction, whichever occurred first by 30 days follow up.
Results: A total of 203 ST episodes (135 clinically silent) were detected in 76 patients (25.0%). Myocardial revascularization was performed in 200 patients (65.8%), through percutaneous intervention in 146. Median time from admission to revascularization was between 24 and 48 hours. The detection of ST episodes was independently associated with worse 30-day outcome, even after adjustment for baseline clinical characteristics, ECG changes and cardiac troponin I levels (adjusted odds ratio 4.9; 95% CI, 1.9 to 12.9; p=0.001). In the group of patients with ST episodes, myocardial revascularization had a beneficial impact on prognosis (10.5% event rate versus 36.8% in patients not revascularized; odds ratio 0.2; 95% CI, 0.1 to 0.7; p=0.022). In the group of patients without ST episodes, the effect of myocardial revascularization was modest (2.8% event rate versus 5.9% in those not revascularized; odds ratio 0.5; 95% CI, 0.1 to 1.8; p=ns).
Conclusion: In non-ST-elevation acute coronary syndromes, continuous ST segment monitoring provides early prognostic information, additional to that of clinical characteristics and biochemical markers of myocardial injury and is useful for selection of patients who most benefit from early myocardial revascularization.

P3003 Management and predictors of 30-day events in the French registry on acute coronary syndromes without persistent ST elevation (FRACAS)

M. Angioi[1], P. Joly[2], M. Bertrand[3], N. Danchin[4], J. Puel[5], F. Baigts[6], M. Fouchard[6]. [1]*CHU Nancy, Cardiology, Vandoeuvre-les-Nancy, France;* [2]*Clinique Claudel Parc, Cardiology, Marseille, France;* [3]*Hopital Cardiologique, Cardiology, Lille, France;* [4]*Hopital Européen Georges Pompidou, Cardiology, Paris, France;* [5]*Hopital Purpan, Cardiology, Toulouse, France;* [6]*MSD et Chibret, Cardiology, Paris, France*

Background: Most of the available data about acute coronary syndromes (ACS) were provided by randomised trials. We therefore sought to investigate the current management and the early outcome of ACS without ST elevation in French centres with on-site percutaneous coronary intervention (PCI) facilities.
Methods: 89 centres selected on a geographic basis were asked to complete a prospective record for 10 consecutive patients (pts) admitted in their coronary care unit for ACS without persistent ST elevation (chest pain<48 hours with ECG changes and/or myocardial damage marker elevation).
Results: 873 pts were included (mean age 65±13, male 73%). Most of the patients experienced chest pain within 12 hours prior to admission (87%) and a history of coronary artery disease was present in 51%. Following ECG changes were observed: ST depression 42%, transient ST elevation 5%, T waves abnormalities 42%. Only 13% of the pts had normal ECG. During the first 24 hours, abnormal serum cardiac markers were elevated in 40% of the pts (either CK>2ULN or Troponin>N). Initial antithrombotic regimen included a combination of heparin+antiplatelet agents in 86% with either heparin or antiplatelet agents in 99%. Initial prescription of GP IIB/IIIA inhibitors was low (8.6%). In addition, 71% of the pts were on bblockers and 70% on IV nitrates. During the index hospitalisation, coronary angiography was performed in 790 pts (90%) and coronary revascularisation in 529 pts (61%, PCI 484, CABG 45). PCI were mainly performed within 48 h following admission (55%) and the procedure included GP IIB/IIIA inhibitors infusion in 21% and stent implantation in 80%. At 1 month, 572 pts (66%) had undergone coronary revascularisation (PCI, 493, CABG 85). 30-day outcome was available in 804 pts and the predefined combined endpoint of death, Q-wave MI or refractory ischemia was noted in 10.1%. Endpoint rate according to the TIMI risk score, was, 2.8, 9.8 and 13.9% for the low, medium and high risk, respectively (p<.006). Independent predictors of an impaired outcome were: ST depression or prior Q-wave on ECG, initial CK or troponin elevation, presence of 3-vessel disease and no coronary angiogram performed as well as the TIMI risk score if entered in the model.
Conclusion: Management of ACS without persistent ST elevation in centres with on-site PCI facilities was characterised by an early invasive strategy with a high percentage of myocardial revascularisation. The early outcome was similar to that of reported in randomised trials and was easily predicted by a risk score derived from these trials.

P3004 Which stress test is superior for perioperative cardiac risk stratification in patients undergoing major vascular surgery?

M.D. Kertai[1], D. Poldermans[1], E. Boersma[1], R. Sicari[2], G.J. L'Italien[3], J.J. Bax[1], H. van Urk[1], J.R.T.C. Roelandt[1]. [1]*Erasmus Medical Centre, Cardiology, Rotterdam, Netherlands;* [2]*CNR Institute of Clinical Physiology, Pisa, Italy;* [3]*Pharmaceutical Research Institute, Bristol-Myers Squibb, Wallingford, United States of America*

Background: Patients undergoing major vascular surgery are at increased risk of cardiac complications. Cardiac risk factors can be used in conjunction with appropriate diagnostic testing to identify high-risk patients. We explored the comparative added prognostic value of Dobutamine Stress Echocardiography (DSE), Dipyridamole Stress Echocardiography (DiSE) and Perfusion Scintigraphy (DTS) in large cohorts of vascular patients.
Methods: Prior to major vascular surgery 2204 consecutive patients were screened for cardiac risk factors: age>70 years, history of myocardial infarction, angina pectoris, heart failure and diabetes mellitus. These patients then also underwent DiSE (n=394), DSE (n=1093), or DTS (n=717) testing. Positive DiSE or DSE results were defined as new or worsening wall motion abnormalities (NWMA), whereas a positive test result for DTS was defined as a reversible perfusion defect during stress. Logistic regression analyses were applied to evaluate the relation between clinical risk factors, noninvasive cardiac tests, and a composite of cardiac death or non-fatal myocardial infarction (MI).
Results: There were 138 patients (6.3%) with cardiac death or MI. Patients with 0, 1-2, and 3 or more clinical risk factors experienced respectively 3.0%, 5.7%, 17.4% cardiac events. No statistically significant difference was observed in the predictive value of NWMA for DiSE and DSE (Odds ratio (OR) 37.1 [95%CI, 8.1-170.1] vs. 9.6 [95%CI, 4.9-18.4]; P=0.12), whereas a positive test result for DTS had significantly lower prognostic value (OR=1.95 [95%CI, 1.2-3.2]). Estimated cardiac event rate for individual patients according to the number of risk factors and test result is shown in the table.

Estimated cardiac event rate

No. of Risk Factors	SE		DTS	
	negative	positive	negative	positive
0	1%	15%	4%	3%
1 to 2	1.3%	10.4%	11%	16%
>3	3.3%	27.6%	20%	31%

SE, stress echocardiography; DTS, dipyridamole perfusion scintigraphy

Conclusion: A result of stress echocardiography effectively stratified patients into low- and high-risk groups for cardiac complications, irrespective of clinical risk profile. In contrast, a positive DTS result did not differentiate between those who did and did not have a cardiac complication.

P3005 Cardiac death in scleroderma: a linkage with autonomic dysfunction

M. Emdin[1], D. Giuggioli[2], A. Ripoli[3], C. Passino[1], M. Sebastiani[2], C. Ferri[2]. [1]*CNR Institute of Clinical Physiology, Cardiovascular Neuroendocrinology Unit, Pisa, Italy;* [2]*Depatment of Internal Medicine, Rheumatology Unit, Pisa, Italy;* [3]*CNR Institute of Clinical Physiology, Pisa, Italy*

Ventricular arrhythmias and cardiac death occur in patients with systemic sclerosis (SSc), even in absence of overt myocardial dysfunction- In order to evaluate the eventual prognostic significance of abnormalities in autonomic nervous control of the heart, or in ventricular repolarisation. as compared to other validated humoral and clinical markers of disease severity, 100 patients with systemic sclerosis (SSc) without overt myocardial involvement at Echo-Doppler examination, neither other systemic disease, underwent prospectively 24-hour ECG ambulatory recording while free-living spontaneous. A computerized algorithm was used to identify T wave on the precordial lead and to measure the QT interval; QTc was computed by the Bazett's formula; heart rate variability was investigated by means of time-domain and spectrum analysis. Out of the 100 SSc patients (17% males, 83% females, aged 54.8 ± 12.1 years, mean ± S.D., 64% was diagnosed with the limited form of the disease, 15% with the intermediate, 21% with the diffuse form). At the survival analysis a mean follow-up of 2100 days has been assessed, wit an overall mortality of 22% and cardiac mortality of 5%. Many conventional clinical and humoral markers of disease severity were considered with EKG-derived indices in the statistical analysis. Multiple logistic regression with forward stepwise selection (Wald) has been used to test the independent relation between the death and the covariates found to be significant at the univariate logistic regression. Kaplan-Meier life table estimates of spontaneously occurring event-free survival have been used to summarize the follow-up. Statistical significance has been taken as a p value of < 0.05.
At the multivariate analysis, cardiac death was predicted by abnormalities in lung diffusion properties (p= 0.011; 95%CI for Odds Ratio -OR- 0.837 0.978), LF/HF ratio (p= 0.05; OR= 0.00001-0.044), LF (low frequency power, normalised units, p= 0,0264; OR= 0.591-0.968), whereas overall mortality was predicted by SCL70 antibodies level (p=0.004; OR= 2.366-102.391) and by LF/HF ratio (p= 0. 014; OR= 0.00001-0.0006). QT and QTc value had not prognostic value. Increasing values of SCL70 antibodies significantly augmented the probability of cardiac death, which was decreased by increasing values of LF/HF and LF power. The latter abnormalities, detectable by a feasible, non-invasive diagnostic approach, indicate the presence of autonomic cardiac neuropathy in SSc patients and its prognostic value as for cardiac and overall mortality.

P3006 Lack of effect of warfarin in patients with diabetes mellitus after myocardial infarction

P. Smith[1], M. Hurlen[2], M. Abdelnoor[2], H. Arnesen[2]. [1]*Baerum Hospital, Department of Medicine, Baerum, Norway;* [2]*Ulleval University Hospital, Department of Cardiology, Oslo, Norway*

Following results of subgroup analyses in a previous study we investigated whether diabetes mellitus (DM) might adversely modify the effect of warfarin in the Warfarin Aspirin Re-Infarction Study (WARIS II). The entry criterion of this study was clinically stabilized acute myocardial infarction. Patients (n=3630) who had no clear indication/contraindication for any of the study drugs were randomly allocated to one of three regimens: aspirin 160 mg/d, aspirin 75 mg/d and warfarin with a target INR of 2 to 2.5, or warfarin alone aiming for an INR of 2.8 to 4.2. The average follow-up period was four years. The primary endpoint of the parent study was the composite of death, nonfatal reinfarction and nonfatal thromboembolic stroke.
At baseline the prevalence of DM was 6.8% in the warfarin group, 8.7% in the combination group and 9% among those allocated to aspirin alone (n.s). Altogether there were 241 endpoints in the aspirin group, 203 in the warfarin group and 181 in the combination group.
Outcome was calculated in in terms of odds ratios. DM was an effect modifier for the association between endpoints and treatment. Statistically significant heterogeneity was found for nondiabetic subjects (OR 0.75, 95% CI 0.60-0.93) versus diabetic subjects (OR 1.54, 95% CI 0.80-2.94), p=0.038. The odds ratio exceeded 1 in diabetic patients, hence suggesting an adverse effect of warfarin therapy in this group. A Cox model was used to control for the effect of age and gender within the two strata. The following risk ratios (95% CI) and p-values were calculated for therapy with warfarin vs. aspirin (table):

	Warfarin + aspirin vs aspirin	Warfarin vs aspirin
Non-diabetes	0.65 (0.53-0.81) p=0.0001	0.79 (0.64-0.96) p=0.022
Diabetes	1.48 (0.88-2.50) p=0.14	1.52 (0.87-2.63) p=0.14

Our observation suggest a lack of a beneficial effect by warfarin therapy in subjects with diabetes mellitus, when the therapy is given for the sole purpose of prophylaxis after a sustained myocardial infarction.

P3007 Initiation of therapy with angiotensin-converting enzyme inhibitors in patients with severe angina pectoris and heart failure

Y. Lopatin[1], V. Ivanenko[2], N. Ryazantseva[1]. [1]*Volgograd Cardiology Centre, Coronary Artery Disease, Volgograd, Russian Federation;* [2]*Volgograd Medical Academy, Cardiology, Volgograd, Russian Federation*

Background: One of the risk factor of first-dose hypotension (FDH) in pts with angina pectoris and heart failure (HF) is high doses of vasodilators and beta-blockers. Therefore, we investigated the first-dose effects of various angiotensin-converting enzyme inhibitors (ACEI) by monitoring 24-hour blood pressure (BP) in patients with severe angina pectoris and HF.
Methods: 85 male pts (mean age 56.0±1.0 years) with stable severe angina pectoris (CCS class III-IV) and HF (NYHA class II-III, mean 2.5±0.1, mean ejection fraction 32.1±0.6%) were included into the single-blind, parallel-group study. Mean BP (MBP), was calculated every 15 minutes during the first 24 hours of the study. First-dose hypotension (FDH) was defined as MBP fall >20 mm Hg. At the first stage 55 pts were randomized to captopril 6.25 mg, enalapril 2.5 mg, ramipril 1.25 mg, cilazapril 1.25 mg and perindopril 2 mg. Diuretic therapy was stopped 24 hours before ACEI initiation. At the second stage of study FDH of two ACEI with the least hypotensive effects (perindopril and enalapril) in 30 pts were investigated. Concomitant treatment with isosorbide dinitrate (41.9±2.8 mg/24h) and bisoprolol (10 mg/24h) was continued.
Results: Maximal reduction of MBP was -25.6±2.7% (captopril), -21.3±1.8% (enalapril), -24.5±3.6% (ramipril), -22.0±2.6% (cilazapril) and -16.1±2.8% (perindopril). In pts taking combined antianginal therapy first dose of enalapril produced maximal reduction of MAP on 20.4±1.9% while perindopril on 15.7±1.8% (p=0,05). MAP decrease on 20 mm Hg and more was 46.7% in enalapril group and 13.3% in perindopril group (p=0,03). Analysis of MAP hourly average changes showed BP reduction at 2H (-5.7 mm Hg, p=0.01), at H3 (-5.7 mm Hg, p=0.002) and H10 (-8 mm Hg, p=0.02) in enalapril group while in perindopril group there was no significant BP reduction. The attacks of angina were fixed at 20% pts only in enalapril group.
Conclusion: FDH is an important factor that might explain underuse of ACEI in patients with HF and angina pectoris. However, ACEI might differ in their safety profile at initiation of therapy. Large comparative trials are indicated.

P3008 Effects of a missed dose of antianginal therapy evaluated by 24-hr ambulatory electrocardiogram monitoring and exercise testing. Data from the CAPE II study

P. Sellier[1], J.M. Detry[2], J. Deanfield[3], B. Beckerman[4] on behalf of the Scientific Committee of the CAPE II study. *[1]Broussais-HEGP, Cardiac Rehabilitation Dept., Paris, France; [2]Cliniques universitaires Saint Luc, Cardiology, Brussels, Belgium; [3]Great Ormond Street Hospital, Cardiology, London, United Kingdom; [4]Pfizer Inc, New York, United States of America*

Aim: In clinical practice, patients (pts.) frequently miss doses of antianginal medication. The aim of this study was to compare the consequences on myocardial ischemia of missed doses of different medical regimens.
Methods: 212 pts.(177 male, 25 female, aged 61±8 yrs) were included in a randomized trial comparing 2 drug regimens during stable dosing. Three-day ambulatory ECG monitoring (AECG) and exercise testing (ET) were performed on regular therapy with Amlodipine (A: 106 pts.), Diltiazem (D: 96 pts.) and combination therapy: A + Atenolol (AT;104 pts.) or D + 5 mononitrate (5mn; 91 pts.). On the third day of AECG pts. were given a matched placebo to simulate omission of a single drug dose, and both tests AECG and ET were repeated. The variables measured were for ET: time to 1mm ST depression (TimeST1), time to angina (TimeAng.), exercise duration (Ex.Dur), and for AECG: Nb ischemic episodes (N.epis.), total duration of ischemia (Isch. Dur.). Findings on active treatment were compared to those after omission. Statistics concern between treatments comparisons of changes due to omission.
Results:

Variables	Changes in	monotherapy		Changes in	combination	therapy
	A	D	p	A	D	p
ET						
Ex. Dur. (sec)	-2±63	-22±78	0.039	-14±67	-41±79	0.010
Time ST1 (sec)	0±97	-24±116	0.021	-17±85	-45±99	0.049
Time Ang. (sec)	-5±74	-6±89	0.847	-13±75	-45±85	0.005
AECG						
N. Epis. (/24h)	12	92	0.005	71	145	0.276
Isch. Dur. (min)	-215	800	0.022	1364	1498	0.696

Conclusions: Thus there are important clinically relevant differences in the impact of missed doses of different drug regimen, evaluated both by exercise test and by AECG. In contrast to (D) +5momonitrate, the intrinsically long acting calcium channel blocker (A) provides consistent benefits as monotherapy or in combination with atenolol.

P3009 Recurrent ischaemia in acute coronary syndromes: differential impact of electrocardiogram changes on outcomes

P.H.G. Steg[1], L.J. Feldman[1], M. Brami[2], A. Vahanian[1], K.A. Eagle[3], J. Lopez-Sendon[4], O. Dabbous[5], S.G. Goodman[6] on behalf of the GRACE investigators. *[1]Hôpital Bichat, Service de Cardiologie, Cedex 18, Paris, France; [2]CMC Europe, Port Marly, Cardiology, Paris, France; [3]University of Michigan Health System, Cardiology Division, Ann Arbor, USA; [4]Hospital Universitario Gregorio Marano, Dept. of Cardiology, Madrid, Spain; [5]Univ. of Mass. Medical School, Center for Outcomes Research, Worcester, USA; [6]St Michael's Hospital, Cardiology, Toronto, Canada*

It is generally accepted that reinfarction following myocardial infarction is associated with worse short- and long-term outcomes but few data are available regarding the various types of recurrent ischaemia (RI) and their impact on outcomes after acute coronary syndromes (ACS). The Global Registry of Acute Coronary Events (GRACE) is an international registry of patients with ACS in 94 hospitals and 14 countries. We analysed the demographics and outcomes of 17,511 patients with and without in-hospital RI (see Table for results).
Results: Multivariate analysis showed that male gender, history of previous angina, infarction, low heart rate, elevated systolic blood pressure and bleeding were independent predictors of RI during the hospital stay. Finally, RI itself was an independent predictor for hospital death after adjusting for baseline characteristics: the whole ACS population (odds ratio(OR): 1.6, 95% confidence interval: 1.36-1.95); and among patients presenting with ST-segment elevation myocardial infarction (STEMI) (OR: 1.96, 95% confidence interval 1.36-1.98), and non-STEMI/unstable angina (OR: 1.5, 95% confidence interval: 1.17-1.99).
Conclusions: RI is a frequent event in patients admitted with ACS (30.2%) but its impact is highly dependent on electrocardiographic (ECG) changes or reinfarction. Two-thirds of patients with RI have neither reinfarction nor ST changes and their outcomes appear to be very similar to those of patients without RI. Conversely, in ACS patients with reinfarction or with RI and ST changes (9.7% of all ACS pts), in-hospital outcomes were worse and length of stay was longer. These results highlight the persistent need for improvement in the treatment of ACS.

P3010 Long-term cardiac medication after acute myocardial infarction: is it maintained consequently?

S. Hoffmann, A. Mohadjer, D. Andresen. *Vivantes Klinikum am Urban, Cardiology, Berlin, Germany*

Long-term therapy with aspirin (ASS), beta-blockers (BB), lipid lowering drugs (LLD) and ACE inhibitors (ACE) improves short and long-term prognosis of patients (pts) suffered from acute myocardial infarction (AMI). However, little is known about wether medication at hospital discharge is maintained during subsequent follow up. Between May 1999 and December 2000, 400 consecutive pts with AMI (72% male, mean age 61 years) were included in the Berlin Myocardial Infarction Study. Cardiac medication was documented at hospital discharge. Follow up was performed after 6 and 12 months (mean 259 and 449 days) with documentation of the actual medication. Information was obtained with a standardized questionaire by telephone contact and clinical visit.
Results: Among the 400 pts discharged from hospital after AMI, follow up response was 97% (388). 12 months follow up mortality was 10% (40/388).
There was no significant drop-out rate in taking ASS during follow up: among all 348 survivors 87% (303/348) received ASS at discharge, 6 months later 89% (306/348) and 12 months later 86% (301/348). The respective numbers for BB are 93% (324/348) vs. 82% (286/348) vs. 80% (278/348) (p=0,0001 for the comparison discharge vs. 6 months, p=0,0001 for the comparison discharge vs. 12 months), for LLD 81% (282/348) vs. 70% (243/348) vs. 67% (233/348) (p=0,0006 and p=0,0001) and for ACE 54% (188/348) vs. 51% (178/348) vs. 57% (198/348)(for both n.s.).
Conclusion: The present results indicate that pts behavior in taking ASS and ACE remains constant during one year follow up. Nonetheless there is a substantial drop-out-rate of benificial long-term medication with BB and LLD. Wether this is due to inadequate patient education, decreasing budget or limited patient compliance due to side-effects, has to be investigated.

P3011 Do we have to treat asymptomatic patients after myocardial infarction with angiotensin-converting enzyme inhibitors and betablockers? Results from the ABC-trial

H. Theres, A. Müller, P. Fotuhi, W. Mildenberger, G. Baumann. *Charité, Medical Clinic, Cardiology, Berlin, Germany*

Introduction: Combined treatment with ACE-inhibitors and betablockers of symptomatic patients suffering from heart failure (NYHA II-IV) is well established. Until now there was no randomized, controlled study for asymptomatic patients with only moderate reduced left ventricular ejection fraction (LVEF >40%) after myocardial infarction (MI) available.
Methods: 160 asymptomatic patients (mean age 59 years, 135 male, 25 female) after MI with a LVEF >40% were treated for 18 month with open label (OL) Metoprolol (Meto) or Ramipril (Rami). In addition patients were randomized to receive a double-blinded (DB) medication with either Placebo (Pla) or the corresponding medication (Meto or Rami). This resulted in 4 patient groups: group (G) 1: Meto (OL) + Rami (DB); G2: Meto (OL) + Pla (DB); G3: Rami (OL) + Meto (DB); G4: Rami (OL) + Plac (DB). Primary endpoint was LVEF after 18 months. There was no difference in the baseline LVEF between the 4 groups.
Results: LVEF after 18 months in G1 was 48,6% (±13,1), in G2 46,2% (±13,4), in G3 48,8% (±10,7) and in G4 50,8% (±9,9%) (p=ns).
Conclusion: The combination of ACE-inibitors and Betablockers compared to monotherapy with either one in asymptomatic patients with only moderate reduced LVEF after MI did not result in a higher LVEF after 18 months. Further studies are warranted to clerify the value of combined treatment compared to monotherapy in this patient group.

Abstract P3009 – Table: Outcomes with and without in-hospital RI

	RI	Reinfarction	RI with ST-seg changes	RI without ST change or reinfarction	P comparisons for the three types of RI	Without RI	P (with vs without RI)
N (%)	4828 (30.2)	261	1433	3134		11,170 (69.8)	
Age (years)	66.7	69.0	67.5	66.0	<0.0001	66.0	NS
Male (%)	64.0	64.3	63.4	63.6	0.9623	68.4	<0.0001
STEMI at admission (%)	35.8	67.4	41.0	30.8	<0.0001	44.4	<0.0001
Death (%)	5.6	29.5	7.2	3.0	<0.0001	5.0	0.022
Congestive heart failure (%)	16.6	34.8	19.7	13.7	<0.0001	13.8	<0.0001
Cardiac arrest (%)	5.7	27.1	8.0	3.0	<0.0001	4.8	0.018
Median length of stay (days)	7	12	8	7	<0.0001	6	<0.0001

Demographics and outcomes of 17,511 patients.NS=not significant

P3012 Concerted action of various angiogenic factors during acute myocardial infarction in patients: the three lines of defense

K.I Kapetanios[1], C.E. Pitsavos[2], S. Kastelanos[2], G.P. Vyssoulis[2], D.B Panagiotakos[2], M.G. Toutouza[2], C.I. Stefanadis[2], P.K. Toutouzas[2]. [1]*Athens, Greece;* [2]*University of Athens Medical School, Cardiology Department, Athens, Greece*

It is well documented that angiogenesis plays a key role in the process of ventricular remodeling following acute myocardial infarction (AMI). However, the exact contribution of each of the numerous angiogenic agents in this process is still an issue of debate. We sought to evaluate the role of three major angiogenic peptides: free Insulin-like Growth Factor-1 (fIGF-1), basic Fibroblast Growth Factor (bFGF) and Angiogenin (ANG), in AMI patients.

Methods: 40 pts with first attack of AMI admitted in our department and thrombolysed during the acute phase,without previous history of any other disease, were examined for plasma levels of fIGF-1, bFGF and ANG, measured by ELISA, and compared to corresponding levels of 20 sex and age- matched normal controls (NC) with mean values: 7,78 ± 0,75 ng/ml for fIGF-1, 1,62 ± 0,53 pg/ml for bFGF and 210,12 ± 25,6 ng/ml for ANG. Plasma samples were collected on hospital admission (0 hours) and 3h, 6h, 9h, 12h, 18h, 24h, 36h, 48h, 3 days, 4d, 5d, 7d, 15d and 30d thereafter.

Results: Data is expressed as mean values ± SEM in ng/ml for fIGF-1 and ANG and in pg/ml for bFGF. For the statistical analysis the non-parametric Wilcoxon test was used with a statistical significance of $p<0,05$ compared to corresponding values of: a) NC (*), b) the relevant plasma value on admission (°). fIGF-1 exhibited significantly high initial plasma levels on admission (10,92 ± 0,93 *) followed by a gradual increase up to a maximum level at 36h (16,64 ± 2,12 *°). This peak was succeeded by a progressive decline that ended to a minimum value at 30d (12,14 ± 1,35 *). bFGF developed a significant early peak at 0h (5,27 ± 1,13 *) followed by a steep decline leading to a nadir at 24h (1,63 ± 0,46 °), that was reversed leading to a late peak at 15d (8,93 ± 2,06 *). ANG also exhibited a double-peak increase at 0h (327,12 ± 31,75 *) as well as at 4d (305,86 ± 29,44 *) with the lowest plasma value at 24h (233,74 ± 18,32 °).

Conclusions: Thus, the activation of the numerous angiogenic agents seems to be triggered at different time points. Some of them exhibit an immediate peak shortly after AMI onset probably as a result of acute hypoxia due to coronary artery occlusion, while others develop an intermediate or a late peak, therefore exerting their cardioprotective potential in three distinct lines of defense. At the same time, they all act in concert to stimulate angiogenesis either by playing a pivotal role in the induction of this process, or by manipulating its multiple steps later in an attempt to modulate ventricular remodeling and preserve cardiac function.

P3013 Changes in the frequency spectrum of the endocardial electrogram in acute myocardial ischaemia and recent infarction

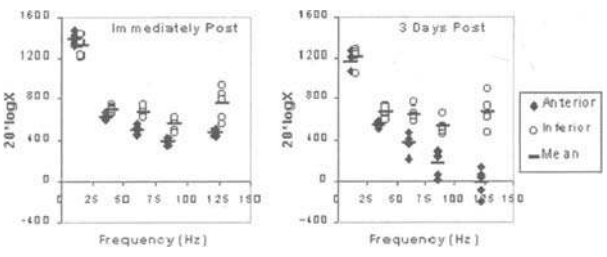
J. Lessick[1], A. Schwartzman[2], L. Gepstein[3], G. Hayam[3], T. Wolf[3], S.A. Ben Haim[3]. [1]*Rambam Hospital, Cardiology, Haifa, Israel;* [2]*Biosense Webster, Haifa, Israel;* [3]*Technion - ITT, Faculty of Medicine, Haifa, Israel*

Peak-to-peak unipolar endocardial voltage (Vuni) is useful in identifying chronically infarcted myocardium but is insensitive in recognising acute ischemia. Vuni also has limited spatial resolution, due to significant far-field effects. We postulated that analysis of the high frequency components of the electrogram would improve the delineation of acute and chronic ischemia.

Methods: Eight dogs underwent LAD ligation and had 'Biosense' electromechanical mapping and echocardiography performed at baseline and immediately post-occlusion. Five dogs survived to repeat the studies at 3 days. A representative electrogram was obtained for the ischemic anterior zone and the remote inferior zone for each ventricle. Frequency spectra for each zone were obtained by performing FFT and a log scale was used to amplify high frequency components.

Results: Small baseline differences were found; anterior zones having a larger low frequency (0-30 Hz) component (p=0.02) and inferior zones a larger high frequency (>50 Hz) component ($p<0.03$). Immediately post-occlusion, there was a small reduction in voltage throughout the spectrum in both zones, while a consistent more prominent reduction occurred in the high frequency components (>30 Hz) of the anterior zones ($p<0.005$). At 3 days, a further diffuse reduction was noted in amplitude, but predominantly in the very high frequency components (>75 Hz) of the anterior zones ($p<0.02$). A clear threshold could distinguish between the high but not the low frequency components of ischemic and remote zones in all ventricles in acute ischemia (p=0.0005) and in recent infarction (p=0.002).

Thus, specific changes in the frequency spectrum of the endocardial electrogram permit a consistent distinction between ischemic and remote zones.



Frequency spectrum.

P3014 Differences in hospital reinfarctions complicating acute myocardial infarction as observed in current randomised trials will not influence long-term mortality

R. Zahn, R. Schiele, S. Schneider, K. Dönges, J. Senges on behalf of the MITRA study group. *Herzzentrum Ludwigshafen, Kardiologie, Ludwigshafen, Germany*

Background: In 2001 three large RCT's (GUSTO V, ASSENT 3, HERO 2) on non-mechanical reperfusion strategies in AMI were published. All studies did not find a mortality benefit for the new treatment strategies, however they found a reduction in the rate of non-fatal hospital reinfarction from 1.1% to 2.4%. Non-fatal in-hospital reinfarction is known to be a predictor of further death. Therefore the true benefit of the new treatment strategies might be realized at late follow up.

Methods: We analysed the prospective observational MITRA data base selecting AMI patients similar to the RCT patients, to determine whether the observed differences in reinfarction rates will have a influence on long term mortality.

Results: Out of 6737 patients included in MITRA between 1994 and 2000 and a completed follow-up, 2109 (31%) fulfilled the selection criteria. Non-fatal in-hospital reinfarction occurred in 3.6% of patients. During the hospital stay urgent coronary revascularization (PCI or CABG) was performed in 43.4% of patients with non-fatal reinfarction compared to 12.5% without non-fatal reinfarction ($p<0.001$). Follow-up was performed at a median of 18 months.

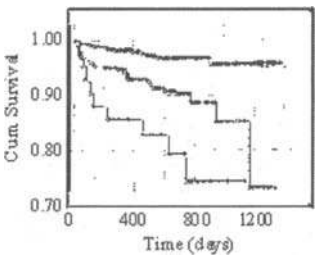
Mortality at 1-year after discharge was 6.8% (95%CI: 2.3% - 11.3%) in patients with versus 4.4% (95%CI: 3.5% - 5.3%) in patients without a non-fatal reinfarction (absolute difference 2.4%, p = 0.04 by log rank test). Using the largest difference in non-fatal reinfarction rates described by the RCT's of 2.4% (ASSENT 3 trial) case load calculation resulted in 4111792 patients needed to find a significant difference in 1-year mortality. Even in the "worst" scenario, using the upper and lower 95%CI limits, still 317748 patients would be needed.

Conclusion: Our data make it very improbable that the observed differences in the rates of non-fatal in-hospital reinfarctions between the treatment arms in the GUSTO V, the ASSENT 3 and the HERO 2 trials will result in reduced 1-year mortality rates.

P3015 New heart rate variability algorithm is a powerful tool for risk prediction after acute myocardial infarction

A. Bauer[1], R. Schneider[2], P. Barthel[1], M.T. La Rovere[3], P.J. Schwartz[4], M. Malik[5], G. Schmidt[2]. *[1]Deutsches Herzzentrum München, Munich, Germany; [2]Technische Universität, I. Medizinische Klinik, München, Germany; [3]Fondazione S Maugeri IRCCS, Montescano, Italy; [4]University of Pavia, Department of Cardiology, Pavia, Italy; [5]St.George's Hospital Medical School, Department of Cardiological Sciences, London, United Kingdom*

Aim of the study: To validate a new HRV algorithm in post MI patients derived from 24 hour Holter recordings.
Methods: The algorithm selects all RR intervals in 24-hour Holter ECGs which are slightly longer (>100% & <=105%) than their preceding RR intervals and calculates the mean interval prolongation (MIP).
The cut-points of MIP were optimised in a training sample consisting out of 591 patients (primary endpoint: total mortality, median follow up 22 months). The method was validated in the ATRAMI population (1284 patients, primary endpoint: fatal or non fatal cardiac arrest, median follow up 20 months). Univariate and multivariate analyses (sex, age, HRV index, SDNN, mean heart rate, LVEF, baroreflex sensitivity (BRS)) were performed.
Results: In the training sample, we observed two optimal cut-points for MIP: 8 ms and 18 ms. In the ATRAMI population, LVEF was the strongest univariate and MIP the second strongest risk predictor (p=0,0037 and p=0,0038, respectively). With multivariate analysis, LVEF, MIP and BRS were independent risk predictors (LVEF: p=0,0061; MIP: p=0,0017; BRS: p=0,021). Kaplan Meier survival curves of patients with MIP >= 18ms, 8-18ms and <8ms are shown in the figure.



Conclusions: MIP is a strong and independent risk predictor in post-infarction patients.

ENDOTHELIAL FUNCTION

P3016 Endothelial dependent vasodilatation and incidence of cerebrovascular events in healthy postmenopausal women

R. Rossi, G. Fantini, D. Monopoli, M. Zennaro, M.G. Modena. *Policlinico, Internal Medicin. Institute of cardiol, Modena, Italy*

Background: Postmenopausal women have been shown to have abnormal endothelium-dependent vasodilatation (EDVD). However, the prognostic role of an impaired EDVD was only poorly investigated, particularly in relation with the incidence of cerebrovascular events (CE). This study was aimed to investigate the relationship between an abnormal EDVD and the long-term incidence of CE. It also allowed the assessment of CE risk in a less studied specific subgroup of patients.
Method: 188 consecutive healthy postmenopausal women (mean age 65 ± 11 years) underwent a ultrasonographic study of the brachial artery, and were then followed up for a mean period of 75 months (range: 67-88). Women with previous cardio and cerebrovascular diseases, hypertension, diabetes mellitus, hyperlipidemia were excluded from the study. EDVD was evaluated by measuring the diameter of the brachial artery before and during reactive hyperaemia (induced after deflation of a blood pressure cuff inflated to suprasystolic pressure for 5 minutes) and was calculated from the diameters as: (reactive hyperemia – baseline)/baseline X 100%.
Results: The median value of EDVD in the entire study population resulted in 9.5% (25th-75th percentiles were 6.4% and 12.9%, respectively). The 94 women with an EDVD < 9.5% were classified in group 1 (abnormal EDVD); the remainder women (n = 94), with an EDVD > 9.5%, in group 2 (normal EDVD). There were no intergroup differences regarding age, blood pressure values, cholesterol plasma levels, fasting glucose plasma levels, duration of menopause and hormone replacement therapy use. During follow up, 14 of 94 women (14.9%) experienced a CE in group 1 (abnormal EDVD), versus 4 of 94 (4.2%) in group 2 (normal EDVD) (p < 0.0001). There were 12 cases of transient ischemic attack (TIA) in group 1 as opposed to 3 cases in group 2 (p < 0.0001). Moreover, only few women experienced an ischemic stroke (2 cases in group 1 versus 1 case in group 2; p = ns). Multivariate logistic analysis revealed that an abnormal EDVD [Odds Ratio = 2.89 (95% Confidence Intervals from 1.76 to 4.43)] is the only variable that remainder as a significant and independent predictor of TIA in our population. All the cases were validated by review of hospital records.
Conclusions: This study demonstrates that an abnormal EDVD clearly identifies postmenopausal women with an high risk of TIA.

P3017 The plasma NO/ET-1 ratio is a useful marker for the grade of coronary vascular disease

A. Kurita, B. Takase, T. Ishizuka, K. hagisawa, T. Matsui. *Japan, Naitonal Deense Medical College, Division of Biomedical Engineering, Tokorozawa, Japan*

Background: The arterial endothelial function (AEF) is used for detecting of coronary vascular disease (CVD) in clinical research setting. Further it is regulated by local release of nitric oxide (NO) and endothelin-1 (ET-1). However there were no reports whether AEF and/or plasma NO/ET-1 ratio can be useful marker in comparing with exercise testing (EXT) and coronary risk factors. Methods: We measured the brachial artery (BA) vasodilative response to both endothelium-dependent (ED) and endothelium-independent vasodilation (EID, NTG 0.3mg SL) by using high resolution ultrasounds(7.5MHz) of 38 hypertensive patients (HT pts) with normal coronary artery and 32 patients with CVD (>=70%). The plasma NO and ET-1 levels were measured using ENO-200 and RIA. Soon after these procedures, symptom limited EXT was performed by Bruce protocol. Results:The sensitivity and specificity for detecting of CVD in plasma NO/ET-1 ratio >= 2.0 was 90% and 85%, whereas ST depression >=1.0mm (80 msec from J point) was 80% and 78%.

	BA-RH (%)	BA-IND	NO/ET-1	ST	TC	HDL
CVD	5±6	6±7	1.1±1.1	-1.4±0.9*	199±36	52±36
HT	6.3±4	10±4*	2.7±2.2**	-0.8±0.4	189±36	51±16

Conclusion: Our results suggest that plasma NO/ET-1 ratio is a useful new marker for estimating of CVD, which is equivalent to usual EXT and superior to AEF. EXT capacity might be based on vasodilative and vasoconstrictive products ffrom AE cell. (*p<0.05 **p<0.01)table

P3018 Chronic smoking is associated with endothelial dysfunction and increased levels of tumour necrosis factor-α, interleukin-1β and interleukin-6

D. Tousoulis, C. Antoniades, C. Tentolouris, C. Toutouzas, K. Marinou, C. Pitsavos, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, Cardiology Unit, Athens University, Athens, Greece*

Background: Smoking is known to be associated with endothelial dysfunction, mainly through an increase of oxidative stress. Tumor necrosis factor (TNF-a), a pro-inflammatory cytokine as well as interleukines -1b (IL-1b) and -6 (IL-6) are implicated in the pathogenesis of atherosclerosis. In this study we investigated the effects of chronic smoking on endothelial function, inflammation and lipid peroxidation.
Methods: In this study, 45 smokers (23 males 22 females, aged 34±1 years, smoked 18.1±2.1 pack-years) and 11 non smokers (6 males 5 females, aged 30±2years) were enrolled. Forearm blood flow was measured using venous occlusion strain-gauge plethysmography. Endothelium dependent flow mediated vasodilation (FMD) was expressed as the % change from baseline to post reactive hyperemia blood flow. Endothelium independent flow (NTR%) was assessed as the % change from baseline to post sublingual nitroglycerin administration flow. Serum levels of TNF-a, IL-1b and IL-6 were determined by enzyme linked immunosorbent assay. Lipid peroxidation was evaluated by measuring lipid hydroperoxides (LPO) using a spectrophotometric assay. All values are expressed as mean±SEM.
Results: Blood pressure, heart rate, body weight, basal forearm blood flow and NITR% were similar between smokers and non smokers. FMD was significantly greater in non smokers (111.2±17.1%) compared to smokers (49.8%±3.0, p<0.001). Plasma levels of TNF-a, IL-1b and IL-6 were significantly greater in smokers (1.73±0.12, 0.21±0.022 and 2.55±0.46, pg/ml respectively) than in non smokers (1.1±0.10, 0.12±0.011 and 0.80±0.12 pg/ml respectively) (p<0.05 for TNF-a and p<0.01 for interleukines 1b and 6). However plasma level of LPO was not significantly different between the two groups. Pack-years was correlated with FMD (r=-0.475, p=0.001) and serum levels of TNF-a (r=0.379, p=0.004), IL-1b (r=0.227, p=0.048) and IL-6 (r=0.438, p=0.002).
Conclusion: Smoking is associated with endothelial dysfunction and increased levels of TNF-a, IL-1b and IL-6. These findings provide evidence that smoking may be associated with a vascular inflammatory process.

P3019 Impaired endothelial function and increased intina-media thickness of the common carotid arterial wall in patients with â-thalassemia major

G. Hahalis[1], A. Kalogeropoulos[1], A. Chrysanthopoulou[2], G. Terzis[2], C. Stathopoulos[1], D. Alexopoulos[1], A.S. Manolis[1]. [1]*University Hospital, Cardiology Department, Patras, Greece;* [2]*University Hospital, Divisions of Hematology and Radiology, Patras, Greece*

Cardiovascular complications are common in patients (pts) with b-thalassemia major (bTM). Both endothelial dysfunction and thickening of the carotid arterial wall are associated with atherosclerosis or its risk factors. In pts with bTM an increased vascular oxidative stress has been reported. Desferrioxamine has favorable effects on endothelial dysfunction in pts without bTM.

Methods: We evaluated endothelial function and thickness of the common carotid arterial wall in pts with bTM by means of high-resolution ultrasonography. In twenty seven pts with bTM (age 25±7years, serum ferritin 2380±1664 ng.ml-1, 59% on optimal chelation therapy) without cardiac disease or diabetes mellitus and 27 healthy control subjects, flow-mediated dilatation (FMD) was measured as % change of the post-ischemic right brachial artery (BA) diameter. Endothelium-independent, nitroglycerin-induced vasodilatation (NID) and intima-media thickness (IMT) of the posterior common carotid arterial wall were also assessed.

Results: (table 1) The two groups were matched for age, gender, body surface area, blood pressure and smoking habits. Serum cholesterol was lower in pts with bTM (124±37 versus 185+33 mg.dl-1, $p < 0.0001$).

(table 1)

	Patients with bTM	Healthy subjects	p
BA diameter (mm)	3.84±0.66	3.95±0.58	ns
Post-ischemic BA blood flow (ml.min-1)	341±209	384±174	ns
FMD (%)	6.98±2.5	10.05±4.2	<0.01
NID (%)	14.86±6.22	16.66±4.23	ns
Carotid artery IMT (mm)	0.51±0.08	0.45±0.06	<0.01

No correlation was found between FMD or IMT and serum ferritin levels. Conclusion: These data point toward a proatherogenic milieu with reduced bioavailability of nitric oxide in thalassemic patients despite near absence of cardiovascular risk factors. Our findings may be explained by iron-mediated oxidative stress on vascular endothelium.

P3020 The effect of red wine on endothelial function and oxidative stress in patients with acute coronary syndrome

E. Guarda, I. Godoy, R. Foncea, D. Perez, C. Romero, R. Venegas, F. Leighton. *Catholic University of Chile, Santiago, Chile*

Background: Moderate red wine consumption may improve endothelial function in normal volunteers. This can be related with antioxidant properties present in red wine. Since in coronary patients both endothelial dysfunction and oxidative damage play an important role, we sought to explore the effects of moderate red wine consumption on these parameters in patients with an acute coronary syndrome (ACS).

Methods: We enrolled 20 patients treated with PTCA and stent after an acute coronary event (unstable angina and non Q AMI). All patients received treatment with step 2 AHA diet, aspirin, clopidogrel, betablockers and atorvastatin. Patients were randomly selected to a red-wine group (n= 9, 250 ml daily, Cabernet Sauvignon variety) or to a control group (n= 11, abstinence from alcoholic beverages). Studies were performed at baseline and after 2 months. Endothelial function was estimated by flow mediated vasodilatation of the brachial artery using a 3-11 mHz linear array transducer at 1, 2 and 3 min after releasing the cuff pressure. To evaluate plasma antioxidant capacity, we measure total antioxidant reactivity (TAR) using a free radical generator and chemiluminiscence, and ferric reducing antioxidant power (FRAP). Oxidative damage was evaluated by 8-OH deoxyguanosine measurements (8-OHdG). Data are shown as mean ± standard error and differences were compared by paired or unpaired t test as appropriate.

Results: There were no diferences in clinical outcomes at follow-up. Flow mediated vascular reactivity increased by 37% (P= 0.20) and 109%($P<0.01$) in control and wine groups, respectively. Total Cholesterol/HDL ratio was significantly increased by approximately 21% in both groups ($p< 0.04$). Plasma total antioxidant capacity increased significantly only in the wine group, from 273±20 to 330±15 μM for TAR ($P<0.03$) and 1219±82 to 1449±63 μM for FRAP ($P<0.001$). Oxidative DNA damage in controls decreased from 13.1±1.1 to 10.0±1.0 ($P<0.003$) whereas with wine, it decreased from 13±0.8 to 5.6±0.7 per 100000 guanosines ($P<0.001$; p=0.002 vs control).

Conclusion: Conventional therapy after an ACS managed with PTCA was useful to reduce lipid alterations and decrease DNA damage, whereas it did not increased significantly brachial reactivity. The addition of moderate red wine consumption to conventional therapy increased plasma antioxidant capacity and decreased DNA damage, which may be related with a significant improvement in endothelial function.

P3021 Endothelial function in salt-sensitive healthy subjects with parental hypertension: strategies of pharmacological correction

G. Simonia[1], N.I. Tatishvili[2], I.T. Andronikashvili[2], I.M. Jashi[3]. [1]*Tbilisi State Medical University, Chair Internal Diseases& UNESCO Chair, Tbilisi, Georgia;* [2]*State Medical University, Chair of Internal Diseases, Tbilisi, Georgia;* [3]*Institute of Cardiology, Tbilisi, Georgia*

Endothelial dysfunction has been considered as a main factor in the development of salt-sensitive hypertension. Previously we have showed that ACE inhibitors significantly improved endothelial function in patients with salt-sensitive essential hypertension. The aim of our study was evaluation of endothelial function in salt-sensitive healthy offspring of hypertensive patients.

Methods: A total of 22 healthy salt-sensitive subjects (12 males, 10 females aged 19 to 26 years) with well documented history of parental hypertension were studied. Age matched control group included 18 healthy subjects whose parents did not suffer from essential hypertension. Salt sensitivity was determined by Weir (1986) method. NO was directly measured by electron spin resonance spectroscopy. Plasma big endothelin (ET-1) level was determined by extraction-based competitive radioimmunoassay (Biomedica; Vienna, Austria).

Results: NO production was reduced approximately by 27% in salt-sensitive subjects in comparison with the control group. In contrast plasma levels of Big ET-1 were significantly increased in offspring of hypertensive patients (8.8±0.87 pmol/l vs. 4.6±0.55 pmol/l in controls, $p<0.05$). Administration of lisinopril resulted in increase of NO production and reduced Big ET-1 plasma levels in salt-sensitive healthy subjects.

Conclusion: Endothelial dysfunction has been revealed in healthy salt-sensitive subjects with parental hypertension, which might be the main mechanism of predisposition to essential hypertension. Early treatment of salt-sensitive healthy subjects with ACE inhibitors is considered to be a valuable method of primary prevention of essential hypertension.

P3022 Endothelial function is negatively correlated to ST-segment depression during exercise in women with angina and normal coronary arteries

S. Jadhav[1], N. Sattar[2], W. Ferrell[3], J. Petrie[3], S. Cobbe[1]. [1]*Glasgow Royal Infirmary, Medical Cardiology, GLASGOW, United Kingdom;* [2]*Glasgow Royal Infirmary, Pathological Biochemistry, Glasgow, United Kingdom;* [3]*Glasgow Royal Infirmary, Medicine, Glasgow, United Kingdom*

Background: Women with chest pain and normal coronary arteries present a common and often difficult clinical scenario. It has been suggested that some may have myocardial ischaemia, caused by microvascular disease and that endothelial dysfunction with reduced vasodilator capacity might be an aetiological factor. It is often difficult to separate those with microvascular angina, from those with a non-cardiac aetiology of their chest pain.

Methods: We recruited 51 women with both an electrically positive exercise tolerance test (ETT) and a coronary angiogram in the previous two years demonstrating normal epicardial vessels. The ETT was repeated with manual measurement of maximal ST segment deviation. Endothelial function (EF) was assessed non-invasively in the forearm cutaneous vascular bed by means of laser-doppler imaging in response to iontophoretic application of acetylcholine (ACh) and sodium nitroprusside. An arbitrary cut-off point of 10000 units (area under the curve) for the ACh response was used to categorise subjects those with 'normal' or 'impaired' EF.

Results: 33 women (65%) had impaired EF. Only 13 women (26%) had a second unequivocally positive ETT (greater then 2mm ST depression). There was a negative linear correlation between the extent of ST depression and EF ($r=0.44$ $p=0.001$). All 13 women with greater than 2mm ST depression had impaired EF and no women with 'normal' EF had 2mm or more of ST depression. However, 20 women with 'impaired' EF did not have significant ST depression. In addition, 25 healthy aged-matched controls were recruited and had their endothelial function measured. There were statistically significant differences between the EF of the controls and that of the 13 women with a positive ETT Discussion. There was an association between endothelial dysfunction and ST changes on ETT in these women with chest pain and normal coronary arteries. Women with reproducible ECG changes had impaired EF when compared to healthy controls. Our data suggest a potential novel application of non-invasive assessment of endothelial function as an adjunct to ETT in identifying with greater sensitivity and specificity, women with and without microvascular angina. This hypothesis should be tested in an independent sample of these patients.

P3023 Reactive hyperemia peripheral arterial tonometry: a novel non-invasive test to identify patients with coronary endothelial dysfunction

P. O. Bonetti, G. M. Pumper, S. T. Higano, A. Prasad, D. R. Holmes Jr, A. Lerman. *Mayo Clinic, Division of Cardiovascular Diseases, Rochester, United States of America*

Background: Coronary endothelial dysfunction (CED) is considered the very early stage of coronary atherosclerosis and is associated with myocardial ischemia and an adverse prognosis. Because CED is reversible early identification of this disorder may have therapeutic implications. Reactive hyperemia peripheral arterial tonometry (RH-PAT) is a novel, non-invasive plethysmographic method to assess peripheral vasomotor function using a finger-mounted probe. This study was designed to test the hypothesis that CED is associated with an attenuation of RH-PAT values.

Methods and Results: 31 patients without obstructive coronary artery disease, undergoing coronary endothelial function testing with graded intracoronary acetylcholine infusion, were studied and divided into two groups according to the presence (n=15) or absence (n=16) of CED. Using RH-PAT digital pulsatile arterial volume changes were assessed at rest and during reactive hyperemia following transient complete brachial arterial occlusion with a blood pressure cuff. In addition, PAT response to the endothelium-independent vasodilator nitrogycerin was assessed in 8 patients with and 10 patients without CED. RH-PAT index was calculated as the ratio of the peak pulsatile blood volume response at 1, 2, 3, and 4 minutes after cuff deflation divided by the pulsatile blood volume changes at rest. RH-PAT indices were significantly lower in patients with CED compared to those with normal coronary endothelial function during the first 3 minutes of reactive hyperemia (1 minute: 1.3±0.1 vs. 1.8±0.1, p=0.002; 2 minutes: 1.3±0.1 vs. 1.6±0.1, p=0.006; 3 minutes: 1.2±0.1 vs. 1.4±0.1, p=0.04), whereas the PAT response to nitroglycerin was similar in both groups.

Conclusions: This study demonstrates that peripheral hyperemic response, as measured by RH-PAT, is attenuated in patients with CED, suggesting a role for RH-PAT as a novel, non-invasive test for the identification of patients with CED.

P3024 C reactive protein protects endothelial nitric oxide synthase expression in bovine endothelial cells in culture

E. Garcia-Colis, M.M. Gonzalez, J. Farré, L. Sánchez de Miguel, L. Molero, L. Rico, J. Gomez, A. Lopez-Farré. *Fundación Jiménez Díaz, Cardiovascular Research Laboratory, Madrid, Spain*

C reactive protein is a acute phase inflammatory marker and it has been considered as a coronary syndrome marker. However, C reactive protein can also produce biological actions.

Objective: The aim of our study was to analyze the C reactive protein effects on endothelial nitric oxide synthase expression (eNOS) in aortic bovine endothelial cells (BAEC) in culture.

Method and Results: BAEC were incubated with two different cytokines, tumor necrosis factor-alpha (TNF-alpha, 500 U/mL) or with interleukin-6 (IL-6, 10 ng/mL) during 24 hours in the presence and in the absence of increasing concentrations of C reactive protein (0-25 μg/mL). TNF-alpha reduced eNOS protein expression in BAEC and this effect was associated to an increase in the interaction of a 60 KDa cytosolic protein with the eNOS mRNA. This protein has been termed as endothelial dysfunction inductor protein (EDIP). C reactive protein protected eNOS protein expression in a dose dependent manner and reduced the interaction of EDIP with the eNOS mRNA. This effect was associated with a more prolonged half life of eNOS mRNA. Similar results were obtained with the IL-6. IL-6 reduced eNOS expression increasing the ability of EDIP protein to interact with eNOS mRNA. These effects were reverted in the presence of C reactive protein.

Conclusion: C reactive protein although it is considered as an inflammatory marker, protects eNOS expression reducing the interaction of EDIP to eNOS mRNA and favouring eNOS mRNA stability.

P3025 Endothelial function is associated with plasma levels of C-reactive protein in patients with coronary artery disease

G.M.C. Rosano[1], E. Cerquetani[1], O. Gebara[2], C. Vitale[1], A. Silvestri[1], M. Wajngarten[2], J.A. Ramires[2], M. Fini[1]. [1]*San Raffaele, Internal Medicine, Roma, Italy;* [2]*University of Sao Paulo, INCOR, Sao Paulo, Brazil*

Endothelial function is impaired in patients with coronary artery disease (CAD), in these patients plasma levels of C-Reactive protein (CRP) are related to future cardiac events. Aim of the present study was to assess the relation between endothelial function and CRP in 73 patients (52 men, 21 women, mean age 66±9 yrs) with CAD. Endothelial function was evaluated by means of flow-mediated dilatation (FMD) of brachial artery following ischemia and CRP by means of a high sensitive assay. Baseline values of CRP and FMD were compared with those of 32 healthy controls (25 men, 7 women, mean age 65±11 years). After baseline evaluation patients underwent full medical therapy for 3 months at the end of which they were tested for endothelial function and CRP again.

Compared to healthy controls pts had significantly impaired endothelial function (FMD 3.6±3.2% vs 8±2.4%, $p<0.01$) and higher plasma levels of CRP (1.6±0.9 mg/dl vs 0.9±0.56 mg/dl, $p<0.05$). A significant negative correlation was found between plasma levels of CRP and FMD in patients with CAD at baseline ($r= -0.56$, $p<0.05$) while no correlation was found in controls. Medical therapy resulted in a significant improvement in endothelial function (3.64±3% vs 7.2± 3.5%, $p<0.01$), and a decrease of CRP (-0.26±0.19, $p<0.01$), the change in CRP and FMD was indepentent from the drug used. A positive correlation was found between improvement in FMD and degree of CRP reduction ($r= 0.57$, $p<0.01$).

In conclusion plasma levels of CRP are associated with and impaired endothelial function in patients with CAD suggesting a correlation between inflammation and integrity of the endothelium. Full medical therapy reduces CRP and parallely improves endothelial function.

P3026 Endothelial dysfunction is a feature of treated major depression

A.J.M. Broadley[1], C.J.H. Jones[2], A. Korszun[3], M.P. Frenneaux[2]. [1]*Room 1/20, Cardiff, United Kingdom;* [2]*University of Wales, Cardiology, Cardiff, United Kingdom;* [3]*University of Wales, Psychological Medicine, Cardiff, United Kingdom*

There is increasing evidence that depression is a risk factor for the subsequent development of coronary heart disease (CHD), conferring an approximately twofold increased risk. Traditional risk factors for CHD (e.g. smoking, hypertension, diabetes and hypercholesterolaemia), are characterised by arterial endothelial dysfunction, which promotes atherogenesis and is a strong prognostic factor for CHD events. Arterial endothelial dysfunction has been reported in newly diagnosed, untreated depression and is a possible mechanism by which depression confers increased cardiovascular risk. It is not known if endothelial dysfunction persists after effective treatment of depression and symptom remission.

We studied 12 subjects (mean age 39, range 24 to 51, 6 male) who were being treated for primary major depression (DSM-IV criteria) and were in symptom remission, and 10 controls (mean age 37, range 24 to 55, 7 male). All subjects and controls were without other risk factors for CHD. Arterial endothelial function was assessed by measurement of brachial artery flow-mediated dilatation (FMD). We also measured baroreflex sensitivity (BRS), a measure of autonomic control of heart rate in response to changes in blood pressure. Arterial endothelial function measured by FMD was significantly impaired in the depression group(-0.7%, standard error of mean (SEM) 1.7%) compared to the control group (5.9%, SEM 0.9%) ($p=0.004$ by non-paired t-test) whereas glyceryl trinitrate-induced endothelium-independent dilatation of the brachial artery was similar in patients and controls (18.5% (2.4) v 19.0% (2.5), p=NS). BRS did not differ significantly between the groups.

In conclusion, arterial endothelial dysfunction, which has been demonstrated in newly diagnosed, untreated depression, is also present in treated depression. This abnormality may contribute to the increased risk of CHD and does not appear to improve with antidepressant treatment.

P3027 Heavy metal ions and function of vascular endothelium in patients with coronary artery disease

W. Kuliczkowski[1], B. Jolda-Mydlowska[1], M. Kobusiak-Prokopowicz[1], W. Kosmala[1], J. Antonowicz-Juchniewicz[2], J. Orzeszko[1]. [1]*Medical Academy, Department of Cardiology, Wroclaw, Poland;* [2]*Medical Academy, Internal and Occupational Medicine, Wroclaw, Poland*

There is well-established link between dysfunction of vascular endothelium and pathogenesis and progression of atherosclerosis. Many different factors can deteriorate or improve function of endothelium. Many other are still expected to be discovered. Among them we can list heavy metal ions (HMI): selenium (Se), zinc (Zn), lead (Pb), cadmium (Cd), manganese (Mn) and copper (Cu).
The aim of the study was to investigate the relation of concentration of Pb and Cd in blood and Se, Zn, Cu and Mn in plasma with function of endothelium in population of patients with coronary heart disease (CAD).
Study population consisted of 60 patients (32 men and 28 women) mean age 62,4 ± 10,5 yrs, all former or current smokers with no history of working in environment with high exposure to HMI. The diagnosis of coronary artery disease was established upon coronary angiography in which 70% narrowing of the vessel was considered as significant. Blood concentrations of Cd and Pb and plasma concentrations of Cu, Zn, Mn, Se were estimated by SAA method (Spectrophotometry Atomic Absorption). Plasma nitric oxide (NO) served as a marker of endothelial functional status and its level was estimated by ELISA method.
Results: In multivariate analysis significant partial correlations of NO with Zn ($r=0.4$, $p<0.004$), Mn ($r=0.9$, $p<0.002$) and Se ($r=0.76$, $p<0.02$) were revealed. Blood concentrations of Cd and Pb were below threshold limit value for non-exposed population and plasma concentrations of Zn, Mn, Se, Cu were within normal limits.
Conclusions 1. Se, Zn and Mn may have in normal concentrations positive effect on vascular endothelium expressed as production of NO in patients with CAD.

P3028 Direct biochemical evidence for enos stimulation by bradykinin in the human forearm vasculature

T. Lauer[1], P. Kleinbongard[1], M. Preik[1], B H. Rauch[2], A. Deussen[3], M. Feelisch[4], B E. Strauer[1], M. Kelm[1]. [1]*Universitätsklinikum Düsseldorf, Kardiologie, Pneumologie, Angiologie, Düsseldorf, Germany;* [2]*Heinrich-Heine-Universität Düsseldorf, Department of Pharmacology, Düsseldorf, Germany;* [3]*Institut für Physiologie, Med. Fakultät Carl Gustav Carus, Dresden, Germany;* [4]*LSU Health Sciences Center, Dep. of Molecular and Cellular Physiol, Shreveport, United States of America*

Objective: Although it has been shown recently that acetylcholine (ACh)-induced vasodilation of forearm resistance vessels is almost entirely mediated by nitric oxide, direct biochemical evidence for eNOS stimulation by bradykinin (BK) in the human arterial circulation is still lacking. Therefore, the present study was designed to test the hypothesis, that in the human forearm vasculature eNOS stimulation significantly contributes to BK-induced vasodilation.
Methods: BK was infused in the presence and absence of the NOS inhibitor, L-NMMA (8 μmol/min) into the brachial artery of 16 healthy volunteers and the effects compared to muscarinergic NOS stimulation following acetycholine infusion. Forearm blood flow (FBF) was measured by venous occlusion plethysmography and plasma nitrite (NO2-), which represents a sensitive and specific marker of regional eNOS activity, was determined in the antecubital vein and brachial artery by flow injection analysis. Nitric oxide release was calculated as product of the veno-arterial difference of NO2- concentration times FBF. Results: Kininergic (BK: 20, 60, 200 ng/min) as well as muscarinergic (ACh: 1, 3, 10 μg/min) stimulation resulted in a dose dependent increase in FBF and NO2- in each individual. The relationship between FBF and NO release upon BK infusion was comparable to that obtained with ACh ($r= 0.98$; $n=96$, $p<0.01$). Moreover, eNOS inhibition reduced both flow responses and NO release (BK: 54 and 75%; ACh: 57 and 72%) to a similar extent. Conclusions: This is the first direct biochemical evidence for the involvement of eNOS in BK-induced vasodilation of human forearm resistance vessels. BK may represent a suitable alternative tool to assess disturbances of the L-arginine-NO-pathway in vivo.

P3029 Differential effects of nitric oxide species on human platelet function: interaction with thiols

S.R. Willoughby[1], A.P Cap[2], J. Loscalzo[2]. [1]*The Queen Elizabeth Hospital, Cardiology Unit, Adelaide, Australia;* [2]*Boston University, Whitaker Cardiovascular Institute, Boston, United States of America*

Background: Endothelial-derived relaxing factor (EDRF) is an important endogenous modulator of vascular tone and platelet function. Although originally believed to be identical to nitric oxide radical (NO°), recent reports suggest that EDRF may consist of a mixture of various nitric oxide species. In addition, the vasorelaxant effects of EDRF are inhibited by the thiol cysteine (Cys), while those of nitric oxide radical are not. Although the one electron reduction product of nitric oxide, nitroxyl anion (NO-) has previously been shown to possess vasorelaxant properties and to be inhibited by Cys, little is known about its interaction with platelets. Therefore we tested the effect of different nitric oxide species [nitroxyl anion, nitric oxide radical and nitrosonium, (NO+)] on platelet aggregation as well as the influence of thiols [Cys and homocysteine (Hcy)] on the interaction.
Methods: Platelet aggregation was performed on platelet-rich plasma prepared from blood samples from healthy adult volunteers. Nitroxyl anion derived from Angelis' salt inhibited ADP-induced (5-10 μM) platelet aggregation in a dose-dependent manner; total inhibition of aggregation occurred at 50 μM, with threshold effects at 1.0 μM. Nitrosonium from S-nitroso-glutathione and nitric oxide radical from diethylamine NONOate were more potent inhibitors of platelet aggregation with threshold effect at 0.01 and 0.1 μM, respectively. Cys (500 μM) significantly decreased the inhibitory effect of 10μM nitroxyl anion ($p>0.03$), but did not affect the responses of either nitrosonium (1μM) or nitric oxide radical (0.1 μM). Hcy (500 μM) did not affect the inhibitory response of any nitric oxide species tested. Cys (500 μM) or Hcy (500 μM) alone did not inhibit platelet aggregation. The higher (L-cysteic acid) and lower (cystine) oxidative forms of Cys had no affect on nitroxyl anion responses. Similar results were obtained for homocyteic acid and homocystine. Interestingly, Cys did not effect the increase in intraplatelet cGMP content produced by either nitroxyl anion or the other nitric oxide species.
Conclusion: Although nitroxyl anion is a less potent inhibitor of platelet aggregation than either nitrosonium or nitric oxide radical these data confirm that like EDRF, nitroxyl anion is inhibited by Cys. These results suggest that the interaction between nitroxyl anion and Cys may lead to a decrease in bioactive EDRF.

P3030 Activated protein C (APC) modulates the expression and release of monocyte chemoattractant protein-1 (MCP-1) in cultured human endothelial cells

M. Brückmann, A. Marx, V. Liebe, S. Lang, H.M. Weiler, M. Borggrefe, G. Huhle, K.K. Haase. *University Hospital of Mannheim, 1st Dept. of Medicine, Mannheim, Germany*

Background: Monocyte chemoattractant protein-1 (MCP-1) plays a critical role in recruiting monocytes to stressed endothelium as an early response to vascular injury. MCP-1 has been reported to be protective under inflammatory conditions such as sepsis and to favor production of antiinflammatory and immune-stimulating cytokines. The activated protein C (APC) pathway has been suggested to be a common link between coagulation and inflammation. In addition to its anticoagulant properties, APC may also function to restore hemostasis via cytokine/chemokine induction, thereby amplifying the local inflammatory reaction. The aim of this in vitro study was to determine the effect of APC on the expression and release of chemokine MCP-1 in human umbilical vein endothelial cells (HUVEC) and to investigate posssible intracellular mechanisms being involved.
Methods: HUVEC were treated with human APC (2.5-10μg/ml) either alone or in combination with tumor necrosis factor-alpha (TNF-alpha 0.1-1ng/ml). MCP-1 was analyzed in supernatants by ELISA and MCP-1-mRNA was determined by a colorimetric mRNA quantitation assay (Quantikine-assay®). The activities of fifty-four different transcription factors in nuclear extracts were analyzed by a protein/DNA array.
Results: APC stimulated MCP-1-gene transcription and MCP-1-protein-synthesis in a time and dose dependent manner: MCP-1-gene transcription was up-regulated compared to controls after 1 hour of incubation with APC. MCP-1 was detected in HUVEC-supernatants as early as 2 hours after the addition of APC and continued to increase through the 24h incubation period. Transcription factor arrays suggested that neither NF-kappa B nor AP-1 were involved in APC's effect on MCP-1-expression. TNF-alpha stimulated mRNA transcription and release of MCP-1. HUVEC pretreated with APC for one hour strongly enhanced the TNF-alpha-stimulated MCP-1 release.
Conclusion: By modulating mRNA-transcription and protein synthesis of MCP-1 in endothelial cells APC contributes to leukocyte trafficking and adherence at the site of vascular injury. Thereby APC may aid in the local inflammatory reaction and may modulate initiation and progression of atherosclerotic lesions.

P3031 Endothelial dysfunction in myocardial inflammation affects patients with and without left ventricular dysfunction

K.B. Vallbracht, P.L. Schwimmbeck, B. Seeberg, U. Kuehl, H.P. Schultheiss. *University Hospital Benjamin Franklin, Cardiology, Berlin, Germany*

Objective In myocardial biopsies of patients with myocarditis, endothelial activation can be detected by immunhistology. We hypothesize, that the inflammatory process leads to coronary and peripheral arterial endothelial dysfunction. Further, the impact of left ventricular function (LV-F) on endothelial function in these patients is examined.
Methods Endothelial function of the radial artery was assessed in 34 patients with myocardial inflammation (InfCM) and 10 healthy subjects. By use of high resolution ultrasound, endothelium dependent, flow mediated vasodilation of the radial artery was examined in response to reactive hyperemia. To exclude impairment of vascular smooth muscle cell reactivity, we also tested endothelium independent vasodilation by applying an exogenous NO donor (trinitroglycerin). Left ventricular function was assessed by LV-angiogramm and echocardiography. Patients with arteriosclerotic risk factors were excluded from this study.
Results Mean age of the 34 patients was 47±13 years, 14 were male, 20 female, mean left ventricular ejection fraction (EF) was 57±19%. Mean age of the 10 controls was 43±15 years, sex distribution was equal, EF was normal. Endothelial function of the radial artery, as assessed by flow mediated vasodilation (FMD), was significantly impaired in patients with InfCM (FMD 4.3±3.1%), as compared to controls (FMD 10.4±16%) ($p<0.001$). Endothelial dysfunction in patients with InfCM was more pronounced in patients with impaired LV-F (n=16, EF 40±15%, FMD 2.5±2.7%), as compared to patients with normal LV-F (n=18, EF 71±7%, FMD 5.7±2.6%) ($p<0.001$). Endothelial function correlates with left ventricular function. However, endothelial dysfunction was also significantly impaired in patients with InfCM and normal LV-F (FMD 5.7±2.6%) as compared to controls ($p<0.001$). Endothelium independent vasodilation was preserved in patients with InfCM (GTN-MD 28±8%).
Conclusions Endothelial function is impaired in peripheral arteries of patients with InfCM, even when left ventricular function is normal. This is likely to be caused by the inflammatory response in the endothelium and can be potentiated by other factors with impact on endothelial function, like left ventricular function. Endothelial dysfunction in InfCM is not restricted to the coronary arteries, but is systemic.

P3032 C-reactive protein induces endothelial cell migration via activation of distinct chemotactic signaling pathways

S. Goetze, A. Bungenstock, U. Kintscher, P. Stawowy, F. Blaschke, K. Graf, E. Fleck, M. Gräfe. *German Heart Institute, Cardiology Dept., Berlin, Germany*

C-reactive protein (CRP) is a pluripotent mediator of inflammation, and is present at sites of vascular injury and in atherosclerotic lesions. CRP stimulates endothelial cell adhesion molecule expression and monocyte migration, and thereby contributes to the development and progression of vascular lesion formation. In addition to these inflammatory processes, endothelial cell (EC) migration is also involved in the pathogenesis of atherosclerosis, since it plays a major role in the neovascularization of the atherosclerotic plaque. It was the aim of this study to investigate the role of CRP in endothelial cell migration and the chemotactic signaling pathways involved. CRP (0.1-10 ng/ml) induced migration of cultured human umbilical vein EC in a dose-dependent manner (maximal 3.5-fold at 10 ng/ml, $p<0.05$) after incubation for 5 h in a transwell chamber system. Previous studies have shown that EC migration in response to other chemoattractants requires activation of several protein kinases including p42/44 MAPK, p38 MAPK, myosin light chain kinase (MLCK), Akt and eNOS. Using the pharmacological p42/44 MAPK pathway inhibitor PD98059 (30 μM) or the MLCK inhibitor ML7 (1 μM), we observed a significant inhibition of CRP-induced EC migration by more than 90% for each inhibitor (all $p<0.05$). CRP-stimulated EC migration was also dramatically inhibited by the PI3-Kinase->Akt->eNOS-pathway inhibitor wortmannin (-94% at 100 nM, $p<0.05$), whereas the p38 MAPK inhibitor SB203580 (1 μM) had no effect on EC migration. Immunoblotting with phosphospecific antibodies revealed the rapid and transient activation of p42/44 MAPK and MLCK by CRP (10 ng/ml) within 15 minutes, which was completely blocked by PD98059 (30 μM). In contrast, wortmannin did not affect CRP-induced p42/44 MAPK-, or MLCK-phosphorylation. However, CRP-stimulated phosphorylation and activation of Akt and eNOS, which reached maximal responses in EC within 30 minutes, were potently inhibited by wortmannin (100 nM). PD98059 had no effect on Akt- or eNOS-phosphorylation.
Our results indicate, that early activation of two distinct chemotactic signaling pathways, the p42/44 MAPK->MLCK- and the PI3-Kinase->Akt->eNOS-pathway, are essential for CRP-induced EC migration.

P3033 Azithromycin treatment improves endothelial function in patients with coronary artery disease and evidence of chlamydia pneumoniae infection

N. Parchure, E. Zouridakis, J.C. Kaski. *St George's Hospital Medical School, Cardiological Sciences Dept., London, United Kingdom*

Background: It has been suggested that infection with Chlamydia pneumoniae (CPn), can trigger inflammatory mechanisms that may, in turn, impair vascular endothelial function. The aim of the present study was to assess whether treatment with the macrolide antibiotic azithromycin improves endothelial function in patients with coronary artery disease (CAD)and positive antibodies to CPn.
Methods: We carried out a randomised, prospective, double blind, placebo-controlled trial in 40 male patients (mean age of 55±9 years) with angiographically documented CAD and positive CPn-IgG antibody titers (>1:16). After baseline evaluation, patients were randomized to receive either azithromycin or placebo for 5 weeks. Flow mediated dilatation (FMD) of the brachial artery, E-selectin, von Willebrand factor (vWF) and C-reactive protein (CRP) levels were assessed at study entry and at the end of the treatment period.
Results: Baseline evaluation showed that there were no significant differences between the 2 groups of patients treated with azithromycin or placebo regarding patients' age, body mass index, the presence of traditional risk factors and medication including lipid-lowering drugs, as well as glucose and lipid levels.Baseline FMD was also similar in azithromycin and placebo groups (2.66±1.89% vs 3.11±2.06%, P=0.47). Repeated FMD measurements showed that patients who received azithromycin had a significant improvement in FMD (mean change: 2.1±1.1%, $P<0.005$) after 5 weeks of treatment. In contrast, FMD was not significantly changed in the placebo group (mean change: -0.02±0.2%, P=0.64). Azithromycin therapy also resulted in a significant decrease of E-selectin and vWF levels. CRP levels were not significantly altered by treatment with either azithromycin or placebo.
Conclusions: Our findings indicate that treatment with azithromycin has a favorable effect on endothelial function in patients with documented coronary artery disease and evidence of CPn infection. Whether these favorable actions of antibiotic treatment will translate into a beneficial effect on atherogenesis and cardiac events, needs further investigation.

P3034 IL-1RN (VNTR) gene polymorphism predicts a proinflammatory endothelial cell phenotype in HUVEC-Implications for atherogenesis and plaque rupture

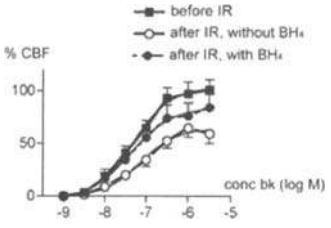
K K. Ray[1], S E. Francis[2], D C. Crossman[2]. [1]*University of Sheffield, Cardiovascular Research Group, Sheffield, United Kingdom;* [2]*University of Sheffield, Cardiovascular Research Group, Sheffield, United Kingdom*

Background: Carriage of allele *2 IL-1RN(VNTR) is associated with angiographic single vessel coronary artery disesae(Francis et al Circ 1999) but the mechanisms are not understood. Interactions between monocytes & endothelial cells (EC) play a significant role in the pathogeneis of atherscIerosis & plaque rupture. These processes may involve an increased expression of adhesion molecules e.g. E-selectin, in response to proinflammatory cytokines which are abundant in atherosclerotic plaques. IL-1RN(VNTR) *2 carriage, results in reduced intracellular levels of IL-1ra in HUVEC (Dewberry et al ATVB 2000. A 1000 fold excess of IL-1ra is required to antagonise the actions of IL-1. We hypothesised that carriage of *2 IL-1RN (VNTR) might result in an inflammatory EC phenotype. Methods: HUVEC were cultured in 24 well plates & genotyped for IL-1RN(VNTR). At confluence they were stimulated with 0.1, 1 and 10ng/ml of IL-1beta for 6 & 24 hours. E-selectin levels were measured in the cell lysate & in the supernatant using an ELISA kit(R&D systems). The association of the homozygous forms of the rarer *2 & common 1 allele, with E-selectin expression, were compared by an unpaired t-test.Results: IL-1 beta significantly increased the expression of E-selction in the cell lysate compared with unstimulated cells for either genotype at 6 & 24 hours. There was no significant difference between the 3 different doses of IL-1 beta on E-selectin expression in the lysate. Levels rose after 6hrs & then fell at 24hrs in both genotypes. However the 2,2 genotype was associated with increased expression of E-selectin for each dose of IL-1 beta compared with the 1,1 genotype(132.5 ± 27.88, 126.25 ± 1.28 & 152.58 ± 6.11ng/ml cf 75.32 ± 3.78, 71.99 ± 8.21 & 67.36 ± 6.48ng/ml respectively: p=0.09, 0.02 & 0.02 respectively) at 6 hours and at 24 hours (27.49 ± 2.86, 32 ± 1.78 & 26.7 ± 5.18ng/ml cf 12.29 ± 0.74, 11.07 ± 0.3 & 13.1 ± 1.42ng/ml respectively: p=0.04,0.007 & 0.1 respectively).Conclusions: Our data suggests that the homozygous form of the rarer *2 allele of IL-1RN(VNTR) is associated with an exaggerated expression of adhesion molecules in response to inflammatory stimuli. This may result in the increased accumulation of inflammatory cells at specific sites. We postulate that this mechanism could result in increased atheroma formation in stable coronary disease (Francis et al) or lead to palque rupture in inflamed vulnerable plaques. Our data also suggests that the release of soluble E-selectin from the cell surface into the supernatant may require more than one stimuli such as activated neutrophils.

P3035 BH4 improves endothelial function after ischaemia/reperfusion

A. Moens, J. Bosmans, M. Claeys, D. Borgonjon, M. Vanderheyden, C. Vrints. *University Hospital of Antwerp, Dept. of Cardiology & Pharmacology, Edegem-Antwerp, Belgium*

Background: Reperfusion after myocardial ischemia augments tissue injury in excess of that produced by ischemia alone, and leads to coronary endothelial dysfunction. Amelioration of endothelial dysfunction after myocardial ischemia represents an attractive goal for therapeutic interventions to reduce symptoms or clinical events. This study was designed to determine whether tetrahydrobiopterine (BH4) improves endothelium-dependent coronary vasomotion after ischemia/reperfusion (IR). BH4 is an essential cofactor of nitric oxide synthase (NOS) and a scavenger of oxygen-derived free radicals. Decreased availability of BH4 leads, under in vitro conditions, to reduced NO production and increased superoxide formation. BH4 improves endothelial function in patients with cardiovascular risks or with chronic coronary artery disease, but it has never been proven that BH4 ameliorates endothelial disfunction after ischemia/reperfusion injury.
Methods and results: Vasoresponses to bradykinine (bk, 50×10^{-6} l, 10^{-9} to 10^{-5} M) were recorded in isolated Langendorff perfused rat hearts (n=12), before and after ischemia/reperfusion (15/30 min.).
BH4 (10^{-2} M) was added to the perfusate of during reperfusion (n=7). The vasodilator responses to bk after reperfusion (% of coronary bloodflow, CBF) were very significantly improved (p<0,0001, ANOVA)



Conclusion: Administration of BH4 during reperfusion reduces endothelial dysfunction after IR. This observation may represents a new therapeutic option in patients with a recent myocardial infarction.

P3036 Risk/benefit ratio of revascularisation versus medical therapy in chronic coronary artery disease of the elderly

C. Kaiser[1], G.M. Kuster[1], P. Erne[2], F.W. Amann[3], O. Bertel[4], S. Osswald[1], P. Buser[1], M. Pfisterer[1] on behalf of the TIME Investigators. [1]*University Hospital, Division of Cardiology, Basel, Switzerland;* [2]*Kantonsspital, Cardiology, Luzern, Switzerland;* [3]*University Hospital, Cardiology, Zurich, Switzerland;* [4]*Triemli Hospital, Cardiology, Zurich, Switzerland*

Background: The mortality risk of revascularisation increases with age. To determine the revascularisation risk in relation to the risk of medical therapy in elderly patients (pts) during a 1-year follow-up, we analyzed all 176 pts of the prospective TIME study in whom revascularisation was attempted (REVASC) and compared them to all 125 pts who received medical treatment alone (MED) (on-treatment analysis).
Methods: The REVASC group consisted of 112 pts randomized to PCI or CABG and 64 pts initially randomized to medical therapy but needing PCI or CABG during follow-up. The MED group consisted of 84 pts randomized to medical therapy who stayed on that therapy and 41 invasive pts who were not revascularized (revascularisation not possible, refused or no coronary artery disease). All pts had quality of life (QoL) and angina severity assessed by questionnaire at baseline and after 1 year.
Results: Baseline characteristics of REVASC and MED pts were similar with an age of 80±4 years and 40% vs. 49% women (p=ns). After 1 year, total mortality was 9.7% vs. 9.6%, and cardiac mortality 6.8% vs. 8.8% (REVASC vs. MED, p=ns). The corresponding cardiac death/myocardial infarction (MI) rates were 15.3% vs. 12.8% (p=ns). REVASC pts improved angina severity and measures of QoL significantly more than MED pts (p<0.01). The 34% of pts treated by CABG differed from PCI pts in the rate of hypertension (78% vs 56%, p<0.01) and of 3 vessel disease (88% vs. 53%, p<0.0001), whereas left ventricular ejection fraction was not significantly different (60±13% vs. 55±16%, p=ns). PCI pts had a similar 30 d cardiac mortality (2.6% vs. 3.3% after CABG) and 1 year cardiac death/MI rate (16.4% vs. 13.3%) as compared to CABG pts; however, angina severity decreased and QoL increased significantly more after CABG (p<0.01).
Conclusion: In this prospective on-treatment analysis, pts with REVASC had no increased cardiac mortality risk compared to MED treated pts but a greater improvement in QoL and angina. PCI in pts selected for suitable anatomy for PCI had a similar early mortality and 1 year death/MI rate as CABG surgery; however, the benefit in QoL and angina was smaller.

DRUG THERAPY IN HEART FAILURE

P3037 Efficacy and safety of tadalafil in men with erectile dysfunction: an integrated analysis of registration trials

S. Carrier[1], C. McMahon[2], K.K. Chen[3], G. Anglin[4], T. Costigan[4], W. Shen[4], V. Watkins[4], J.S. Whitaker[5]. [1]*Jewish General Hospital, McGill University Health Center, Montreal, Canada;* [2]*St. Luke's Hospital, Sydney, Australia;* [3]*Taipei Veterans General Hospital, Taipei, Taiwan, Province of China;* [4]*Eli Lilly & Company, Indianapolis,* [5]*ICOS, Bothell, United States of America*

Purpose: Tadalafil is a selective and potent inhibitor of phosphodiesterase type 5 for the treatment of men with erectile dysfunction (ED). In the presence of sexual stimulation, tadalafil has been shown in clinical trials to enable men with ED to achieve and maintain erection sufficient for successful intercourse. This integrated analysis was undertaken to assess the efficacy and safety of tadalafil.
Methods: Tadalafil doses of 2.5 to 20 mg, taken as needed up to once daily, were evaluated in 5 (four 12-week; one 24-week) randomized, double-blind, placebo-controlled Phase 3 trials enrolling 1112 men (mean age, 58 years; range, 21-82 years). Patients were free to choose the time of sexual attempts after dosing, and to take the medication with no restrictions on food and alcohol intake. Three widely used, self-administered instruments (International Index of Erectile Function, Sexual Encounter Profile diaries, and Global Assessment Question) were used to evaluate treatment effects.
Results: Compared with placebo, tadalafil significantly improved all primary and secondary endpoints. Up to 81% of tadalafil-treated men (n = 972 from the four 12-week studies) reported improved erections. The mean percentage of successful intercourse attempts improved to up to 75%. Efficacy was consistent in each of these studies and in mild-to-severe ED of psychogenic, organic, or mixed etiology. The adverse events (AEs) reported with tadalafil were generally mild-to-moderate in intensity, were transient, and attenuated with continued dosing. Discontinuation rates were similarly low in tadalafil- and placebo-treated patients. Headache, dyspepsia and back pain were the most commonly reported AEs (>5%) across studies.
Conclusion: Findings of these studies support the conclusion that on-demand tadalafil is a well-tolerated treatment that significantly improves erectile function in men with mild-to-severe ED. These data suggest that tadalafil may become an important new treatment option for men with ED.

P3038 Efficacy of beta-blockers in diabetic patients after myocardial infarction. From silent left ventricular dysfunction to overt heart failure

E. Balli[1], A. Giomi[1], E. Magagnini[2], F. Del Citerna[1]. [1]*Della Robbia Hospital, Coronary Care Unit, Pistoia, Italy;* [2]*S.Chiara Hospital, Cardiovascular Medicine, Pisa, Italy*

Diabetes is a powerful risk factor for an adverse outcome during the acute phase and after myocardial infarction (MI). In spite of their proved efficacy beta blockers are still underused after MI. We analysed the long term effect of beta blockers in diabetic patients (pts) with LV dysfunction or overt heart failure (HF) early after MI. Among 3424 pts admitted to our CCU with acute MI from 1992 to 2001, 600 (17,5%) had diabetes mellitus. In-hospital mortality (11 vs 6.6%,p<0.0001), Killip class >1 (15 vs 5%,p<0.0001) and LV dysfunction, as measured by 2-D echo EF<40% (30 vs 11%,p<0.0001) were all more frequent in diabetic vs non diabetic pts. Diabetes was an indipendent predictor of all these complications at multivariate analysis. Beta-blocking drugs were administered to 69% of pts with LV dysfunction (125/180) and to 40% HF patients (36/90), with a steep increase of the percentage in the last four years (p<0.0001 vs 1992-1997). Inability to reach a stable clinical cardiovascular status, severe bronchospastic pulmonary disease or peripheral vascular disease, bradycardia or hypokinetic arrhythmias uncorrected by pacemaker implantation, clinically significant hypotension were the only contraindications to therapy. The beta-blockers used, with slow, gradual and progressive dose titration were metoprolol up to 200 mg, atenolol up to 100 mg and carvedilol up to 50 mg. Worsening of clinical status necessitating the interruption of therapy ensued in 11.1% (4/36) HF and 6.4% (8/125) LV dysfunction pts. At 1-year follow-up, diabetic pts who received beta-blockers had a lower total mortality (4 vs 9%, p<0.0001), incidence of presumed sudden cardiac death (1 vs 5% p<0.0001), acute MI (2 vs 6%, p<0.001), a lower progression to clinical HF (6 vs 14%, p<0.0001), less hospitalizations (5 vs 13%, p<0.0001), a lower need for ICD implantation (1 vs 3%, p<0.05) and CABG (12 vs 18%, p<0.05). Beta-blockers were indipendent predictors of all these outcomes at multivariate analysis. The comparison of different periods of time (beta-blockers were administered mainly during the last four years) with global differences in patients' treatment may be a significant limit of our observations. Nevertheless, at intermediate follow-up beta-blockers do exert a beneficial effect on clinical hard end-points and are also cost-effective in preventing costly outcomes. Our data suggest that a trial of beta-blocking therapy is worth in most diabetic patients with LV dysfunction or clinical HF early after MI.

P3039 Effects of nebivolol on myocardial performance after long-term treatment in heart failure patients: a double-blind, placebo controlled study

F.I. Parthenakis, A.P. Patrianakos, E.A. Zacharis, G.F. Diakakis, M.I. Hamilos, M.C. Saatsaki, P.E. Vardas. *Cardiology Dept., Heraklion University Hospital, Heraklion, Greece*

Background: Beta-adrenergic blocking drugs have been shown to have beneficial effects on patients (pts) with heart failure. Nebivolol, a new, third generation, selective beta 1- blocking agent, that possesses a peculiar pharmacodynamic profile, has not been widely studied.
Objectives: The purpose of our study was to examine the long-term (3 months) effects of Nebivolol on cardiac systolic and diastolic function in patients with Idiopathic Dilated Cardiomyopathy (IDC).
Methods: Sixty patients, aged 55±9.5 y, with angiographically proven IDC, ejection fraction (EF)<45%, in stable New York Heart Association (NYHA) class II-III, entered a double-blind, randomized Nebivolol and placebo-contolled trial. Variables of left (LV) and right (RV) ventricular function at baseline and after 3 months of oral administration of Nebivolol (1,25 to 5 mg/day in four weeks) or placebo were assessed echocardiographically.
Results: There were no significant baseline differences regarding NYHA class, heart rate (HR), LVEF, systolic blood pressure (BP) or echocardiographic variables between the 2 groups. During follow-up, 4 pts in the Nebivolol (13,3%) and 5 (16,6%) in the placebo group discontinued the medication because of symptoms aggravation or significant hypotension. After 3 months of Nebivolol treatment, there was a decrease in resting HR (74,2±8, vs 69,2±8,4,p=0,05) and systolic BP (144.8±12,1 vs 119,6±9,7 mm Hg p<0,001)and a significant increase in LVEF (33,1 ±10% vs 38,8% ±7.3, p=0,04), mainly due to decreased end-systolic volume (104±35 ml vs 88.4±30.5 ml, p=0,03) while the LV diastolic volume showed a slight decrease (151,6±40,8 vs 140,6±37,7 ml, p=NS).
Left ventricular systolic wall stress also decreased (193,4± 44,3 vs 161,7±36.8 Kdynes/cm^2, p=0,06) and the right ventricular EF increased significantly (40,3±8,7vs 50,9±9,3%, p=0,04).Indices of diastolic LV function also improved. The velocity time integral of late LV filling increased (5,5±1,3 vs 7,3±2,1 cm, p=0,01) while the pulmonary veins atrial wave, decreased significantly (0,39±0,06 vs 0,29±0,04 cm/sec, p=0,01). There were no significant differences in the placebo group at 3 months concerning all aforementioned parameters.
Conclusion: Nebivolol is an effective and relatively safe treatment in idiopathic dilated cardiomyopathy. After 3 months of treatment, there was an improvement in LV and RV systolic function, with evidence of increased intrinsic contractility, while beneficial effects on LV diastolic function indices were found.

P3040 Prescribing for heart failure in general practice: the relationship between physician knowledge and prescribing quality

L.G Pont[1], W.H. van Gilst[2], D.J.A. Lok[3], J.A. Kragten[4], F.M. Haaijer-Ruskamp[2] on behalf of The Dutch Working Group on Heart Failure. [1]*Clinical Pharmacology-GUIDE,* [2]*Clinical Pharmacology, University of Groningen, Groningen, Netherlands;* [3]*Deventer Hospital, Department of Cardiology, Deventer, Netherlands;* [4]*Atrium Medical Centre, Department of Cardiology, Heerlen, Netherlands*

Objectives: To investigate the relationship between different aspects of GP knowledge of the drug groups (diuretics, angiotensin converting enzyme inbibitors, beta-blockers, digoxin, spironolactone and angiotensin II antagonists) commonly used to treat chronic heart failure (CHF) and their actual use of these agents in daily practice.
Design: Cross-sectional survey: GP questionnaire and patient chart review.
Setting: General Practice
Participants: 78 GPs and 769 CHF patients participating in the IMPROVEMENT study.
Main outcome measures: GP knowledge was assessed by a questionnaire covering 3 domains: awareness of the current evidence, perceptions of how often each agent should be used for CHF and indications and contraindications. Current practice was assessed by the percentage of patients per GP prescribed each drug group.
Results: No relationship between knowledge and actual use of a drug group was observed for any of the 3 domains. Knowledge regarding the current evidence and how often a drug group should be used for CHF were high while knowledge regarding indications and contraindications was lower. No correlation between the 3 knowledge domains was found.
Conclusions: GP knowledge of the current evidence for the drug groups commonly used in CHF, with the exception of the beta-blockers, was good. A knowledge deficit was identified regarding the indications and contraindications for each drug group. No relationship between knowledge and actual use was found indicating that interventions addressing the use of CHF drugs in daily practice could be more useful in bridging the gap between evidence and practice than interventions that simply concentrate on improving GP knowledge.

P3041 Urine pH decreases strikingly in response to the loop diuretic torasemide

A.J. Reyes[1], W.P. Leary[2]. [1]*Institute of Cardiovascular Theory, Montevideo, Uruguay;* [2]*University College, Dept. of Pharmacology and Therapeutics, Cork, Ireland*

Background: Measures should be adopted to avoid the development of acidosis in patients with heart failure (HF). Furosemide (Fur) decreases urine pH mildly, and potassium-retaining diuretics alkalinize the urine and thus tend to cause acidosis. At variance with Fur, torasemide (T) does not inhibit carbonic anhydrase in the nephronal proximal tubule and thus may be expected to reduce urine pH markedly. The aim of this study was to assess the response of urine pH to an amount of T that is frequently prescribed to be taken once daily in HF.
Methods: Fourteen healthy subjects (age range: 20-26) in a metabolic unit took single oral doses of placebo and of T 20 mg, at 08.00 hours, on two conveniently separated single-treatment days. The design was individually randomised, crossover and double-blind. Data are presented as mean ± SD. Mean values were compared by the t test for paired samples.
Results: Urine pH was 5.76 ± 0.44, 6.54 ± 0.66, 6.62 ± 0.57, 5.99 ± 0.40, 6.17 ± 0.58 and 5.70 ± 0.37 in urine collected 0-1.5, 1.5-3, 3-6, 6-9, 9-12 and 12-24 h after dosing with placebo, respectively. Corresponding values after dosing with T 20 mg were 5.35 ± 0.65, 4.97 ± 0.63 ($p < 0.001$ vs. placebo), 4.93 ± 0.66 ($p < 0.001$), 4.93 ± 0.42 ($p < 0.001$), 5.39 ± 0.60 ($p < 0.001$) and 5.34 ± 0.24 ($p < 0.001$). Urinary sodium excretion was 14 ± 5, 11 ± 4, 27 ± 16, 30 ± 11, 32 ± 14 and 66 ± 25 mmol over the 0-1.5-, 1.5-3-, 3-6-, 6-9-, 9-12- and 12-24-h periods after dosing with placebo. Corresponding values after dosing with T 20 mg were 125 ± 23 ($p < 0.001$), 98 ± 22 ($p < 0.001$), 54 ± 25 ($p < 0.05$), 17 ± 11 ($p < 0.05$), 9 ± 4 ($p < 0.001$) and 19 ± 7 ($p < 0.001$).
Conclusion: T 20 mg reduced urine pH values throughout the 1.5-3-, 3-6-, 6-9-, 9-12- and 12-24-h post-dosing periods. Urine pH mean values fell by 1.06-1.69, with respect to post-placebo urine, between 1.5 and 9 h after administration of T 20 mg, and they decreased by 0.36-0.78 between 9 and 24 h after dosing. In a similar study that we carried out on fourteen healthy subjects, Fur 40 mg reduced pH only in urine collected between 1.5 and 3 h after dosing and by a mean value of only 0.3. Thus, T 20 mg could decrease serum pH by more than equinatriuretic amounts of those loop diuretics that also act on the proximal tubule (Fur, bumetanide and piretanide) in patients with HF. This possibility merits research, and it is worthy of consideration in the treatment of HF patients who are prone to develop acidosis, including type 1 diabetics, individuals also receiving spironolactone and/or amiloride, and elderly subjects.

AORTIC VALVE STENOSIS

P3042 Assessment of aortic valve calcification allows risk stratification in mild and moderate aortic stenosis

R. Rosenhek, T. Binder, J. Pixner, U. Klaar, M. Heger, C. Scholten, G. Maurer, H. Baumgartner. *University of Vienna, Cardiology Dept., Vienna, Austria*

Background: The degree of aortic valve (AV) calcification has been shown to be a significant predictor of outcome in severe aortic stenosis (AS). In addition, aortic sclerosis has recently been reported to be associated with a significant increase in mortality. However, it remains unknown whether the degree of AV calcification is of prognostic value in mild and moderate AS.
Methods: 176 consecutive patients (73 female, age 58±19 yrs) who were found to have mild to moderate AS defined by a jet velocity between 2.5 and 4.0 m/s in 1994 were followed for 51±18 months. The degree of AV calcification and other risk factors were assessed. The rate of hemodynamic progression was determined and the clinical outcome was analyzed.
Results: Kaplan-Meier event-free survival for the entire patient group, with endpoints defined as death (n=34) or aortic valve surgery (n=33) indicated by the development of severe symptomatic AS, was 95±2% at 1 yr, 75±3% at 3 yrs, and 60±5% at 5 yrs. Presence of moderate or severe AV calcification, presence of coronary artery disease and peak aortic jet velocity (AV-Vel) at entry were significant independent predictors of outcome ($p<0.0001$, $p<0.001$ and $p<0.01$, respectively). Event-free survival for patients with moderate or severe valve calcification was 92±4% at 1 year, 61±7% at 3 and 42±7% at 5 years versus 100%, 90±4% and 82±5% for patients with no or mild calcification. Diabetes, hypercholesteremia and arterial hypertension were not significant predictors of outcome. The mean rate of hemodynamic progression was significantly faster for patients with an event (0.43±0.04 m/s/yr) than for those without an event (0.14±0.02 m/s/yr, $p<0.0001$). Of 129 patients with a follow-up echocardiographic exam, 59 (46%) developed severe AS (AV-Vel > 4 m/s) during follow-up. 15 cardiac and 19 non-cardiac deaths occurred. Mortality was 1.8 times higher than that of an age and gender - matched control population ($p<0.005$).
Conclusion: Rapid progression to severe AS and an increased mortality have to be considered in mild and moderate AS. In particular, patients with significant calcification of their AV but also those with coronary artery disease and patients in whom serial echocardiograms reveal a rapid progression of the aortic jet velocity have a poor outcome. Thus, moderate and even mild AS cannot be considered a benign disease. Serial Doppler studies and the assessment of valve calcification are crucial for the management of these patients as they identify high-risk patients who require closer follow-up than currently recommended.

P3043 Operative risk in patients with severe aortic stenosis

P. Stutzbach[1], R.R. Favaloro[2], C. Gomez[3], A. Macchia[4], E. Gabe[2], E. Dulbecco[2], A. Machain[2], H. Raffaelli[2]. [1]*Favaloro Foundation, Valvular Heart Disease, Buenos Aires, Argentina;* [2]*Favaloro Foundation, Surgery Dept., Buenos Aires, Argentina;* [3]*Favaloro Foundation, Department of Anesthesia, Buenos Aires, Argentina;* [4]*Favaloro Foundation, Data Base, Buenos Aires, Argentina*

Background: Some authors suggest patients with asymptomatic aortic valve stenosis should undergo aortic valve replacement (AVR). However, no consensus has been reached as regards this indication since valve replacement mortality is higher than that of the natural evolution of the disease.
Objective: To identify populations with low operative risk among patients undergoing elective AVR for symptomatic severe aortic stenosis.
Methods: From June 1996 to February 2001, 2,100 patients underwent valvular replacement. Severe aortic stenosis was present in 934 patients (44%). Mean age was 68±13 years; 373 patients (41%) were female. Outcomes of isolated AVR or combined with mitral valve replacement (RVM), coronary artery bypass graft (CABG) or more than two procedures were analyzed. Parsonnet stratification score was used to assess operative risk.
Results: Multivariate analysis showed: age p=0.01, female sex p=0.01, combined AVR p=0.002, reoperation p=0.002, severe LVSF p=0.01. Parsonnet 5 (43 patients, 5%), identified a subset without operative mortality, between 6 and 10 (384 patients, 41%) mortality was 2.6% (10 patients), between 11 and 15 (310 patients, 33%) was 7% (22 patients), and higher than 15 (256 patients, 21%) was 15% (38 patients) (p=0.0001).

	AVR	AVR+CABG	AVR+MVR	AVR+Other
N	489	331	49	65
Age	63.5±13	69±8	56±12	65±12
Severe LVSF	12.6%	13.9%	6%	17%
NYHA FC	2.2±0.9	2.4±0.8	2.5±0.7	2.1±0.9
Parsonnet score	8.2±3.3	13±5.1	13±5.4	17.6±10
Mortality	3.1%	9%	5.5%	11%

LVSF=left ventricular systolic function; NYHA FC= New York Heart Association functional class

Conclusion: Patients <70 years of age, male sex, and without coronary artery disease or other heart valve disease had the lowest hospital mortality (Parsonnet score 5). Parsonnet score is useful to identify different operative risks in populations with aortic stenosis.

P3044 Association of coronary artery disease with aortic valve calcification and calcified plaque in the thoracic aorta

A. Abaci[1], A. Oguzhan[2], I. Ozdogru[2], T. Sirkeci[2], N.K. Eryol[2], E. Basar[2], A. Ergin[2], S. Cetin[2]. [1]*Kayseri, Turkey;* [2]*Erciyes University School of Medicine, Department of Cardiology, Kayseri, Turkey*

Aortic valve calcification and coronary atherosclerosis share many risk factors and a possible association of aortic valve calcification with coronary artery disease (CAD) has been suggested. It has also been showed that the presence of aortic atheromas detected by transesophageal echocardiography is strongly associated with CAD. The purpose of this study was to evaluate the relation between calcification of the aortic valve, calcified plaques in the thoracic aorta and CAD in patients undergoing coronary angiography.
Methods: Consecutive 1100 patients (771 men, age 63±11 years) undergoing elective coronary angiography were evaluated by echocardiography for the presence of aortic valve calcification. Chest x-rays was used to detect calcified plaques in the thoracic aorta. Aortic calcified plaques were considered present when typical calcific densities were seen in the aortic arch or in the descending part of the thoracic aorta.
Results: Of the 1100 patients included in the study, 812 (73.8 percent) had CAD, and 288 (26.2 percent) had normal coronary arteries. Aortic valve calcification was present in 420 (38%) and aortic calcified plaques in 180 (16%) of the entire study population. The patients with aortic valve calcification had a significantly higher prevalence of CAD (88% vs 65%, $p<0.0001$) and higher rates of multivessel disease (65% vs 55%, p=0.003). Also, the prevalence of CAD (86% vs 71%, $p<0.0001$) and multivessel disease (66% vs 57%, p=0.035) were significantly higher in patients with aortic calcified plaques compared the patients without aortic calcified plaques. Logistic regression analysis showed that aortic valve calcification (p=0.003) and aortic calcified plaques (p=0.004) were strongly and significantly associated with CAD after adjusting for coronary risk factors. In addition, patients with aortic valve calcification had a high incidence of aortic calcified plaques (23% vs. 12%, $p<0.0001$).
Conclusions: We found a significant association of CAD with the presence of aortic valve calcification and aortic calcified plaques. Our study further demonstrates that aortic valve calcification are significantly associated with calcified plaques in the thoracic aorta. Therefore, it is reasonable to suggest a common etiologic basis for these calcifications and coronary atherosclerosis, and their presence should be regarded as a sign for the presence of CAD.

P3045 Aortic stenosis and haemorrhagic syndrome: close correlation between severity of AS and acquired abnormalities of von Willebrand factor

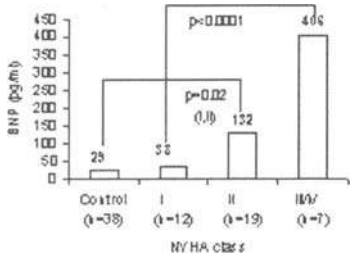
T. Le Tourneau[1], I. Six[2], S. Susen[2], O. Fabre[3], F. Juthier[3], C. Caron[2], B. Jude[2], A. Vincentelli[3]. [1]*Hôpital Cardiologique, Service d'EFCV, Lille, France;* [2]*Hôpital Cardiologique, Laboratoire d'Hémostase, Lille, France;* [3]*Hôpital Cardiologique, Service de Chirurgie Cardiaque, Lille, France*

Background: Hemorrhagic syndrome has been previously reported in severe aortic stenosis (AS), related to abnormal proteolysis of von Willebrand Factor (VWF). However, little is known about physiological determinants as well as clinical consequences of these abnormalities of VWF.
Methods: We prospectively enrolled 47 patients (70±10 yrs) with moderate (mAS, 7) or severe (sAS, 40) AS. Forty patients with sAS underwent subsequent aortic valve replacement. History of bleeding events was recorded in each case and severity of AS was evaluated in echocardiography. Selected parameters of primary hemostasis reflecting VWF abnormalities (closure time of PFA 100® (CTADP), VWF:Ag, VWF:CB, and multimeric analysis of VWF) were evaluated in all patients, with early (day 1 and 7) and late (6 months) postoperative assessment in sAS.
Results: Aortic orifice area and mean transvalvular gradient were 0.67±0.17 cm^2 and 58±12 mmHg in sAS, compared with 1.14±0.17 cm^2 and 32±11 mmHg (both $p<0.01$) in mAS. In sAS, 33% (14/40) of patients presented recent history of bleeding, and 76% had prolonged CTADP. In mAS 29% of patients had prolonged CTADP, but mean CTADP was significantly longer in sAS compared with mAS (193±64 vs 121±32 s, p=0.01). Plasma level of VWF:Ag was in the normal range in all patients. Four patients with sAS had decreased level of VWF:CB. The percentage of high molecular weight multimers (%HMW multimers) of VWF was decreased in sAS, compared with mAS ($p<0.05$). Nevertheless, abnormal multimeric profile was also observed in mAS. Interestingly, for overall patients there were a highly significant correlation between either mean transvalvular gradient or stenosis-induced shear stress and CTDAP (both r=0.54, p=0.001). History of preoperative bleeding and severity of VWF abnormalities (%HMW multimers) were associated with per and early postoperative bleeding in sAS (respectively Chi-square p-value: 0.002, and Mann-Whitney p-value: 0.009). Complete correction of %HMW multimers was obtained the first day after valve replacement.
Conclusion: Our study demonstrate for the first time a close correlation between severity of AS assessed with mean transvalvular gradient or stenosis-induced shear stress and VWF abnormalities, explaining pre and postoperative bleeding. Moreover, abnormalities of VWF may be found also in non surgical AS. Surgical correction of AS result in an early and sustained correction of VWF abnormalities. Consequently, acquired bleeding history in this setting should not contraindicate a mechanical prostheses implantation.

P3046 Clinical interest of brain natriuretic peptide serum levels in aortic stenosis

P. Lim[1], J-L. Monin[2], A. Carayon[3], P. Guéret[2]. [1]*Henri-Mondor, Cardiology, Créteil, France;* [2]*Henri Mondor Hospital, Cardiology, Créteil, France;* [3]*Pitié-Salpétrière Hospital, Biochemistry, Paris, France*

Background: timing of valve replacement in aortic stenosis (AS) is currently based on the presence of symptoms. However, in elderly patients symptoms may be difficult to evaluate and there is no validated parameter indicating the timing of surgery in asymptomatic patient with severe AS. Brain Natriuretic Peptide (BNP) is secreted predominantly from the cardiac ventricles and has been shown to have a diagnostic and prognostic value in congestive heart failure. Few studies have reported its clinical interest in AS.
Methods: Serum BNP levels were measured by radio immunoassay in 38 control subjects and 38 patients with severe AS and normal left ventricular function with concomitant clinical and echocardiographic evaluation.
Results: 18 women and 20 men (mean age, 72 ± 13 years) with a severe AS (mean aortic valve area, 0. 7± 0.1cm^2; mean transaortic pressure gradient, 50 ± 21mm Hg) and preserved left ventricular function (mean left ventricular shortening, 0.38 ± 0.1) were enrolled. Mean BNP values differed significantly between patients according to NYHA functional class with a positive predictive value of 96% to detect symptomatic patients (cut-off value, 65 pg/ml). By single linear regression, BNP value appeared to correlate with aortic time-velocity integral (r = 0.34, p = 0.03) and peak diastolic atrial velocity by tissue Doppler (r = 0.57, p = 0.01). BNP serum levels were not correlated to aortic valve area.



Mean BNP value.

Conclusion: BNP serum level is an objective non invasive parameter witch can be helpful to detect symptomatic patient with AS when clinical evaluation is difficult. Correlation to diastolic and systolic left ventricular echographic parameters may reflect myocardial adaptation to increased afterload.

P3047 Common biological features between calcific aortic valve stenosis and carotid atheromasic plaque: an histological and immunohistochemical study

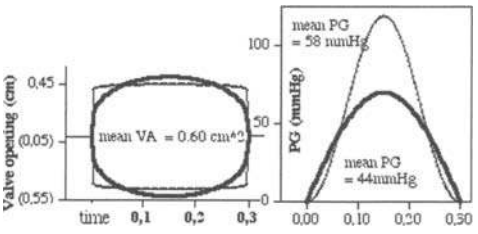
A. Mazzone[1], P. Tanganelli[2], M.C. Epistolato[2], J. Gianetti[1], E. Neri[2], M. Glauber[1], S. Bevilacqua[1], A. Biagini[1]. [1]*Ospedale Pasquinucci, Massa, Italy;* [2]*University of Siena, Pathological Dept and Vasc Surg, Siena, Italy*

Background: Many observations support the hypotesis that calcific aortic valve stenosis is an active and chronic inflammatory process with similar characteristics of atherosclerotic plaque.
Methods: We selected 26 non-rheumatic aortic valves from symptomatic patients (AVA mean value 0.6±0.12cmq) undergoing surgical replacement and the stable carotid artery plaques from 15 previously symptomatic and 22 asymptomatic patients undergoing carotid endarterectomy with >60% stenosis. We performed histological analysis on paraffin-embedded carotid plaque samples and aortic valve leaflets for a semiquantitative assessment of inflammatory cell abundance, neoangiogenesis, atheroma, sclerosis, and calcium. Tissue samples were semiquantitatively analyzed by immunohistochemistry for Intracellular Adhesion Molecule-1 (ICAM-1) and Vascular Cell Adhesion Molecule-1(VCAM-1)expression.
Results: Calcific aortic valve (A) showed a prominent calcium deposits in nodular form, dense inflammatory lymphocytes infiltrates and neoangiogenesis close to calcium deposits, fibrosis.. Stable carotid plaques (B) showed dense inflammatory cell infiltrates in shoulder atheroma with lymphocytes prevalence and neoagiogenesis, diffuse sclerosis and local calcifications. In both A and B we found thin vessels (wall thickness<10μm) and thinless vessels (wall thickness>30μm). In A angiogenesis was correlated with inflammation (p=0.0007), the most significativity was between thin vessels and local abundance of lymphocytes ($p<0.00001$).Neoangiogenesis correlates with calcium(p=0.003). In B we found a correlation between neoangiogenesis and inflammation (p=0.04) exspecially between thin vessels and lymphocytes infiltrates (p=0.0005). In A and B adhesion molecules (ICAM-1 and VCAM-1) expression was detected on the neovessel cells to confirm the endothelial activation.. In A was found a significative correlation between inflammatory infiltrates and ICAM-1 (p=0.003).
Conclusions: Calcific aortic valve and stable carotid atheromasic plaque showed common areas of biological activity expressed by neongiogenesis associated to inflammatory infiltrates and endothelial activation. Neoangiogenesis may have a role in the plaque evolution as well as in aortic valve stenosis progression.

P3048 Influence of valve orifice variability during ejection on haemodynamics of aortic stenosis: a computer numerical simulation study

K. Isaaz, S. Schouvey. *Hôpital Nord-CHU de Saint Etienne, Service de cardiologie, Saint Etienne, France*

Background: Recent experimental and clinical studies based on high speed video and transesophageal planimetry measurements have reported variations of valve orifice area (VA) during ejection in aortic stenosis (AS) with cusps opening/closing rates (OCR) slower than in normal valves. VA variability during ejection may be different between 2 AS valves due to various degrees of cusps thickness, calcifications and commissural fusion leading to different elastic and inertial properties of the valve. The impact on AS hemodynamics of VA variability during ejection remains unknown.
Methods: Using a computer simulation modeling, we evaluated the impact of AS VA variability during ejection on transvalvular pressure gradients (PG) and on the Gorlin formula derived mean VA. Based on mathematical analysis of patterns reported in the literature, OCR were simulated using a complex powered sine function accounting for mechanical properties ot the valve. The model allowed to make vary the following input: outflow tract velocity profile, outflow tract and ascending aorta diameters, ejection period, mean VA, OCR patterns.
Results: At similar outflow condition and mean VA, VA variability resulted into significant changes in peak and mean PG (range 0%-54% and 0%-32%, respectively). The Gorlin formula accurately predicted VA when VA was constant during ejection but overestimated it up to 32% when maximal opening was delayed to mid-ejection.

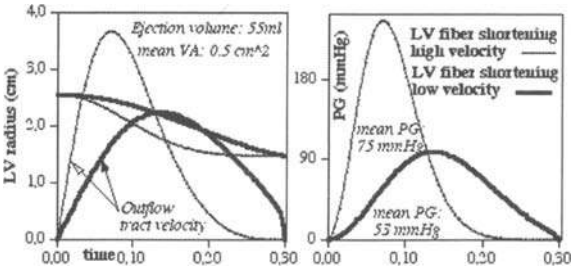


Conclusion: Despite similar mean anatomical VA and outflow conditions, stenotic valves with different intrinsic mechanical properties may result into different total afterload burdens and Gorlin formula data due to different VA variability patterns during ejection. This new concept should be taken into account when evaluating AS hemodynamics.Figure

P3049 Importance of left ventricular dynamics/valve orifice matching during ejection for afterload minimization in aortic stenosis. A computer study

K. Isaaz, S. Schouvey. *Hôpital Nord-CHU de Saint Etienne, Service de cardiologie, SAINT ETIENNE, France*

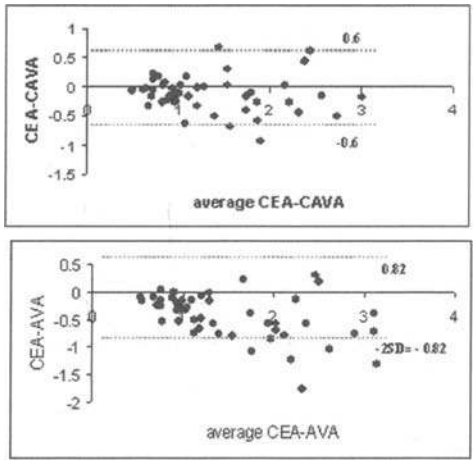
Background: Why outflow tract velocity temporal profile (OVP) in aortic stenosis (AS) is characterized by a slow systolic upstroke with a delayed peak flow remains unknown. Recent experimental and clinical studies based on high speed video plaminetry measurements have reported variations of AS valve orifice area (VA) during ejection due to various degrees of leaflets thickness, rigidity, calcifications and commissural fusion leading to different elastic and inertial properties of the cusps.
Methods: Using a computer simulation modeling, we evaluated the impact of LV dynamics/VA variability ejection coupling on AS transvalvular pressure gradients (PG). Dynamics of LV fiber shortening was computerized using a powered cosine function during ejection. Based on mathematical analysis of patterns observed in clinical studies, VA variability was computer simulated first as a complex sine function of time and then VA(t) to PG(t) relation during ejection was fitted by a curvilinear function accounting for mechanical properties of the valve(r= 0.99-1.00). The model allowed to make vary the following input parameters: LV fiber shortening extent, LV fiber shortening velocity and OVP, outflow tract and ascending aorta diameters, ejection period, mean VA, VA variability.
Results: At similar ejection volume and LV ejection fraction and mean VA, a slower LV fiber shortening velocity resulted into a typical AS OVP with a PG lower than did a normal OVP due to a rapid LV fiber shortening rate.
Conclusion: Slow outflow acceleration with late peak flow as typically observed in aortic stenosis reflects adaptative LV fiber shortening rates in order to optimize LV dynamics/valve coupling and to minimize LV afterload.



P3050 Overestimation of valve area in bicuspid aortic – stenosis by transoesophageal planimetry as a function of jet eccentricity stenosis

E. Donal, Z.B. Popovic, G. Novaro, N.L. Greenberg, D. Deserranno, J.D. Thomas, M.J. Garcia. *The Cleveland Clinic Foundation, Cardiology, Cleveland, United States of America*

Background: Bicuspid aortic stenosis (AS) is the most frequent congenital anomaly. Because of the 2 cusps arrangement, valve is often obstructive and the stenotic jet eccentric. 2-D transesophageal echocardiography (TEE) has been proposed as a reliable method for determining aortic valve area (AVA) in patients with AS.
Purpose: We sought to compare AVA by TEE planimetry and by Doppler-derived continuity equation (CEA) in patients with bicuspid and tricuspid AS and determine the effect of stenotic jet eccentricity.
Methods: Fifty patients (age 49±15 years) with bicuspid and 22 patients with tricuspid (71±13 years of age) AS undergoing transthoracic (TTE) and TEE were studied. CEA area was obtained from TTE and AVA by TEE as the smallest area during systole. The stenotic jet angle was measured from off-line analysis of the TEE color Doppler images and used to derive an eccentricity index (EI). The cosine of this angle is proposed to correct AVA.
Results: 1) In the tricuspid valve group, there was an excellent correlation between CEA (1.13±0.46cm^2) and AVA (1.15±0.36cm^2) ((r=0.91, p<0.001, delta=0.14±0.13, p=0.37). 2) In the bicuspid group, AVA (1.80±0.93 cm^2) overestimated CEA (1.36±0.77 cm^2, r = 0.89, delta = 0.44 ±0.41 cm^2, p<0.001) EI was 33.4±9.7° (p<0.001 compared to tricuspid group). The agreement between CEA and AVA was improved after correction for the cosine of the angle of the jet (CAVA = AVA∗angle cosine) (figure).



Bland&Altman CEA-CAVA/CEA-AVA.

Conclusion: TEE planimetry of AVA may cause under-estimation of stenosis severity, depending on jet eccentricity. AVA overestimation is attenuated by an adaptation based on the stenotic jet angle cosine (CAVA).

P3051 Reglonal differences in the haemodynamic stress at the ascending aorta in patients with bicuspid and tricuspid aortic valve

M. Bauer, H. Siniawski, M. Pasic, R. Meyer, B. Schaumann, R. Hetzer. *Deutsches Herzzentrum, Department of Cardiac Surgery, Berlin, Germany*

Patients with bicuspid aortic valve have a higher incidence of dilation of the ascending aorta in comparison to the normal population. It is unclear whether it is caused by abnormal hemodynamics or by an underlying congenital aortic wall defect. This echocardiographic study examined the differences in hemodynamic stress at the ascending aorta in patients with bicuspid and tricuspid aortic valve.

Methods: 58 consecutive patients with aortic valve stenosis and either bicuspid or tricuspid valve and an ascending aortic diameter of $\leq$ 4.5cm were divided into two groups: group A (bicuspid aortic valve, 26 patients, age 61 $\pm$ 10 years) and B (tricuspid aortic valve, 32 patients, age 65 $\pm$ 10 years). Preoperative echocardiographic examinations (2-dimensional, M-mode, CW Doppler, aortic wall tissue Doppler) were performed from parasternal long axis view using ALOKA 5.5.

Results: There were no differences between the groups in regard to the diameter of the ascending aorta (38.0 $\pm$ 7.4mm versus 36.1 $\pm$ 4.1mm, p = 0.87), the maximal pressure gradient across the aortic valve (88.0 $\pm$ 11.6mmHg versus 85.1 $\pm$ 13.3mmHg, p = 0.66) or the percentual systolic increase of the ascending aorta diameter (6.2 $\pm$ 2% versus 5.8 $\pm$ 3%, p = 0.9). However, the peak systolic wall velocity in the anterolateral region of the ascending aorta was significantly higher in group A (bicuspid valve) than in group B (tricuspid valve) (12.2 $\pm$ 4.3cm/s versus 8.8 $\pm$ 2.6cm/s, p = 0,047) but not in the posteromedial region (10.3 $\pm$ 3.6cm/s versus 8.6 $\pm$ 2.6cm/s, p = 0.24).

Conclusions: Bicuspid aortic valve causes higher hemodynamic stress in the anterolateral region of the ascending aorta than tricuspid aortic valve.

VALVE PROTHESES

P3052 Time course of the prosthetic valve function after aortic valve replacement with tilting-disc mechanical valves

T. Uejima, Hitoshi Sawada, Keiichi Aoki, Tadanori Aizawa, Long-Tai Fu. *The Cardiovascular Institute, Internal Medicine, Tokyo, Japan*

Most of the previous investigations on the outcome of the prosthetic valve have focused on the clinical events. This study was designed to investigate the time course of the mechanical valve functions after aortic valve replacement and the influence of the intensity of the anticoagulation on them.

Methods: This study included 115 patients who underwent aortic valve replacement with Medtronic-Hall valves and had no history of prosthetic valve thrombosis (64 males, mean age: 58±9.1y.o.). The sizes of the valves were 21 mm in 50 patients, 23 mm in 52 patients, and 25 mm in 13 patients. Valve resistance (R) (dynes sec cm^{-5}) and peak transprosthetic gradient (PG) (mmHg) were estimated by transthoracic echocardiography every year. The patients were divided into 2 treatment groups based on the mode of PTINR values measured during follow up: more intensive treatment group (the mode>2.3) and less intensive treatment group (the mode<2.3).

Result: The mean follow up period was 53±39 months. R and PG showed time-dependent increases in 21 mm and 23 mm valve patients (R: 6.3/year, 2.4/year, respectively; PG: 1.5/year, 1.2/year, respectively). In 21 mm valve patients, R and PG showed more time-dependent increases in less intensive treatment group than in more intensive treatment group (R: 7.8/year vs. 5.5/year, p = 0.0002; PG: 1.9/year vs. 1.3/year, p = 0.0002). However, there was no difference between 2 groups in 23 mm, 25 mm valve patients.

Conclusion: The tilting-disc mechanical valve functions showed time-dependent deterioration in smaller valves. Additionally, in smallest valve, less intensive anticoagulation might progress its deterioration.

P3053 The influence of mechanical valve noise on quality of life results from the ESCAT study

H. Körtke, K. Minami, D. Seiferet, G. Kleikamp, A. El Banayosy, G. Tenderich, R. Koerfer. *Heart Center Northrhine Westfalia, Bad Oeynhausen, Germany*

Objective: The "Early Self Controlled Anticoagulation Trial" (ESCAT) was conducted to evaluate the thromboembolic and hemorrhagic complications, other aspects of patient outcomes were also studied. This report analyzes data related to quality of life impairment due to the sound made by different mechanical prostheses.

Methods: A total of 1255 patients who received one of three different valves (St. Jude, CarboMedics, Medtronic Hall) were included in this study. Patients were asked "Have you recently felt impaired by heart valve noise?" as part of the ESCAT protocol and were additionally asked to complete the SF-36 quality of life questionnaire. The SF-36 was used to evaluate patients' perceptions of their physical and psychological well-being to see if these criteria were related to patients' perceptions of valve noise. Descriptive statistics (mean, sd) were used to summarize continuous data and percentages were used to summarize categorical data. Analyses of variance and covariance were calculated in accordance with the general linear model.

Results: The majority of patients felt they were not significantly impaired by valve noise. The number who felt significantly impaired at six months (10.6%) fell to 5.7% by 24 months. The perception of valve noise and the change in this perception over time were not related to valve type, valve position or the number of valves implanted (p>0.05). Evaluation of gender differences indicated an increased perception of valve noise by female patients (p=0.0001), especially those in younger age groups. This difference remained significant throughout the follow-up period. The results of the SF-36 questionnaire indicate that patients who feel less able to work, less able to function in their role, more pain and a lower perception of general physical health are also more likely to be moderately or very disturbed by the noise of their valve. Furthermore, a marked relationship with the psychological subscales of the SF-36 was also shown.

Conclusion: Based on the results of this study, we conclude that patients' perceptions of being impaired by the noise of their prosthetic valves might be predicted by four factors: female gender, young age, impairment of social contacts and a negative perception of one's own state of health. Contrary to previous beliefs, valve type, valve position and the number of valves implanted were not predictors of valve noise impairment.

P3054 Treatment with erythropoietin for severe haemolytic anemia caused by small periprosthetic leaks

C. Piper, D. Horstkotte. *Heart Center North Rhine-Westphalia, Department of Cardiology, Bad Oeynhausen, Germany*

Background: Severe hemolytic anemia due to small periprosthetic leaks is an indication for a surgical refixation or re-replacement of the prosthesis. We report about three patients, who previously had three or more cardiac operations and in whom a decompensated hemolytic anemia was recompensated by chronic treatment with erythropoietin (EPO) and a high-risk reoperation could be avoided.

Patients: . Patient A (male, born 1941) had St. Jude Medical (SJM) valve replacement for severe aortic regurgitation and reoperation for prosthetic valve endocarditis caused by S. aureus in 1988 with re-re-operation for severe periprosthetic dehiscence four months later. 10 months later he developed a decompensated hemolytic anemia (lactat dehydrogenase [LDH] 1140 U/l, hemoglobin [Hb] 8.7 g/dl) due to a small periprosthetic leak. Hb could be stabilized (12.2 g/dl) with a weekly dosage of 25.000 IE EPO, while LDH still amounts to 1100 U/l.

Patient B (female, born 1933) had open mitral commissurotomies in 1963 and 1978, and combined mitral and aortic valve replacement with Björk Shiley (BS) prostheses in 1983. The mitral prosthesis had to be re-replaced in 1997 (Carbomedics M30) for prosthetic valve dysfunction due to tissue ingrowth. 5 months postoperatively severe hemolytic anemia (LDH 980 U/l, Hb 9.5 g/dl) due to a small periprosthetic leak occurred and could be stabilized by 20.000 IE EPO/week at a Hb of 11.6-12.5 g/dl.

Patient C (male, born 1955) had aortic surgery for coarctation in 1972, aortic and mitral valve replacement (BS) during acute infective endocarditis in 1982, emergency re-re-operation (SJM-M31) for strut fracture of the BS mitral prosthesis in 1990. In 1999 refixation of the mitral prosthesis because of a small and aortic valve re-replacement (SJM-A25) because of a large periprosthetic leakage was mandatory. 5 months later he developed severe hemolysis (Hb 9.2 g/dl, LDH 1170 U/l) due to a small periprosthetic leak of the aortic prosthesis. With 30.000 IE EPO/week the hemolysis was compensated (Hb 12.4 g/dl, LDH 1040 U/l).

Conclusion: Erythropoietin may recompensate severe hemolytic anemia in patients with hemodynamically insignificant periprosthetic leaks, so that a high-risk reoperation may be postponed or even avoided.

P3055 Are mechanical valves with enhanced inner diameter advantageous in the small sized aortic annulus?

J.M. Albes[1], V. Rudolph[1], M. Hartrumpf[1], E. Hüttemann[2], K. Reinhart[2], T.H. Wahlers[1]. [1]*University Hospital Jena, Cardiac-, Thoracic-, Vascular Surgery, Jena, Germany;* [2]*University Hospital, Anaesthesiology and Intensive Care Med, Jena, Germany*

Background: Mechanical bileaflet valves with enhanced inner diameter may offer superior hemodynamic properties in patients with a small aortic annulus. The aim of this study was to compare these valves with standard prostheses in vivo.

Methods: Mechanical aortic valve replacement for combined stenosis and insufficiency was performed in 48 patients with standard CarboMedics prostheses (CM: 21mm, 23mm, 25mm) and two types of diameter enhanced St. Jude Medical prostheses (SJMAHPJ: 21mm, 23mm, 25mm; SJMRegent: 21mm, 23mm). Intraoperatively, transvalvular mean gradients (TVG) were assessed by means of transesophageal echocardiography (TEE) and by means of simultaneously assessed direct pressure monitoring of the left ventricle and the ascending aorta (CATH) after weaning from cardiopulmonary bypass at 100beats/min constant heart rate (sinus rhythm or atrial pacing).

Results: In all valves and sizes both TVG assessments exhibited consistent findings although TEE assessment appeared to overestimate TVG moderately. Small sized conventional valves of 21mm showed a marked initial TVG while both valve types with enhanced inner diameter exhibited significantly lower TVG. These differences disappeared in larger sized valves.

Transvalvular Gradients

(n=6)	TVG (CATH)	TVG (TEE)
CM 21mm	15.6±3.9*	22.6±4.1*
CM 23mm	7.8±0.8	10.3±1.0
CM 25mm	9.2±2.2	10.9±1.9
SJMAHPJ 21mm	11.9+.1.6	14.4±1.6
SJMAHPJ 23mm	7.7±1.4	9.3±1.1
SJMAHPJ 25mm	8.2±1.1	10.7±1.7
SJMRegent 21mm	9.9±1.1	11.5±1.7
SJMRegent 23mm	9.5±1.8	11.8±1.9

*=p<0.05 CM 21mm vs. SJMAHPJ 21mm, SJMRegent 21mm

Conclusion: In patients with a small aortic annulus, who require a 21mm valve, diameter enhanced prostheses should be implanted in order to provide adequately low gradients. Proper left ventricular remodelling in the intermediate course can then be expected.

P3056 Native and prosthetic aortic valve endocarditis: replacement with new Stentless valves

H. Siniawski, Y.G. Weng, M. Pasic, H. Lehmkuhl, M. Hoffmann, R. Hetzer. *Deutsches Herzzentrum Berlin, Cardiovascular Surgery, Berlin, Germany*

The valve substitute of choice in aortic valve endocarditis with annulus abscess is the cryopreserved homograft. The Shelhigh™ No-React® stentless (SNRS) valves and conduits were considered as an alternative when no suitable homograft was available

Methods: From January 2000 to October 2001, 76 SNRS valves and conduits were implanted in patients with native/prosthetic endocarditis at the Deutsches Herzzentrum Berlin. In 41 consecutive patients (study group) suffering from the most severe form of endocarditis, including aortic ring abscess in 27 (68%), urgent aortic valve replacement with the SuperStentless® valves and stentless aortic valve conduit was undertaken (size 21 to 27 mm, mean 23.2). The control group consists of 68 patients with abscess in whom an aortic homograft was implanted for endocarditis with ring abscess. There were no significant differences between the two groups in incidence of epinephrine use, heart failure and demographic data preoperatively.

Results: Sixty-day mortality was 16% (11 patients) for the control group (homografts), compared with 7% (three patients) in the study group. Re-infection occurred in 4% (three patients) in the control group and in 2% (one patient) in the study group. Mean EOA for the stentless valve was 2.3 ± 0.6 cm^2, which is an optimal value. Postoperative echocardiographic LVEDD differed significantly ($p < 0.05$) for the study group compared with controls (46 ± 8 mm vs. 56 ± 9 mm), whereas LVEF and mean cw-Doppler gradient did not (56 ± 18% vs. 53 ± 17% resp. 11 ± 5 mmHg vs. 12 ± 6 mmHg).

Conclusions: Our early experience with No-React® stentless valves and conduits in patients with aortic native/prosthetic ring abscess demonstrates good results similar to those of cryopreserved homografts.

COMPUTER DEMONSTRATION

3197 Morphology of ST depression during isolated subendocardial ischaemia: computer simulation and clinical validation

M. Bertella[1], F. Scalise[1], G. Eriano[1], L. Melchiorre[1], P. Valentini[1], F. Bruni[1], M. Nanna[2]. [1]*Vimercate Hospital, Dept. of Cardiology, Vimercate, Italy;* [2]*/Albert Einstein Coll of Medicine, Montefiore Med Ctr, Bronx, New York, United States of America*

We have developed a software capable of deriving surface ECG patterns based on endocardial and epicardial action potential curves simulating intact versus ischemic myocytes. We observed that during simulated unambiguous subendocardial ischemia the morphology of ST-segment depression (STD) is essentially " horizontal" and that unnatural changes of the endocardial action potential curve are needed to obtain a downsloping pattern of STD. To define the morphologic STD pattern ("horizontal" or "downsloping"?) associated with "isolated" subendocardial ischemia, we performed a clinical validation of our computer simulation. Methods: From a series of consecutive patients (pts) with high pre-test probability of coronary artery disease and displaying STD in leads V3-V4 during exercise stress test (EST), two groups were selected: I, 25 consecutive pts (19 males, age 60 + 8 years) with horizontal STD (>1mm), becoming downsloping into the recovery; II: 16 consecutive pts (11 males, age 61±7 years) with a horizontal pattern also into the recovery ("only horizontal"). Pts underwent coronary angiography within 10 days from EST. A luminal diameter of > 50% was considered significant coronary stenosis. We considered the presence of isolated anterior subendocardial ischemia when V3-V4 STD was observed in association with an isolated left anterior descending (LAD) lesion. In presence of right coronary artery (RCA) or circumflex (Cx) lesions and normal LAD, the V3-V4 STD was considered a reciprocal ECG change manifestation of an inferior/ posterior-lateral wall transmural ischemia. A combination of anterior subendocardial ischemia and inferior posterior transmural ischemia could be present when both LAD and RCA/Cx lesions co-existed. Results: Group I pts showed significant coronary lesions in the Cx (in I pt), in the RCA/ Cx (in 4 pts) and in the LAD, RCA/Cx (in 20 pts). Group II showed isolated LAD lesion in 15 pts. One patient had normal coronaries. Group I pts demonstrated more severe angiographic coronary lesions both in terms of number (I= 2.5 ± 0.5 vs II= 1.1 ± 0.5 vessels, $p < 0.0001$) and severity of vessels involved (I=94 ± 6 vs II= 82 + 7%, < 0.0001). Conclusions: in our pts, V3-V4 STD during "isolated" subendocardial ischemia appeared to be of the "only horizontal" type. A downsloping morphology of V3-V4 STD appeared to be associated with EST inducible TMI in the opposite wall, supplied by severely stenotic branches of the Cx and/or RCA, with or without concomitant LAD lesions. Our computer model accurately predicted the observed clinical results.

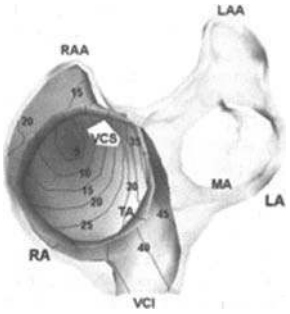
3198 Is accurate non-invasive imaging of the human atrial activation sequence feasible?

F. Roithinger[1], G. Fischer[2], R. Modre[2], F. Hanser[2], F. Hintringer[1], T. Berger[1], M. Schocke[3], B. Tilg[2]. *[1]LKH Innsbruck, Dep. of Cardiology, Innsbruck, Austria; [2]Technical University Graz, Department of Biomedical Engineering, Graz, Austria; [3]University Hospital Innsbruck, Clinical Department of Radiology I, Innsbruck, Austria*

Non-invasive determination of the focal origin of atrial arrhythmias may be important for catheter ablative treatment of atrial fibrillation. The aim of our study was to reconstruct human atrial activation (AT) maps, using 65-lead body surface mapping (BSM) and MRI.

Methods: MRI scanning (torso: 10 mm slice thickness; atrium: cine mode, short axis, 4 mm) was performed in 4 patients (2f, age 33±9) without structural heart disease. Following ablation of supraventricular arrhythmias, BSM and electroanatomic CARTOTM mapping was performed: Right atrium (RA), during sinus rhythm (SR, N=3) and coronary sinus ostium pacing (CS, N=1); and left atrium (LA, N=1, SR and CS). After 3D anatomic reconstruction, using MRI data, AT maps were estimated for the respective atrium. The reconstructed AT patterns were validated with the CARTO TM maps.

Results: Figure: Anatomical reconstruction of both atria. Color-coded AT map of the RA during SR (dark - earliest activation; isochronal lines with numbers in ms; MA=mitral annulus; LAA/RAA= RA/LA appendage; VCI/VCS=inferior/superior vena cava; TA=tricuspid annulus). The mean geometric error between CARTOTM maps and the atrial model was 5.3 ±1 mm, the localization accuracy of the first endocardial breakthrough was 11±6 mm. Sufficient qualitative correlation with the CARTOTM maps was found.



Conclusion: Our findings demonstrate that noninvasive imaging of the atrial activation sequence with a high spatio-temporal resolution is feasible in man. Further studies for quantitative validation in patients with clinical focal arrhythmias are necessary.

Day 5

Wednesday 4 September 2002

PULMONARY VEIN ISOLATION IN ARTIFICIAL FIBRILLATION

3213 Clinical and electrophysiologic predictors of pulmonary vein stenosis following radiofrequency catheter ablation for atrial fibrillation

L. Leite, S. Asirvathan, S. Hammill, P. Friedman, T.M. Munger, W.K. Shen, D.L. Packer. *Mayo Clinic, Cardiac Electrophysiology, Rochester, United States of America*

Background: Radiofrequency catheter ablation (RFCA) has been used for treating atrial fibrillation (AF). However, pulmonary vein (PV) stenosis is still an important limitation. The predictors of PV stenosis are not well established.
Methods: To determine predictors of PV stenosis as a consequence of RFCA, we studied 139 patients presenting with refractory paroxysmal or persistent AF. 333 PVs were ablated in 158 procedures (126 RSPV (37.8%), 97 LSPV (29.1%), 81 LIPV (24.3%), and 29 RIPV (8.8%). PV stenosis was defined as greater than 50% narrowing of the PV, according to baseline measurements by contrast-enhanced spiral CT scanning. The following variable were evaluated: gender, age, type of AF, duration of AF, presence of structural cardiac disease, LVEF, left atrial size, PV ablated, number of burns, maximal temperature of ablation, total energy applied, baseline PV diameter at the orifice and 1-2 cm into the vessel. The data were analyzed using t-test or Fisher's exact test as appropriate.
Results: Of a total of 333 PV ablated, PV stenosis was observed in 20 (5.9%) veins (6/126 RSPV, 5/97 LSPV, 8/81 LIPV, and 1/29 RIPV). There was no difference in clinical features between patients with and without PV stenosis, including age, duration of AF, left atrial size, and LVEF. The mean energy applied was higher in pt with PV stenosis (31±1.3 KJ vs. 21±3.9 KJ, p=0.017). There was no difference in highest temperature reached and number of burns in patients with and without PV stenosis (23±12 vs. 19±12, p=0.14). The mean PV orifice at baseline was smaller among pt with acquired PV stenosis 18±6 mm vs. 24±7 mm, 0=0.003). The number of PVs with a diameter of 15 mm or less at baseline was significantly higher in PV stenosis patients (25% vs. 8.1%, p=0.03, OR: 3.8, 95% CI: 1.2; 12.1).
Conclusions: In this study, ablation of the LIPV, the amount of energy applied, and the baseline size of PV was correlated to PV stenosis after RFCA for treatment of AF. These data could be helpful in avoiding PV stenosis.

3214 Correlating the pathology and physiology of long-term block in circumferential pulmonary vein ablations

W.W. Su, S.B. Johnson, L. Leite, D.L. Packer on behalf of Mayo Clinic. *Rochester, United States of America*

Background: Circumferential ablation at the pulmonary vein (PV) orifice for the treatment of atrial fibrillation has had limited success, which maybe due to difficulties in creating continuous and full-thickness lesions. In theory, small discontinuities may occur without jeopardizing block, since muscle fibers are not continuous around the PV orifice. However, the correlation between pathology and successful electrical block is unclear.
Methods: To assess the impact of any discontinuity within a circumferential lesion on long-term block, 38 PV lesions were created in 18 dogs, which were then survived to either 4 or 6 months. Circumferential ablation using a laser-energy balloon catheter was performed at 3.5 to 5.5 W/cm. End-points were either successful acute bi-directional electrical isolation or a cumulative energy delivery time of 600 seconds. Entrance and exit block were reassessed at the end of the survival period. Post-mortem examination of the gross and histological specimens was performed to categorize the circumferential PV discontinuities in terms 12 clock-face sectors.
Results: Of the 38 PVs ablated, chronic entrance and bi-directional block was confirmed in 9 PVs (24%). Of these, 6 PVs (5 RSPV and 1 LSPV) had 100% circumferential lesion around the PV orifice, and 3 PVs (all LSPV) contained < 8% gaps, located at the inferior aspect of the PV. Of the 29/38 PVs without long-term block, 15/29 PVs had initial acute block: RSPV in 8 with 30±24% discontinuities inferiorly, and LSPV in 7 with 32%±27% discontinuities inferiorly. In the remaining 13/29 PVs, acute block was never achieved: RSPV in 3 with 29±11% gap inferiorly; LSPV in 6 with 29±10% gap inferiorly; LIPV in 5 with 58±45% gap inferiorly.
Conclusions: Excellent correlation exists between the pathology of pulmonary vein ablation and the physiology of long-term block. Chronic bi-directional block of the PV usually requires complete circumferential ablation, although small gaps do not preclude successful disconnection. Most discontinuities greater than 8% will preclude long-term block in the canine heart.

3215 Distinguishing left superior pulmonary vein potentials from left atrial far field activity

D. Shah[1], M. Haissaguerre[2], P. Jais[2], M. Hocini[2], L. Macle[2], K.J. Choi[2], T. Yamane[2]. [1]*Cantonal Hospital, Cardiology, Geneva, Switzerland;* [2]*Hopital Haut Leveque, Electrophysiologie, Pessac, France*

Elimination of distal pulmonary venous muscle activity is considered necessary to treat atrial fibrillation by catheter therapy. However, inspite of extensive proximal ablation, potentials may persist particularly in the left pulmonary superior veins (LSPV).
Methods: 35 patients with PAF (29 M, 56±11 yrs) were studied. A Lasso decapolar circular catheter was placed within the LSPV and RF ablation performed at electrophysiologically defined proximal inputs into the vein. Recordings were obtained from the Lasso 10 to 15 mm inside the LSPV and from the left atrial appendage (LAA) during sinus rhythm, distal and proximal coronary sinus as well as left atrial appendage pacing. Angiography of the LAA was performed in at least 2 different radiographic projections to view the 10 Lasso electrodes en face and their anatomic relationship to the LAA.
Results: Before ablation, pacing from the coronary sinus or LAA separated single sinus rhythm LSPV electrograms into two components linked by continuous electrograms at the input(s) into the vein. LAA pacing produced greater separation compared to distal, while proximal CS pacing resulted in least separation (98±29 vs 83±30 vs 55±30ms, $p<0.05$)The first component was synchronous with LA appendage activity, while the second was sharper with a proximal to distal sequence of activation in the vein. LAA stimulation captured this component with a very short activation time or made it disappear by incorporation within the stimulation artifact. After proximal ablation the first component was still recorded either limited to anterior Lasso bipoles or recorded in all but with the greatest amplitude and sharpness in anterior electrodes within the LSPV.This consistently corresponded to the position of the nearest atrial structure demonstrated by angiography to be the left atrial appendage.
Conclusion: A fusion potential composed of LA appendage and venous muscle activity is recorded in sinus rhythm within the LSPV. Therefore even after successful PV ablation, residual potentials recorded within the left superior pulmonary vein emanate from the left atrial appendage and should not be the target of continued ablation.

3216 Discordance of post ablation exit and entrance block from circumferential pulmonary vein energy deliveries

W.W. Su, S.B. Johnson, D.L. Packer on behalf of Mayo Clinic. *Rochester, United States of America*

Background: Electrical isolation of the pulmonary vein (PV) is crucial in treating atrial fibrillation originating within the vessel. In most clinical settings, entrance block is used as the end point to assess the efficacy of PV ablation. This presupposes that entrance block equates to exit block.
Method: To verify the concordance between entrance and exit block after circumferential ablation of PV ostium, 32 PVs were ablated in 20 dogs with a circumferential laser energy balloon catheter. 3.5 watt/cm^2 to 5.4 watt/cm^2 (average= 4.3 watt/cm^2) energy was delivered for 120 to 600 seconds (average= 225 seconds). Pre and post ablation study of entrance and exit block was assessed in each PV using a multi-polar catheter positioned across the PV sleeve. Entrance block was assessed during normal sinus rhythm and pacing from the coronary sinus, with exit block assessed during pacing from the distal PV sleeve.
Results: Absence of intra-PV potentials with NSR and distal coronary sinus pacing (entrance block) was seen in 26 of 32 PVs (81%). Exit block determination was confounded by incomplete PV capture after ablation. Nevertheless, with local capture, block was seen in 17 of 32 PVs (53%) Reversal of orifice level activation at the line of block was seen in 2 of 32 PVs. Discordance of entrance and exit block was noted in 9 of the PVs (28%) after the ablation, for which 8 of the PVs had only entrance block, and 1 PV showed exit without entrance block. Concordant bi-directional block was present in 18 of 32 PVs (56%). Similarly, concordant absence of entrance and exit block was present in 6 of 32 PVs (19%).
Conclusion: Exit and entrance block after PV ablation is frequently discordant. Therefore, entrance block after PV ablation is an inadequate surrogate endpoint for cure. This may be important in explaining recurrent AF in clinical cases using entrance block as the indicator for completion.

3217 Adenosin induces pulmonary vein activity after successful ostial pulmonary vein isolation: evidence for a "new pathway"

T. Arentz[1], J. von Rosenthal[1], T. Blum[1], G. Bürkle[1], P. Jais[2], D. Kalusche[1], M. Haissaguerre[2]. *[1]Herzzentrum, Abt. Interventionelle Kardiologie 2, Bad Krozingen, Germany; [2]Hopital Cardiologique du Haut-Lévêque, Bordeaux-Pessac, France*

Arrhythmogenic triggers originating from the pulmonary veins (PV) have been identified as cause for paroxysmal atrial fibrillation (AF) in selected patients (Pts). Currently, radiofrequency (RF) catheter ablation of the PV ostium with resulting pulmonary vein isolation offers a potential for cure in these pts. We studied the effects of isoproterenol (ISO) and adenosine (ADO) on PV activation after successful ostial PV isolation.

Methods: We studied 19 pts (mean age 53±8 years, 11 male) with refractory highly symptomatic persistent (n=8), or paroxysmal (n=11) AF. PV isolation was performed utilizing RF catheter ablation technology during left atrial to pulmonary vein activation mapping in sinus rhythm guided by a LASSO- (CORDIS) or multipolar BASKET-catheter (EPT). After successful PV isolation we studied the effects of intravenous ISO (0.2-0.3 mg) and intravenous ADO (12-18 mg) on activation of the upper PVs during CS pacing.

Results: A total of 48 PV were successfully isolated. Intravenous ISO had no effect on PV activity. After ADO, PV activity could be recorded in 9 of 19 left upper PV studied coupled to the atrial activity. This pulmonary vein activation was documented as lasting an average of 21 ± 11 seconds. In 6 of these 9 cases the PV activation was from distal to proximal. No effect of ADO was seen on PV activity in the right upper PV.

Conclusions: ADO induces PV activity in the left but not the right upper PV following successful ostial PV isolation procedure. The distal to proximal activation sequence suggests a possible PV activation via the ligament of Marshall. The pathophysiological role of this "pathway" is not yet known.

3218 Pulmonary veins ostia electrical disconnection and anatomical pulmonary veins isolation: two sides of the same treatment?

P. Adragão[1], M. Scanavacca[2], D. Cavaco[1], C. Aguiar[1], F. Morgado[1], D. Chotalal[1], D. Bonhorst[1], R. Seabra-Gomes[1]. *[1]Hospital Santa Cruz, Department of Cardiology, Carnaxide, Portugal; [2]Instituto do Coração, São Paulo, Brazil*

There are currently two radiofrequency (RF) ablation techniques for percutaneous electrical isolation of pulmonary veins (PV): circumferential isolation and electrical disconnection of the PV ostia.

In order to assess how different these techniques are, we evaluated how close do contiguous RF lesions need to be to achieve electrical disconnection.

Population and methods: We studied 26 PV, in 9 patients with paroxysmal atrial fibrillation who underwent PV mapping and RF ablation. To map the PV ostia we used a circumferential 10-electrode catheter (Lasso™) and a Navistar™ catheter for precise anatomical definition of PV ostia and for RF ablation. After assessment of circumferential distribution and activation sequence of PV potentials, atrial ablation (near PV ostia) was performed at segments showing earliest activation to obtain PV electrical disconnection. Each RF application aimed at <50°C, output<30W and duration<30 seconds.With electroanatomical mapping we measured the PV ostia diameter and the RF maximal circumferential distance between contiguous RF applications.

Results: 26 PV were mapped (6 left superior, 6 left inferior, 9 right superior and 5 right inferior). To obtain PV electrical disconnection, RF energy was applied following the activation sequence. In some areas several applications were needed, and in others few or no applications were performed. A larger PV ostium diameter was associated with the need for a superior number of applications (r=0.51; p=0.008). However, no relation was found between PV ostium diameter and the maximal distance between contiguous RF applications (r=0.13; p=ns). Considering an expected radius of the RF lesion of 2.5 mm, the mean distance between lesion areas was thus inferior to 5 mm (see table).

	RF applications number (mean±SD)	PV ostium diameter mm (mean±SD)	Maximal distance between RF appl. mm (mean±SD), range
LSPV	14.5±2.7	15.1±2.2	9.3±3.0 (5.9 to 14.0)
LIPV	13.5±4.5	13.5±1.8	9.1±1.5 (7.3 to 11.6)
RSPV	23.8±9.4	16.5±2.6	8.1±1.6 (6.4 to 11.1)
RIPV	12.8±5.3	12.8±2.6	9.9±1.2 (8.8 to 12.0)

Conclusions: The density of the RF applications performed on the PV ostium was heterogeneously distributed over the ostium's perimeter. The electrical disconnection endpoint was only achieved after an almost circumferential RF lesion was created.

NEW TRENDS IN IMAGING

3219 3D reconstruction of coronary arteries using intravascular ultrasound and biplane x-ray projections and its quantitative validation

C. Bourantas[1], M.E.P. Marina Plisiti[2], D.I.F. Dimitrios Fotiadis[2], L.K.M. Lampros Michalis[3]. *[1]Ioannina, Greece; [2]University of Ioannina, Dept of computer Science, Ioannina, Greece; [3]Medical school, University of Ioannina, Dept. of Cardiology, Ioannina, Greece*

The aim of the present study was the validation of a novel method for three dimensional reconstruction of coronary arteries.

Methods: We assessed the accuracy of: I) the catheter path reconstruction, II) the relative axial twist of IVUS frames, III) the absolute orientation of IVUS frames, IV) our automated contour detection algorithm for IVUS images. The accuracy of catheter path reconstruction was tested using a metal wire with 11 radiopaque markers, attached at 15mm intervals. The wire was bent in helical turn. The reconstructed wires length and the intervals of radiopaque markers were compared with the real values. For the determination of the relative axial twist of IVUS images, a gutter was machined in helical course on the surface of a plastic cylinder. The gutter was closed by a flat strip. In this way gutter cross-sections had a flat side aligned to the cylinder surface. The validation of our algorithm was achieved by comparing the 3D reconstructed gutter with the original. However, to establish the accuracy of our algorithm in real vessels and determine the accuracy of absolute frame orientation, the coronary arteries of 3 cadaveric pig heart were reconstructed using metal clips for markers. The validation of absolute frame orientation and the angular rotation of IVUS frames was based on the comparison of the 3d reconstructed peak of IVUS stamps with the reconstructed metal clips. Image registration technique was used for the evaluation of the segmentation algorithm for the identification of luminal and media/adventitia borders in IVUS images. For this propose, 64 frames from 8 patients were used for manual determination of the regions of interest by two expert observers and the results were compared with the outcome of the automated segmentation algorithm. Correlation coefficient, slope, y interception, regression analysis, WI, inter – and intra – observer variability were applied so as to determine the reliability of our algorithm.

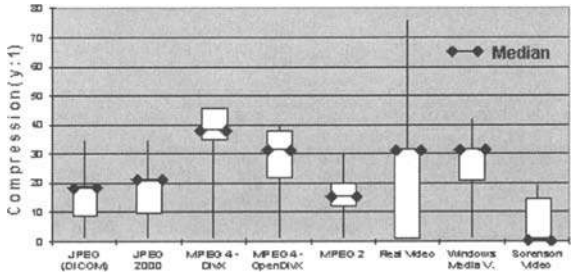
Results: The results include inter-observer variability less than 3%, intra-observer variability less than 2% for the examination of arteries segments from different patients. Details also are given for the absolute orientation of IVUS frames as it is computed by experimental data.

Conclusion: By the proposed validation method we are able to determine the reliability of each step, which was made for the 3D reconstruction of the coronary arteries and to estimate the accuracy of our 3D reconstruction algorithm.

3220 Angiographic data compression: a comparison of different methods

K. Kronberg[1], W. Vocke[1], T. Warns[2], W. Hofmann[1], A. Müller-Eichelberg[1], R. Kussebi[1], A. Brucksch[1], G-H. Reil[1]. [1]*Klinikum Oldenburg, Kardiologie, Oldenburg;* [2]*OFFIS, Health Information Systems, Oldenburg, Germany*

Background: Compression of angiographic data offers easy storage and fast transmission over narrow band networks. We evaluated the image quality of various compression schemes.
Methods: A set of 10 coronary angiogramms was compressed with 8 different methods: Joint Photographic Experts Group (JPEG), JPEG 2000, Moving Picture Experts Group (MPEG) in MPEG-4 from DivX, MPEG-4 from Open DivX, MPEG-2, Real® Video, Windows® Media Video and Sorenson® Video. A team of 10 experienced cardiologists (mean of 3954 examinations each) reviewed the angiogramms. The 80 angiogramms were presented in a randomized, databased sequence with 6 different compression factors and the original for comparison (total data set of 490 films). The examiner selected in each of the 80 series the image quality he judged adaquate for diagnostic purpose.
Results: The median of tolerable compression for diagnostic purposes was for JPEG 19:1, for JPEG 2000 21:1, for MPEG-4 (DivX) 38:1, for MPEG-4 (Open DivX) 31:1, for MPEG-2 15:1, for Real® Video 32:1, for Windows® Media Video 32:1 and for Sorenson® Video at 1:1. The table shows the boxplot.



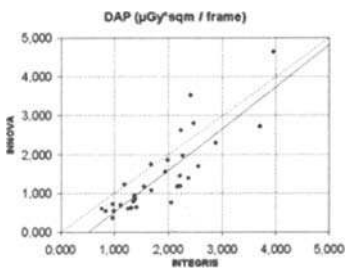
Comparison of compression methods.

Conclusion: The Digital Imaging and Communications in Medicine (DICOM) protocol uses the single image compression of JPEG and JPEG 2000, which allows a moderate compression ratio. The film compressor MPEG-2 shows no advantage. The proprietary formats of Real® Video, Windows® Media Video and Sorenson® Video revealed wide changes in acceptable compression ratio. The international MPEG-4 standard offers the best compression ratio regarding image quality and seems suitable for large archives and telemedicine applications.

3221 Better angiographic images at lower Xray dose with an integrated flat panel detector

R. Simon, M. Lins, G. Herrmann, D. Krüger, V. Plate. *University Hospital Kiel, Cardiology, Kiel, Germany*

Recently integrated flat panel detectors (FPD) have become available for angiocardiography with enhanced image content quality due to a better signal-to-noise ratio and enlarged gray level resolution (12 to 14 bit) as compared to conventional image intensifier/digitized video systems (8 bit), which renders possible advanced image processing techniques (DRM) leading to a picture quality so far unseen. We have reported previously on static phantom studies that have yielded better flat panel image resolution for fluoroscopy as well as cine-like aquisition (2.3 to 2.5 lp/mm for 12cm through 20cm fields of view (FOV)) as compared to contemporary conventional (CON) equipment (<2 lp/mm for all FOV >14cm). Despite this increase in resolution, Xray doses were consistently lower for FPD than CON at identical gantry positions.
Since it is unclear whether these data can be extrapolated to the situation of clinical coronary angiography (CA), we have compared image quality and measured Xray dose-area-product per frame (DAP/fr) in patients who had coronary stent implantation in our institution. CA was performed with CON (Integris H 5000, Philips) and FPD equipment (Innova, GE) at identical FOV and gantry settings for 32 paired assessments in 4 different views.

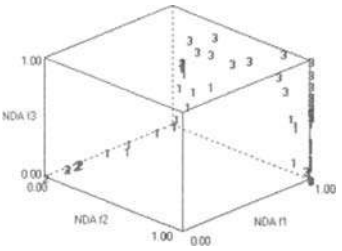


Average DAP/fr was 1,837 µGy m^2 for CON vs 1,423 µGy m^2 for FPD ($p < 0.001$). The distribution and regression line of paired DAP measurements is given in the graphic. Stent strut visibility and stent structure recognition was significantly better in all FPD runs.
In conclusion, FPD imaging allows for improved image quality with at least comparable, if not lower X-ray dose during clinical coronary arteriography.

3222 Application of neuronal network for tissue identification of intracardiac masses in adults

J.D. Kasprzak[1], M. Strzelecki[2], M. Krzeminska-Pakula[1], L. Chrzanowski[1], A. Materka[2], K. Wierzbowska[1], M. Zwierzak[1], J. Drozdz[1]. [1]*Medical University, Cardiology IMW, Lodz, Poland;* [2]*Institute of Electronics, Technical University of Lodz, Lodz, Poland*

Aim: Intracardiac masses differ in their echocardiographic appearance although the visual recognition of their histological classification remains a challenge. We aimed to evaluate the feasibility of neuronal network-based approach for the computer-based identification of tumors.
Methods: 108 images from echocardiograms of patients with masses classified as thrombi (62 images), benign neoplastic (31) and malignant neoplastic (15) were digitized and analyzed with custom software. For each image, a region of interest covering a representative section of the image was defined and 254 image features were calculated (including 9 from pixel histogram, 6 from gradient matrix, 20 from Run length matrix and 220 from 2nd order histogram). 10 most efficient parameters were selected using classification error minimalization approach. Linear and non-linear (neuronal network) discriminative analysis was used in the same dataset.
Results: Simple analysis based on pixel feature histograms was insufficient for mass classification. Analysis based on 3 best parameters was 52% successful and linear discriminative analysis still classified correctly only 55% of images. Neuronal network approach allowed correct classification of 91% (10/108, $p<0.0001$). Graph shows distribution of classes in nonlinear discriminative analysis.



Conclusions: Simple parameters of tissue texture derived from echocardiogram are insufficient for the discrimination of intracardiac thrombi, benign and malignant neoplasms. However, the use of neural network allows correct classification of >90% images in our preliminary series. Validation of this approach in broader dataset is required to create a framework for digital expert systems supporting qualitative echocardiographic diagnosis of intracardiac masses.

3223 Proximal arbitrary surface conservative assessment of leakage (PASCAL): a new Echo-Doppler method for quantification of mitral regurgitation

G. Tonti[1], G. Pedrizzetti[2], M. Grigioni[3], P. D'Avenio[3], P. Trambaiolo[4], A. Salustri[5]. [1]*Hospital SS. Annunziata, Echocardiography Laboratory, Sulmona, Italy;* [2]*University of Trieste, Department of Civil Engineering, Trieste, Italy;* [3]*Istituto Superiore di Sanità, Roma, Italy;* [4]*Hospital Sandro Pertini, Echocardiography Laboratory, Roma, Italy;* [5]*Roma, Italy*

Background: The proximal isovelocity surface area (PISA) method used for quantification of mitral regurgitation is based on the assumption that the isovelocity contours proximal to the regurgitant orifice are hemispherical, however in the complex flow fields of the heart this assumption is limited. In addition, the two-dimensional color Doppler display, while able to provide detailed information regarding the instantaneous velocity of flow parallel to the Doppler scan direction, is unable to represent the orthogonal components of flow velocities. We developed a new approach for quantification of mitral regurgitant flow [proximal arbitrary surface conservative assessment of leakage (PASCAL)] based on physical principles and mathematical handling of echocardiographic images of flow convergence. This approach has been described in this study, tested using a mathematical model, validated with an in vitro study, and finally applied in patients with mitral regurgitation.
Methods and Results: A color Doppler image of a mitral regurgitant flow at peak systole was transformed into a numerical matrix of the axial component of the velocity. The velocity vector was evaluated by the condition of incompressibility integrating the continuity equation, then the instantaneous flow rate was computed by application of the control volume method. Finally, determination of peak velocity and time velocity integral by continuous wave Doppler allowed calculation of the total regurgitant volume. Numerical simulation demonstrated that regurgitant flow rate evaluated by PASCAL is independent of the selected value of radius, whereas PISA method underestimates the real value for small radius and overestimates for large radius. Experiments with an in vitro model demonstrated the high accuracy of PASCAL (error 0.26%). Finally, application on patients with mitral regurgitation confirmed the feasibility and consistency of PASCAL, with a relative error <7%.
Conclusions: A rigorous application of the fluid dynamic laws to color Doppler images allows a non-invasive quantification of mitral regurgitation which is independent of geometric assumption.

CATHETER ABLATION IN ATRIAL FIBRILLATION – LINEAR LESIONS

3228 Are contineous linear lesions associated with ablation success in patients with chronic atrial fibrillation

K. Seidl, M. Rameken, M. Vater, H. Schwacke, A. Brandt, J. Senges. *Klinikum Ludwigshafen, Cardiology Dept., Ludwigshafen, Germany*

A catheter-based, left atrial (LA) ablation procedure was performed using non-contact mapping (NCM) in 14 patients (pts) with chronic atrial fibrillation (CAF). The LA lesion geometry used has been shown to be effective in pts with CAF, in whom intraoperative RF-catheter ablation was performed to eliminate anatomically defined "anchor" reentrant circuits. Aim of this study was 1) to translate a successful surgical LA intervention into a catheter procedure, 2) to evaluate the usefulness of NCM to identify and close discontinuities in linear lesions, 3) to assess the impact of linear lesion continuity on ablation success of CAF.
Methods: LA-ablation was performed with four linear lesions between the mitral annulus and the left inferior pulmonary vein (PV), to the left upper PV, then to the right upper PV, and finally to the right lower PV in 14 pts with CAF. During online analysis, NCM revealed conduction across gaps in the linear lesions in all pts (overall 58 gaps were found with a mean of 4.5 ± 0.9 gaps/pts). In addition contact mapping was performed. With contact mapping a discontinuity of linear lesion was identified by a localized loss of double potentials in 27 of the 58 gaps (47%). In the remaining 31 gaps (53%) interpretation of contact mapping was difficult because of the diminished amplitude of local electrograms. Catheter ablation was guided by NCM until complete conduction block was observed. During follow-up of 12 ± 7 months, 6/14 pts (43%) remained in sinus rhythm without antiarrhythmic drugs (in 5 of the 6 pts no gap was identified during offline analysis) and an additional 4 pts were maintained in sinus rhythm with antiarrhythmic drugs (in all 4 pts 1 gap was identified during offline analysis), resulting in an overall success rate of 71% (10/14 pts).
Conclusions: The intraoperative radiofrequency ablation strategy could be translated into a catheter based procedure using NCM. the overall success rate was 43% without and 71% with additional antiarrhythmic drugs. All pts without gaps during offline analysis were free of recurrence. All pts with a recurrence of CAF had more than 1 gap identified after the initial ablation procedure. Successful ablation of CAF is associated with continuity of linear lesions.

3229 Modification of the atrial substrate by left atrial linear lesions in symptomatic patients after pulmonary vein isolation

S. Ernst, F. Ouyang, M. Goya, T. Vogtmann, A. Schaumann, D. Bänsch, M. Antz, K.H. Kuck. *AK St. Georg, II. Med. Abteilung, Hamburg, Germany*

Trigger elimination by pulmonary vein (PV) isolation has been proposed to cure drug-refractory atrial fibrillation (AF) with varying success. Despite initially successful PV isolation, atrial fibrillation may re-occur during follow-up. Reasons for arrhythmia recurrence might include re-conduction or new atrial triggers.
Methods: Of an initial cohort of 158 pts (36 f, mean age 56 ± 10 years) that underwent pulmonary vein isolation (125 pts with intermittent AF), 38 pts a second ablation attempt was performed because of arrhythmia recurrence during follow-up. After repeat transseptal puncture, a repeat interruption of a conducting fibre was performed, if a spike potential could be recorded (max. 30 W, 50° C over max 180 sec). Again, the loss of PV spike was demonstrated at the end of the procedure. Because of ineffectiveness of this approach to ascertain stable sinus rhythm, a total of 5 pts (4 male, mean age 52 ± 12 years) underwent an ablation procedure aiming at a compartmentalization of the left atrium by two linear lesions: one connecting the superior right to the superior left PV ("roof" line) and a second one from the middle of the roof line to the anterior aspect of the mitral annulus. Mapping and ablation was performed with the assistance of the electroanatomical mapping system CARTO (and an irrigated 4 mm ablation electrode in 4/5 pts) during constant right atrial or coronary sinus pacing.
Results: A mean number of 46 ± 23 RF applications were used to deploy the two linear lesion. Procedure duration amounted to a mean of 489 ± 81 min and 21.8 ± 5.4 min of fluoroscopy. Validation of linear lesion completeness was performed using both conventional stimulation techniques and the features of the CARTO system.
During follow-up (median of 113 days), 4/5 pts are in stable SR without the need for antiarrhythmic medication.
Conclusion: Relapse of the arrhythmia after demonstrated complete pulmonary vein isolation might be caused by re-conduction of the previously interrupted conducting fibres into the pulmonary vein. However, even after repeat "successful" pulmonary vein isolation, atrial fibrillation does reoccur in a subset of patients. Modification of the left atrial substrate by long linear lesions offers a further option to finally ascertain sinus rhythm.

3230 Linear epicardial radiofrequency catheter ablation in patients with refractory atrial fibrillation

M. Scanavacca[1], F. Tondato[2], A. d'Ávila[3], D. Hachul[4], F. Darrieux[3], R. Sartini[3], S. Lara[3], E. Sosa[3]. *[1]Heart Institute(Incor) of Sao Paulo, Arrhythmias Dept., Sao Paulo, Brazil; [2]Heart Institute - São Paulo University, Arrhythmias Group, São Paulo, Brazil; [3]Heart Institute - São Paulo University, Arrhythmias Dept., São Paulo, Brazil; [4]Heart Institute - São Paulo University, Arrhythmias, São Paulo, Brazil*

It has been reported that creating a line of block connecting the four pulmonary veins to the mitral annulus during cardiac surgery, prevents sustained atrial fibrillation (Afib) in around 80% of the patients with permanent Afib. Transthoracic epicardial mapping is a method to directly achieve the pericardial space allowing ablation catheters to be inserted inside the oblique sinus against the pulmonary veins. The aim of this study was to evaluate the feasibility of creating epicardial linear lesions to treat patients with refractory Afib in the electrophysiology laboratory. Patients: Seven patients (46.1±9.5, all men) presenting refractory atrial fibrillation, five paroxysmal and two permanent (6 and 12 months) were referred for epicardial catheter ablation. All patients except one (mitral valve disease) presented normal heart. Patients with paroxysmal Afib had been submitted to at least two procedures before, for RF focal ablation or pulmonary vein isolation. Methods: An octapolar catheter (6-mm length electrodes) was inserted, under anesthesia, in the pericardial space through transthoracic pericardial puncture for linear ablation. A 4-mm regular catheter was also inserted in the left atrial through the transeptal approach to explore the endocardial signal during and after the epicardial ablation. We tried to make either two lines of block along the pulmonary veins towards the mitral annulus or to connect the four PV to the mitral annulus. Results: It was possible to place the epicardial catheter in the oblique sinus, close to the pulmonary veins in all patients. Two lines connecting pulmonary veins to the mitral annulus were obtained in three patients. One line connecting right or left PV to the mitral annulus was obtained in four patients. An important electrogram amplitude reduction (>80%) was recorded by both epicardial and endocardial sites in most lines. When the signal amplitude was still high after epicardial RF pulse, we applied RF through the endocardial catheter. During follow-up (3-15 months), three patients remained in stable sinus rhythm (one of them presented one reversible episode of atrial flutter). Conclusion: Pericardial approach is a feasible method to create RF linear lesions in the left atrium to treat patients with refractory atrial fibrillation.

3231 Linear lesions or linear lesion plus pulmonary vein isolation: a comparative study using intraoperative ablation of atrial fibrillation

H. Kottkamp[1], F W. Mohr[2], N. Doll[2], J. Gummert[2], A. Dorszewski[1], U. Wetzel[1], E. Grebe[1], G. Hindricks[1]. *[1]University Leipzig Heart Center, Electrophysiology, Leipzig, Germany; [2]University Leipzig Heart Center, Cardiac surgery, Leipzig, Germany*

Intraoperative radiofrequency ablation of atrial fibrillation by substrate modification with the induction of contiguous left atrial lesion lines has been shown to be highly effective. It is currently unclear whether additional trigger elimination by pulmonary vein isolation adds treatment efficiency. Thus, two different treatment strategies of intraoperative ablation of atrial fibrillation were compared in 30 consecutive patients (pts.; 26 men, 4 women, mean age 53 ± 8 yrs.) undergoing the procedure with minimal invasive surgery: In group one (grp. I, 15 pts.) linear lesions were deployed in the left atrium between the mitral annulus and the pulmonary veins while in group two (grp. II, 15 pts.) linear lesions (same as grp I) and complete isolation of all pulmonary veins was performed. There were no differences in the incidence of paroxysmal (60%) and permanent AF (40%) between both groups. All pts. underwent surgery exclusively for the treatment of AF.
Results: Treatment time for intraoperative induction of linear lesions was 17 ± 6 minutes and treatment time for induction of linear lesions plus pulmonary vein isolation was 24 ± 7 minutes ($p < 0.05$) At discharge, sinus rhythm was present in 91% of pts. in both groups. In 5 pts. of both groups, electrical cardioversion was necessary following surgery. The use of antiarrhythmic drugs (flecainide or amiodarone) in the early postoperative period was moderately lower in grp. II pts. (47% versus 66%; p = n.s.).
The results of this comparative study indicate that pulmonary vein isolation in addition to substrate modification with linear lesions does not significantly add treatment efficiency. Thus, the induction of linear lesions seems to be sufficient to cure both, pts. with paroxysmal and chronic AF.

3232 Right-sided ablation in selected patients with paroxysmal atrial fibrillation: a multicenter prospective study

C. Tondo[1], A. Vicentini[2], C. Storti[3], M. Rillo[4], R. De Ponti[5] on behalf of RALL Investigator Group. *[1]Centro Cardiologico, Arrhythmia Department, Milan, Italy; [2]Pederzoli Hospital, Cardiology Department, Peschiera del Garda, Italy; [3]Città di Pavia Hospital, Arrhythmia Department, Pavia, Italy; [4]Fatebenefratelli Hospital, Arrhythmia Department, Benevento, Italy; [5]Mater Domini Hospital, Arrhythmia Department, Castellanza, Italy*

Controversy still exists regarding the true clinical benefit of right atrial linear ablation in paroxysmal atrial fibrillation (AF). A multicenter study was designed to prospectively investigate the clinical outcome of a selected population with highly symptomatic drug-refractory AF undergoing right-sided radiofrequency ablation. Lack of the typical clinical scenario suggesting focal origin of AF (i.e. occurrence of frequent premature atrial contractions preceding AF onset) along with disorganized right atrial activity at mapping, constituted the main criteria for choosing the right sided approach. Seventy-two patients (pts) (38 males, mean age 58 ±8 years) were enrolled in the study and received three ablation lines by using a 6 pole, 7F ablation catheter (Amazr, Medtronic, Inc.). Systemic hypertension was detected in 33 pts (46%), ischemic heart disease in 4 pts (6%) and no organic heart disease in 34 pts (46%). Procedural time was 105±48 minutes and X-ray exposure 32±18 minutes. No procedure related complications occurred. After ablation, antiarrhythmic drug treatment was unchanged in 58 pts (81%) while the remaining 14 pts (19%) were off-drug. Three categories (Class 0= failure; Class 1= >50% AF reduction; Class 2= >75% AF reduction) identified the clinical outcome over a mean follow up of 268±119 days as expressed in Table 1. Overall data shows that Class 0 included 10 pts (15%); Class 1 18 pts (25%)and Class 2 44 pts (60%). Semiquantitative evaluation of quality of life showed significant clinical improvement in 78% of pts.

	A (9 pts)	B (5 pts)	C (22 pts)	D (36 pts)
Follow up	< 90 days	90-180 days	180-270 days	> 270 days
Class 0	0	0	3 (14%)	7 (19%)
Class 1	4 (44%)	1 (20%)	4 (18%)	9/25%)
Class 2	5 (56%)	4 (80%)	15 (68%)	20 (56%)

Class 0= failure; Class 1= >50% AF reduction; Class 2= > 75% AF reduction.

Conclusions: In a selected patient population, creation of right linear ablation with antiarrhythmic drugs can affect the atrial substrate of AF promoting over the follow-up improvement of quality of life by markedly reducing or abolishing the clinical episodes of the arrhythmia.

3233 Prevention of paroxysmal atrial fibrillation in patients affected by sinus bradycardia: role of right atrium linear ablation and pacing site

L. Padeletti[1], G.L. Botto[2], A. Spampinato[3], P. Pieragnoli[1], A. Sagone[2], M. Martelli[3], R. Raneri[4], A. Grammatico[4]. *[1]University of Florence, Internal Medicine and Cardiology, Florence, Italy; [2]S. Anna Hospital, Cardiology, Como, Italy; [3]Villa Tiberia, Cardiology, Roma, Italy; [4]Medtronic Italia SpA, Clinical, Roma, Italy*

Background: Interatrial septal (IAS) pacing has been proposed for paroxysmal atrial fibrillation (PAF) prevention in pts with sinus bradycardia (SB). Recent studies have shown the role of atrium compartmentalization obtained by RF right atrium linear lesions (RALL) in treating PAF pts.
Aim: 1) Determine if the IAS pacing is more effective than non septal sites (NSS) pacing in reducing PAF burden. 2) Evaluate if RALL supplies additional benefits to atrial pacing.
Methods: 52 pts (26 M, mean age 72±11 years) with SB and PAF (at least 2 symptomatic episodes in the last year) were implanted with the Medtronic AT500TM pacemaker (PM). At implantation, patients were randomized to be treated by PM only (26 pts) or PM plus RALL (26 pts). Pacing site was also randomized (29 IAS pts and 23 NSS pts). RF ablation was performed using 3-D mapping (Carto system) along two lines: 1) from superior vena cava (VC) to inferior VC; 2) between inferior VC and tricuspid anulus. PM diagnostics allowed to measure PAF burden (hours/day). Antiarrhythmic therapy was maintained stable after implant.
Results: All pts were followed for at least 7 months. The first post-implant month was not considered in data analysis. PAF burden, expressed as mean±st.dev, was significantly ($P<0.05$) higher: 1) in NSS pts 2.3±5.9 than in IAS pts 0.2±1.1; 2) in NSS-RALL pts 3.1±6.7 than in IAS-RALL pts 0.3±1.4; 3) in NSS-no RALL pts 0.9±3.2 than in IAS-no RALL pts 0.1±0.7.
Conclusions: 1) in pts with SB and PAF IAS pacing is more effective than NSS pacing in preventing PAF; 2) pts who underwent RALL had no additional benefit from this procedure

DIABETES AND CARDIOVASCULAR DISEASE

3247 Intensive insulin treatment reduces transient ischaemic episodes during acute coronary events in diabetic patients

A. Stefanidis[1], P. Asimacopoulos[2], S. Argyrakis[3], S. Handanis[3], P. Michail[2], T.H. Dosios[3], M. Zairis[3], S. Foussas[3]. *[1]Athens, Greece; [2]University of Athens, Athens, Greece; [3]Tzanio Hospital, Cardiology Clinic, Piraeus, Greece*

Aim: This study tested the impact of intensive metabolic treatment with insulin on transient myocardial ischaemia detected with continuous 12-lead ST segment monitoring during non-ST segment elevation acute coronary syndromes in type 2 diabetic patients.
Methods: The study included 57 type 2 diabetic patients with non-ST segment elevation acute coronary syndromes. Twenty-eight patients randomized to conventional treatment plus intensive insulin therapy (Group A) and twenty-nine to conventional therapy only (Group B). Group A patients received insulin by infusion for 48 hours according to a predefined protocol aiming to maintain normoglycaemia. Group B patients were treated according to coronary care unit usual care. The ST segment monitoring was performed for 48 hours in the coronary care unit. The two groups were comparable in terms of medical history, clinical, and biochemical data.
Results: Three patients from both groups were excluded from the analysis because there was objective evidence for evolution in ST segment elevation acute myocardial infarction. Six patients (24%) from Group A vs. twelve from Group B (46.2%) had evidence of transient ischaemia ($p=0.098$). Group A patients showed significantly lower values in the median number [Group A vs. Group B: 1(range: 1-3) vs. 3.5 (range: 2-14), $p<0.01$] and total duration of ST-episodes [Group A vs. Group B: 10 (range: 3-20) min vs. 37.5 (range: 10-100) min, $p<0.01$]. Multivariate analysis revealed that the mean plasma glucose during the study period was powerful predictor of the presence (b: 0.377, $p<0.01$), the number (b: 0.523, $p<0.001$) and the total duration (b: 0.686, $p<0.001$) of ST-episodes respectively.
Conclusions: Intensive insulin treatment considerably decreases the number and the total duration of ST-episodes in type 2 diabetic patients suffering from non-ST segment elevation acute coronary syndromes.

3248 Acarbose reduces incidence of type 2 diabetes and of myocardial infarction in subjects with impaired glucose tolerance: The STOP-NIDDM trial

M. Hanefeld, T.T-K. Temelkova-Kurktschiev on behalf of on behalf of the STOP-NIDDM Trial Research Group. *GWT-TU Dresden, Zentrum Klinische Studien, Dresden, Germany*

Impaired glucose tolerance (IGT) is a high risk category for type 2 diabetes and cardiovascular morbidity. Atherosclerosis starts before type 2 diabetes (T2DM) is diagnosed. In multivariate analysis postprandial (pp) hyperglycemia was found to be a significant predictor of both development of T2DM and its comorbidities. Acarbose (A), an a-glucosidase inhibitor by its unique mode of action reduces pp hyperglycemia.
The STOP-NIDDM trial therefore investigated the effect of A on the prevention of T2DM and cardiovascular disease in middle aged subjects with IGT. The study was an international multicentre double-blind, placebo-controlled randomised trial. IGT-subjects (n = 1,429) were randomised to either placebo or A 100 mg 3 times a day for a mean follow-up time of 3.3 years. Both males (50.5%) and females (49.7%) participated with a mean age of 54.5 + 7.9 years and a mean BMI of 30.9 + 4.2 kg/m^2. The primary end-point was the development of diabetes based on an oral glucose tolerance test done yearly. Secondary outcomes included the development of hypertension and cardiovascular disease. Sixty-one (61) subjects (4%) were excluded; they did not have IGT or had no post-randomisation data leaving 1,368 subjects for intent-to-treat analysis. Twenty-three (23) percent (n = 341), discontinued prematurely, 211 in the A-treated group and 130 in the placebo group, these subjects were also followed for outcome parameters. A total of 221 (32.4%) subjects randomised to acarbose treatment and 285 (41.5%) randomised to placebo treatment developed diabetes. Using the Cox proportional hazard model, acarbose reduced the risk of diabetes by 25% [relative hazard = 0.75 (95% CI = 0.63-0.90); p = 0.0015]. Furthermore, the study medication also resulted in a significant increase in the reversion of IGT to normal glucose tolerance (NGT) ($p < 0.0001$). A. was also effective in reducing the occurrence of myocardial infarction: relative hazard = 0.08 (95%CI = 0.01-0.59); P = 0.0138]. It furthermore significantly reduced the incidence of newly diagnosed hypertension. This outcome speakes in favour of our working hypothesis that A by control of pp hyperglycemia protects the b-cells of the pancreas from glucotoxity as well as the endothelium from noxious effects of pp glucose spikes.
In conclusion, acarbose treatment delays the conversion of IGT to T2DM and increases the reversion to normal glucose tolerance. It also significantly decreases the incidence of myocardial infarction and hypertension in this high risk population.

3249 Significantly higher mortality in patients with IDDM compared to patients with NIDDM and non-diabetics undergoing coronary interventions

D. Mukherjee, D. Smith, D. Share, E. Kline-Rogers, K A. Eagle, S. Chetcuti, P. Michael Grossman, M. Moscucci on behalf of The Blue Cross Blue Shield of Michigan Cardiovascular Consortium. *University of Michigan, Division of Cardiology, Ann Arbor, United States of America*

Background: Previous studies have demonstrated a significant difference in outcomes between diabetics and nondiabetics undergoing percutaneous coronary interventions (PCI). Differences in outcome between IDDM and NIDDM have not been studied.
Methods: Study samples consisted of 18,309 consecutive PCI performed between July 1997 and February 2001 in a consortium of 8 hospitals. Of the 18,309 patients who underwent PCI, 4,856 were diabetics. In the diabetic cohort, 1,772 had IDDM and 3,084 patients had NIDDM. Clinical, procedural, and outcome data were collected prospectively by use of a standardized data collection form.
Results: Mortality in patients with IDDM undergoing PCI was significantly higher compared to patients with NIDDM and no diabetes (Table 1). There were no significant differences in MI, stroke and emergent CABG rates between groups. The composite endpoint of death/MI/stroke/CABG was significantly higher in patients with IDDM driven by mortality. After adjustment for demographics and comorbidities there was a strong trend towards worse survival in IDDM with the adjusted odds ratio of death for IDDM vs no-DM of 1.41 (95% CI: 0.95-2.09, P=0.08) and for NIDDM vs no-DM of 1.21 (95% CI: 0.84-1.73, P=0.31).
Conclusions: There is significant heterogeneity in outcomes including mortality between patients with IDDM and NIDDM after PCI. Patients with IDDM have higher mortality after PCI compared to NIDDM. Patients with IDDM should be aggressively targeted for risk factor modification and should be the focus of further clinical research to improve outcomes.

Table 1

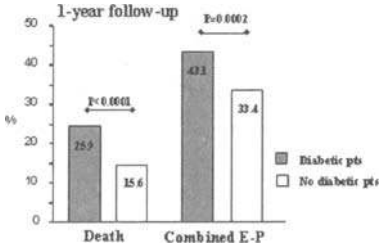
	IDDM (n=1772)	NIDDM (n=3084)	No DM (n=13453)	P
Death	3.05%	1.75%	1.46%	0.003
MI	2.48%	2.14%	2.10%	0.44
Stroke	0.34%	0.32%	0.39%	0.93
Emergent CABG	0.96%	0.71%	0.79%	0.36
Death/MI/Stroke/CABG	6.43%	4.28%	4.30%	0.001

Clinical outcomes in diabetics and nondiabetics undergoing percutaneous coronary interventions. Diabetics are stratified by insulin dependent (IDDM) and non insulin dependent (NIDDM)P value is for outcomes between IDDM and NIDDM patients.

3250 One-year outcome of high-risk patients with acute myocardial infarction with or without diabetes: data from the MISTRAL study

S. Baldasseroni, G. Steffenino, F. Chiarella, G.M. Santoro, A. Bartorelli, M.L. Laudisa, D. Lucci, A.P. Maggioni on behalf of MISTRAL Investigators. *ANMCO Research Center, Florence, Italy*

Background: Pts with diabetes (D) have more often severe and complicated coronary arteriosclerosis with high risk (HR) of acute myocardial infarction (AMI) and cardiac death. We studied in-hospital and 1-year outcomes of HR pts with AMI with or without D treated with reperfusion therapy (thrombolysis or primary-PCI) or drug therapy.
Methods and results: 2227 HR-pts with ST-elevation AMI <12 h were recruited at 17 centres with, and 30 without, feasibility of performing primary PCI (classified at HR having ≥>1 of the following characteristics: female >70 y, diabetic >70 y, Killip class >1, SBP <100 mmHg and heart rate >100 b/m, >4 leads with ST deviation, previous Q-wave AMI, contraindication to thrombolysis [10.2%]). 1795 pts (80.6%) had not D and 432 pts (19.4%) were diabetic: pts with D were more frequent females, older, presented more often with a history of cardiovascular disease, bradi and tachi-arrythmias during hospital stay and heart failure at entry. Pts with D were less treated with reperfusion therapy (74.3% vs 83.0%, p<0.0001) and with betablockers at discharge (41.2% vs 49.5%, p<0.005).
One year mortality rate and combined end-point (death + reinfarction + heart failure + angina) are reported in the figure. When we adjusted the 1-year outcomes for all clinical, haemodynamic variables and therapy, D still remained an independent prognostic predictor (death *OR* 1.54 95%CI 1.13-2.09; combined end-point OR 1.13 95%CI 0.89-1.43).



Conclusion: This study confirms, in a large unselected cohort of HR-pts with AMI, that D is a significant independent predictor of poor prognosis. Neverthless, pts with D are often undertreated with aggressive mechanical or pharmacological therapy.

3251 Exercise and mortality among men with diabetes in the Physicians' Health Study enrollment cohort

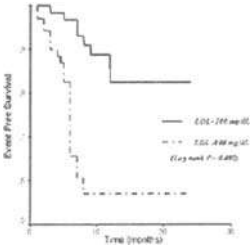
T.A. Gaziano[1], V.Y. Bubes[2], J.M. Gaziano[3]. *[1]Brigham & Women's Hospital, Cardiology, Boston, United States of America; [2]Brigham & Women's Hospital, Division of Preventative Medicine, Boston, United States of America; [3]VA Hospital, Boston, United States of America*

Purpose: Diabetics have at least a 2-3 fold increased risk in overall mortality compared to non-diabetics. Vigorous exercise reduces risk of CVD by 20 to 50% in the general population. We therefore sought to examine the association between exercise and mortality among diabetics.
Methods: The Physicians' Health Study (PHS) is a randomized, double-blind, placebo controlled trial of low-dose aspirin and beta carotene in primary prevention of CVD and cancer. We conducted a prospective cohort study of the 2838 U.S men from the enrollment cohort between the ages of 40-84 years old in 1982 with reported diabetes and without history of MI, stroke or cancer. Assessment of physical activity was estimated by self-reported frequency of vigorous exercise enough to work up a sweat on the enrollment questionnaire. We used Cox proportional hazards regression to analyze the data.
Results: There were 356 deaths over the 5.2 years of follow-up. We observed an inverse linear relationship between frequency of exercise and total mortality. With adjustment for age, smoking, alcohol intake, and history of angina and/or transient ischemic attack, the relative risk of death from all causes for those who exercised 1-3 times/month, 1 time/week, 2-4 times/week, > 5 times/week compared to those who rarely or never exercised were 0.73 (95% confidence interval [CI], 0.50 to 1.05), 0.66 (95% CI, 0.47 to 0.93), 0.57 (95% CI, 0.42 to 0.76), and 0.45(95% CI, 0.31 to 0.66) respectively. When we additionally controlled for body mass index, history of hypertension and high cholesterol, corresponding relative risks were 0.70 (95% CI, 0.47 to 1.05), 0.73 (95% CI, 0.51 to 1.03), 0.58 (95% CI, 0.43 to 0.79), and 0.49(95% CI, 0.33 to 0.73) respectively. The P value for trend was <0.0001 in both multivariate models.
Conclusions: Exercise is associated with a significant reduction in overall mortality among men with diabetes and no history of MI, stroke, or cancer. The association is linear with increasing relative risk reduction through to the highest exercise category. The effect persists when controlled for age, and other mortality associated risk factors. The effect appears to be in part independent of exercise's effect on BMI, hypertension and cholesterol.

3252 Predictors of outcome in diabetic patients after successful percutaneous coronary interventions

C. Briguori[1], F. Manganelli[2], G. Condorelli[3], A. Focaccio[1], A.G. Maione[1], B. Villari[1], A. Colombo[4], B. Ricciardelli[2]. *[1]Naples, Italy; [2]Clinica Mediterranea, Cardiology, Naples, Italy; [3]CNR, CEOS, Naples, Italy; [4]San Raffaele Hospital, interventional Cardiology, Milan, Italy*

Background: Diabetic patients have a worse outcome after percutaneous coronary interventions (PCI). We sought whether long-term outcome of diabetic patients after successful PCI is influenced by: 1) vascular complications, 2) HbA1c levels, and 3) plasma cholesterol levels, at the time of revascularization.
Methods: From January to July 2001, 150 consecutive diabetics underwent successful PCI at our Institution. Differences in: a) clinical, angiographic and procedural variables, b) HbA1c >7%, c) presence of retinopathy, d) creatinine, microalbuminuria and cholesterol levels, were assessed in patients with (n= 40, Group A) and without (n= 110, Group B) major cardiac events (MACE, i.e. myocardial infarction, death, bypass surgery, re-PCI)at follow-up (10±4 months).
Results: The main angiographic and procedural characteristics were similar in the 2 groups. Stent was implanted in 84% of patients (82% in Group A and 85% in Group B, p= 0.66). IIb/IIIa antagonists were used in 29.5% of patients (28% of Group A and 30% of Group B (p= 0.79). Microalbuminuria >20 mg/24h occurred in 23% of patients in Group A vs. 25% in Group B, p= 0.53). HbA1c >7% (37.5% vs. 16%, p=0.007), retinopathy (50% vs. 23%, p= 0.01), chronic renal insufficiency (26% VS. 12%, P=0.033), and higher cholesterol levels (total 208±51 vs. 183±39 mg/dl, p= 0.005; LDL 124±38 vs. 102±33 mg/dl, p= 0.001) were more frequent in Group A. By stepwise logistic regression analysis, predictors of MACE were LDL (RR= 1.02; 95% CI= 1.01-1.04; p= 0.019; figure), HbA1c (RR= 4.45; 95% CI= 1.33-10.26; p= 0.012), and chronic renal insufficiency (RR= 3.93; 95% CI= 1.16-13.32; p= 0.028).



Conclusions: The degree of metabolic (both lipidic and glycemic) control may influence long-term outcome after successful PCI in diabetic patients.

VASCULAR STRUCTURE AND FUNCTION

3253 Progesterone attenuates the beneficial effects of hormone replacement therapy on large artery elasticity in hypertensive postmenopausal women

K. Tzioumis, C. Tsioufis, I. Kallikazaros, D. Tousoulis, P. Zambaras, C. Pitsavos, C. Stefanadis, P. Toutouzas. *Hippokration, University of Athens, Department of Cardiology, Melissia, Greece*

Nowadays, based on the results of HERS study, the cardiovascular beneficial effects of hormonal replacement therapy (HRT) on postmenopausal women are in doubt. Whether there are differential effects of combined and uncombined HRT on large artery stiffness, a well-recognized risk factor for cardiovascular outcome, has not been well defined.

Methods: Towards this end, we studied aortic compliance in 56 postmenopausal women (age 52±5 years, 3.4±1 years after menopause) with untreated, mild essential hypertension randomized to either conjugated estrogen alone (n=20), estrogen plus medroxyprogesterone (n=20) or placebo (n=16). Aortic elasticity was evaluated non-invasively on the basis of pulse wave velocity (PWV) measurements at baseline and at 12 weeks after treatment.

Results: In our women BMI was 27±4 Kgr/m^2, office BP 146/93 mmHg, left ventricular mass index (LVMI) 104±26 gr/m^2, and plasma levels of total cholesterol 230±21mg/d. The three groups were matched regarding age, time since menopause, smoking status, office BP, BMI, LVMI and PWV values at baseline. At 12 weeks of treatment, in the women receiving estrogen alone, aortic PWV was significantly reduced (231±17 vs 209±15 cm/sec, p<0.005), while in the women receiving combined HRT or placebo, PWV did not change (232±20 vs 228±18 and 233±14 vs 230±16 cm/sec, respectively, p=NS for both cases). In all three groups, BP and heart rate values did not change significantly after treatment. At baseline, aortic PWV had a positive correlation with womens' age (r=0.32, p<0.05) and LVMI (r=0.29, p<0.05).

Conclusions: Long-term combined HRT is without beneficial effects on large artery function in hypertensive postmenopausal women. These findings supports the view that progesterone may attenuate the beneficial effects of unopposed HRT.

3254 ETA receptors mediate vasoconstriction whereas ETB receptors clear endothelin-1 in the splanchnic and renal circulation of healthy men

F. Böhm[1], J. Pernow[1], J. Lindström[2], G. Ahlborg[2]. [1]*Karolinska Hospital, Department of Cardiology, Stockholm, Sweden;* [2]*Huddinge Hospital, Department of Clinical Physiology, Stockholm, Sweden*

Background: The study was undertaken to investigate the contribution of endothelin (ET)A and ETB receptors to basal vascular tone and ET-1-induced vasoconstriction in the renal and splanchnic vascular beds of healthy humans.

Methods: ET-1 (4 pmol x kg-1 x min-1 i.v.) was infused alone, in combination with the selective ETA receptor antagonist BQ123 (5 nmol x kg-1 x min-1) or the selective ETB receptor antagonist BQ788 (4 nmol x kg-1 x min-1) in six healthy men. Renal and splanchnic blood flows were determined by para-amino hippuric acid and cardiogreen clearance, respectively.

Results: Administration of ET-1 evoked increase in arterial blood pressure and renal as well as splancnic vascular resistance. BQ123 did not affect basal arterial blood pressure, splanchnic or renal vascular resistance. However, BQ123 greatly reduced the increase in splanchnic and renal vascular resistance induced by ET-1 (58±13 vs. 11±12%; P<0.05 and 36±6 vs. 12±3%; P<0.0001 respectively). BQ788 significantly increased basal splanchnic and renal vascular resistance (38±16%; P=0.01 and 21±5%; P<0.0001 respectively), and potentiated the increase in renal vascular resistance in response to ET-1 (67±14 vs. 36±6%; P<0.01). Plasma levels of ET-1 increased significantly more in the presence of ETB receptor blockade than under control conditions and in the presence of ETA receptor blockade.

Conclusion: These findings suggest that ETA receptors play a more important role in mediating vasoconstriction in the splanchnic and renal vasculature than ETB receptors in healthy humans in vivo. The ETB receptor seems to exert a clearance function which may modulate vascular tone by altering the plasma concentration of ET-1.

3255 Intra-brachial Aldosterone does not acutely alter forearm vascular resistance in healthy male volunteers

P. Gunaruwan[1], M. Schmitt[1], J. Taylor[1], L. Lee[1], A. Struthers[2], M. Frenneaux[1]. [1]*Wales Heart Research Institute, Cardiff;* [2]*Ninewells Hospital/ School of Medicine, Clinical Pharmacology, Dundee, United Kingdom*

Background: Systemic infusions of aldosterone cause an acute increase in systemic vascular resistance (SVR) in healthy subjects. It is not clear whether this is due to local vascular effects or is a consequence of the previously reported effects on baroreflex function. We investigated the non-genomic short-term effects of locally infused aldosterone on the forearm resistance bed.

Methods: We studied 9 healthy male volunteers (age 31±3.8) on an ad libitum diet (24-hour urinary Na excretion 137.8±19.7mmol). Following a baseline 0.9% saline infusion for 6 minutes, Aldosterone was administered into the brachial artery at 0.5ml/min at doses of 20, 100, and 200ng/ml incrementally for 10 minutes each. At baseline and at the end of each infusion, forearm blood flow (FBF) was measured simultaneously using strain gauge plethysmography, in both the infused and the non-infused contralateral arms. Arterial blood pressure was continuously recorded using finger photo-plethysmography. Forearm Vascular Resistance (FVR) was calculated from the flow-pressure data. Venous effluent blood from both arms was analysed for plasma levels of aldosterone at baseline and at the end of each infusion. Changes in forearm blood flow and forearm vascular resistance in the infused arm were corrected for those occurring in the non-infused arm.

Results: Plasma aldosterone levels increased in a dose dependent fashion in venous blood of the infused arm (from 113.3pg/ml at baseline to 1230.6pg/ml at peak infusion rate, p<0.001) but did not change in the non-infused arm. In the infused arm Aldosterone had no effect on absolute FBF (2.62mls/100ml forearm volume at peak infusion Vs 2.68mls/100ml forearm volume at baseline p=NS) or absolute FVR (32mmHg/ml per 100ml forearm volume at peak infusion Vs 30mmHg/ml per 100ml forearm volume at baseline p=NS). Corrected for changes in the control arm, FBF increased by 4.1% (p=NS) and FVR by 4.3%(p=NS) at peak infusion.

Conclusions: Local intra-arterial infusion of aldosterone, sufficient to raise plasma levels to those seen in severe congestive cardiac failure had no acute, non-genomic effect in the forearm resistance bed in healthy male volunteers.

3256 An ultrasound-based method for determining pulse-wave velocity in the carotid artery

S.I. Rabben[1], N. Stergiopulos[2], L.R. Hellevik[3], O.A. Smiseth[1], S. Slørdahl[4], S. Urheim[1], B. Angelsen[4]. [1]*Rikshospitalet University Hospital, Institute for Surgical Research, Oslo, Norway;* [2]*EPFL, Lab Hemodyn Cardiovasc Tech, Lausanne, Switzerland;* [3]*NTNU, MTF/Division of Applied Mechanics, Trondheim, Norway;* [4]*NTNU, IFBT, Trondheim, Norway*

Background: The pulse wave velocity (PWV) is related to arterial stiffness and determines the timing of the reflected wave. It can be estimated from arterial cross-sectional area and brachial pulse pressure by the Bramwell-Hill (BH) method. The aim of this study was to present and evaluate a non-invasive alternative to the BH method.

Method: It can be shown from wave propagation theory that PWV equals the ratio between arterial flow and cross-sectional area during reflection-free periods of the cardiac cycle. PWV can therefore be estimated as the slope of the straight portion of the area-flow (AQ) loop (Fig. 1, left panel, thick line). In two anaesthetized dogs and 21 human subjects (age 23-74) we measured the carotid flow and cross-sectional area non-invasively by ultrasound (Fig. 1, right panel).

Results: As predicted by the pressure dependency of arterial stiffness, the estimated PWV decreased when the aortic pressure was lowered in the two dogs. In the human subjects, the AQ and BH estimates were correlated (r = 0.44, p < 0.05). The difference was -0.14 ± 1.12 m/s (mean ± SD). When the human subjects were divided into three age groups (<35 years, 35-55 years and >55 years), both methods gave group means that increased with age (AQ: 5.62, 5.85, and 6.52 m/s, respectively. BH: 5.29, 6.29 and 6.86 m/s, respectively). For the BH method, the youngest group was significantly different from the middle and oldest age groups (p < 0.05). For the AQ method, the groups of the youngest and oldest tended to be different (p = 0.13).

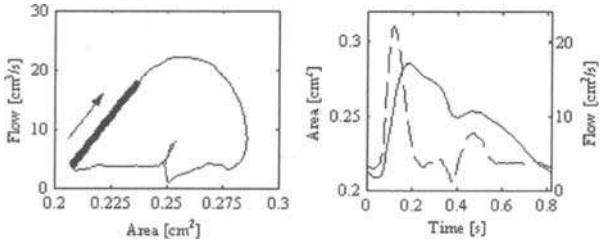


Fig 1: Area (solid) and flow (dashed).

Conclusion: We derived a new method for estimating PWV that can be based solely on ultrasound measurements of cross-sectional area and flow. Hence, the use of brachial pulse pressures is avoided.

3257 Endothelial dysfunction and coronary vasospasm in essential hypertensives with normal coronary arteries

M. Gallopin[1], I. Simonetti[2], D. Neglia[3], A. L'Abbate[3], M. Marzilli[1]. [1]Siena, Italy; [2]Florence, Italy; [3]CNR Institute of Clinical Physiology, Pisa, Italy

Background: The possible relationship between coronary endothelial dysfunction and susceptibility to coronary vasospasm has not been investigated in patients with essential hypertension (EH).
Methods: To this purpose we studied 24 EH patients (mean age with 57±8 yrs, 10 males, mean pressure 109±15 mmHg) with angiographically normal coronary arteries. Coronary flow velocity was continuously measured by Doppler catheter in the proximal LAD together with coronary pressure from the guiding catheter. After baseline measurements (Bas), the protocol included acetylcholine (Ach) (15 mcg/min and 45 mcg/min)and adenosine (Ado) (1mg/min) infusions. Quantitative coronary angiography was scheduled at the end of each step. Coronary Flow (CF) was calculated as coronary flow velocity times coronary cross sectional area.
Results: In all patients Ado infusion could be performed, while only 18 patients completed the Ach protocol. In 6 patients transient coronary vasospasm occurred during the second Ach infusion, associated with chest pain in all and ST segment elevation in 4. In these patients CF measured at the end of the first Ach infusion was used for further analysis. CF changes during Ach were heterogeneous in the whole population. According to the median value of max % CF increase during Ach, patients were divided into two groups, with higher (Group 1) or lower (group 2) CF response, respectively. The % CF change (mean±SE) was higher in Group 1 than in Group 2 either during Ach 15 mcg/min (42.8±16.2 vs minus 14.1±12.3, $p<0.05$) or Ach 45 mcg/min (138.6±37.7 vs 0.6±6.9, $p<0.01$). By contrast, the % CF increase during Ado was not different between the two groups (239±31.9 vs 166±25.8, ns). Spasm occurred in 1/12 pts of Group 1 and in 5/12 pts of Group 2.
Conclusions: In pts with essential hypertension coronary flow response to acetylcholine is heterogeneous and not related to adenosine dependent vasodilating capability. A blunted response to acetylcholine is associated with higher likelihood of coronary vasospasm. These data suggest that coronary endothelial dysfunction is associated with increased vasomotor reactivity in hypertension.

3258 Soluble CD14 influences aortic stiffness but not brachial blood pressure in a population-based study

J. Amar[1], J.B. Ruidavets[2], C. Bal dit Sollier[3], V. Bongard[2], H. Boccalon[4], B. Chamontin[1], L. Drouet[3], J. Ferrières[2]. [1]CHU Purpan, Médecine Interne et HTA, Toulouse, France; [2]INSERM U558, Department of Epidemiology, Toulouse, France; [3]Lariboisière Hospital, Haematology Laboratory, Paris, France; [4]Rangueil Hospital, Department of Angiology, Toulouse, France

Objectives: Soluble CD14 (sCD14), an effective mediator for the activation of monocytes by bacterial endotoxin is involved in the release of substances able to modify the characteristics of the arterial wall. Also, in endotoxin-injected spontaneous hypertensive rats, the duration of delayed hypotensive phase was lower than in WKY rats: this is associated with an attenuated inflammatory response. The aim of the study was to investigate in humans the role of sCD14 on brachial blood pressure (BP) and on aortic stiffness.
Population and methods: A population sample of 905 healthy subjects aged 35-64 years randomly selected from the electoral rolls were recruited between 1995 and 1997 by the Toulouse MONICA centre. After fasting, blood sample was drawn and a questionnaire was administered. Heart rate, BP and carotid femoral pulse wave velocity (PWV) were successively measured in supine position. Carotid-femoral PWV was measured using a semi-automatic device (Complior). Common carotid intima media thickness (IMT) and the presence of plaques were assessed by ultrasonography. sCD14 was measured using an immuno enzymatic method (IBL, GmbH, Hamburg, Germany).
Results: In bivariate analysis, PWV, IMT, the presence of plaques and systolic BP (SBP) were positively associated with sCD14 ($p<0.01$) whereas no significant relationship was observed between sCD14 and diastolic BP. After adjustment for age and sex, no significant relationship remained between IMT, the presence of plaques, SBP and sCD14. A significant and positive relationship ($p<0.05$) was observed between PWV and sCD14 after adjustment for age, sex, heart rate, SBP and insulinemia.
Conclusion: This cross-sectional population-based study yields first evidence that sCD14 strongly influences aortic stiffness independently of age, BP and atherosclerosis.

NEW ASPECTS OF NEUROHORMONAL REGULATION IN HYPERTENSION

3259 Atrial muscarinic M2 receptor down-regulation by insulin in adult rat atrial cardiomyocytes: a link between obesity and hypertension?

A. Pathak[1], M. Galinier[2], F. Smih[1], P. Philip-Couderc[1], S. Buys[1], P. Verwaerde[1], P. Rouet[1], J.M. Senard[1]. [1]Faculté de Médecine, Department of Pharmacology, Toulouse, France; [2]Fédération des Services de Cardiologie, Cardiology, Toulouse, France

Introduction: Mechanisms leading to hypertension in patient with hyperinsulinism (i.e. diabetes or obesity) remain to be defined. In an experimental model of obesity-related hypertension and hyperinsulinism (high-fat diet in dogs) we previously reported a decreased density of M2- cholinoceptors (M2-R) in right atrium. We sought to assess, in vitro, the influence of insulin (I), on M2 muscarinic receptivity in isolated atrial cardiomyocytes issued from adult rat(AC).
Methods: AC were isolated and cultured in the presence or in absence of increasing concentrations of insulin (10^{-12} to 10^{-6} M) for 24 hours. Ligand binding assay using [3H]N-methylscopolamine (a non-specific M2-R antagonist) on intact cells was performed to determine M2-R number and Kd. The expression level of mRNA encoding M2 receptors in controls and treated cells was measured using semi-quantitative RT-PCR analysis using mRNA encoding GAPDH as an internal control.
Results: Insulin induced a dose- and time-dependent down-regulation of M2R. The density of M2-R decreased from 286±45 fmoles/105 cells to 178±32 fmoles/105 cells ($p<0.005$) without any modification of Kd. In the same way, insulin induced a dose-dependent decrease of the ratio M2/GAPDH. These transcriptional modifications are time- and concentration-dependent and were detected after 24 hours of incubation. The ability of carbachol to inhibit the increase in cAMP production induced by forskolin was not modified by incubation of cells in the presence of insuline (10-6M).
Conclusion: These data suggest a role of insulin on atrial M2-R expression. This regulation might be explained by a genic effect involving a Mitogen Activated Protein kinase pathway (data not shown). Our results provide insight about the effect of insulin on the heart and the possible role of this hormon in the genesis of hypertension and arrhythmias (i.e. decreased heart rate variability thus increased risk of sudden) in patient with hyperinsulinism(diabetes or obesity).

3260 Validation of a novel technique to eliminate breathing influence from basic RR interval signals

B. Drieghe[1], M. De Buyzere[1], D. Duprez[1], J.P. Martens[2], T. Gillebert[1]. [1]Ghent University Hospital, Cardiovascular Diseases, Ghent, Belgium; [2]Ghent University, ELIS, Ghent, Belgium

Introduction: Power spectral analysis of RR interval variability is an established technique to investigate the autonomic nervous system. However, power spectra are strongly influenced by respiratory patterns. Until recently, only mathematical adjustments for this confounding factor could be made. We hypothesised that when using frequency-filtering techniques from speech technology, basic RR interval signals can reliably be filtered from respiratory influences.
Methods: In 26 healthy drug-naive subjects (mean age 40 ± 11 y, 13 M/13F, age matched), 5-min recordings of RR interval were made in the supine position. Two 'baseline' recordings were obtained after 30 min of supine rest as well as two during metronomic breathing (slow, 6/min and fast, 15/min) to serve as quality control. RR interval was computed from peripheral continuous ECG leads while breathing pattern was concomitantly assessed using a nasal thermistor. Recordings were separated by a 5 minute rest.
Results: Power spectral indices (auto-regressive method) had a Gaussian distribution and are given in normalised units (NU). Low (LF, ~0.1 Hz) and high (HF, ~0.25 Hz) frequency components in the basic signals were 0.41 ± 0.12 NU (mean ± SD) and 0.59 ± 0.12 NU respectively, resulting in a ratio of 0.763 ± 0.370. After correcting the basic signals from respiratory influence, this yielded LF and HF of both 0.50 ± 0.09 NU and a ratio of 1.043 ± 0.334 (all $p<0.001$). During slow metronomic breathing, we observed a LF peak of 0.64 ± 0.05 NU and a HF peak of 0.36 ± 0.05 NU, resulting in a ratio of 1.836 ± 0.333. After adjustment, we obtained LF and HF peaks of both 0.50 ± 0.07 NU with a ratio of 1.033 ± 0.284 ($p < 0.001$). During fast metronomic breathing, LF and HF peaks were respectively 0.33 ± 0.13 NU and 0.67 ± 0.13 NU, which yields a ratio of 0.551 ± 0.326. Adjustment for breathing transformed both LF and HF to 0.50 ± 0.08 NU, resulting in a ratio of 1.027 ± 0.301 ($p < 0.001$). There was no statistically significant difference between the adjusted values of the baseline and the metronomic breathing spectral indices.
Conclusion: Basic RR-interval signals can be reliably filtered from confounding respiratory influences.

3261 Association of β1-adrenergic receptor polymorphism with blood pressure and left ventricular mass in a population study

M. Castellano, F. Rossi, M. Giacchè, C. Perani, F. Rivadossi, M.L. Muiesan, M. Beschi, E. Agabiti Rosei. *University of Brescia, Dip. Scienze Mediche e Chirurgiche, Brescia, Italy*

An arginine (Arg) to glicine (Gly) substitution at aminoacid position 389 of beta1-adrenergic receptor is characterized by higher levels of basal and isoproterenol stimulated adenylyl cyclase activity in cell cultures. In addition, preliminary data from a case-control study suggest that individuals homozygous for the Arg389 allele are at increased risk to develop hypertension.
To examine the effect of the b1-AR Arg/Gly389 polymorphism on blood pressure and cardiac structure and function in a sample of general population.
Five-hundred and sixty subjects (aged 35 to 64) were enrolled in the study. They were randomly selected from the electoral rolls of a small town of approximately 8.000. Clinic and 24-hour ambulatory blood pressure (ABPM), as well as indexes of left ventricular (LV) structure and function (echocardiography) were obtained in each subject. Beta1-AR Arg/Gly389 polymorphism was characterized by PCR-restriction typing.
Blood pressure was significantly higher in Arg389 homozygotes both at clinic and 24-hours measurements. Differences were similar for systolic and diastolic blood pressure and for day-time and night-time measurements. The relative risk of hypertension for Arg389 homozygotes was 1.26 (1.03-1.55, CI 95%). Heart rate differences were not statistically significant. Interventricular septum and posterior wall thickness, as well as calculated LV mass were higher in Arg/Arg389 individuals. Echocardiographic indexes of LV systolic and diastolic function (ejection fraction, fractional shortening, Ev/Av) did not differ significantly between genotypes.

	Arg/Arg389 (n=279)	Arg/Gly389 + Gly/Gly389 (n=281)	ANOVA
Clinic SBP/DBP, mmHg	137.3/84.4 ±1.15/0.60	133.2/82.6 ±0.95/0.56	p = 0.006/ p = 0.027
ABPM SBP/DBP, mmHg	122.9/78 ± 0.70/0.49	121.0/76.5 ±0.71/0.51	p = 0.057/ p = 0.044
Left ventricular mass index, g/m^2	90.5±1.76	84.8±1.51	p = 0.014
SBP Adjusted LVMI	89.3±1.60	84.8±1.59	p = 0.049

Homozygosis for beta1-AR Arg389 allele is associated to slightly but significantly higher blood pressure and to increased risk of hypertension. Arg389 is also associated to increased LV mass and this relationship seems not only attributable to blood pressure differences but possibly also to increased cardiac adrenergic stimulation.

3262 Transforming growth factor-beta1 levels in hypertensive patients: association with body mass index and leptin

C. Di Febbo[1], E. Vitacolonna[2], G. Baccante[2], A. Angelini[2], F. Febo[2], M. Di Nisio[2], F. Cuccurullo[2], E. Porreca[2]. *[1]University of Chieti, Internal medicine, Chieti, Italy; [2]Policlinico "SS.Annunziata", Internal Medicine, CHIETI, Italy*

Transforming Growth Factor-b1 (TGF-b1) is a multifunctional growth factor/cytokine that has been suggested to be overexpressed in hypertension. A relationship between obesity and hypertension is well known, and leptin, an adipocyte-specific ob gene product, has been shown to play a role in obesity-related hypertension. Since previous in vitro studies demonstrated a biological interaction between leptin and TGF-b1, the aim of this study was to evaluate a possible in vivo association between TGF-b1, body mass index (BMI) and leptin circulating levels in hypertensive subjects.
The study was conducted in 29 consecutive normal weight, 29 overweight and 46 obese hypertensive patients. To study the effect of weight loss, twenty of the hypertensive obese patients (11 women, 9 men, BMI 35.6±6, mean age 37±13 y) were fed a diet providing 1300kcal/day. Metabolic, anthropometric and biochemical parameters were evaluated at the baseline and after weight loss. Plasma TGF-b1 and leptin levels were measured by using a specific ELISA in accordance with the manufacturer's instructions. Peripheral blood mononuclear cells of healthy subjects were separated by Ficoll-Hypaque gradient and seeded into Petri dishes. Adherent monocytes were incubated for 24-hours in serum-free conditions and in the presence of human recombinant leptin (0.1-5nM). Then TGF-b1 mRNA expression from these cells was evaluated by Northern blot analysis.
TGF-b1 was significantly elevated in 46 hypertensive obese patients as compared with TGF-b1 levels of 29 hypertensive patients with normal BMI (8.6±3 ng/ml vs 4.4±2 ng/ml, $P<0.001$). TGF-b1 circulating levels were strongly associated with BMI and leptin levels in an univariate analysis ($r=0.59$, $P<0.0001$; $r=0.62$, $P<0.0001$, respectively) and these associations were still present after stepwise multivariate analysis.The results of a 12-week calories-restricted diet produced a weight loss of 10% and a parallel decrease in TGF-b1 (from 8.9±3 ng/ml to 5.3±2.8 ng/ml; $P<0.01$) and leptin levels (from 30±24 ng/ml to 17±14 ng/ml, $P<0.05$). In vitro experiments showed that leptin is able to induce a dose-dependent increase in TGF-b1 production (from 1.6±0.3 ng/ml to 3.6±0.7 ng/ml) and mRNA expression (about 2.5 fold increase)in human peripheral monocyte cultures.
Our data indicate that TGF-b1 levels are positively associated with BMI and leptin levels in hypertensive patients and suggest that adipose tissue may be an important determinant of TGF-b1 levels possibly by a leptin-dependent pathway.

3263 The effect of 17β-oestradiol on markers of vascular inflammation in postmenopausal women: a randomized, controlled trial

S. Stork[1], C. von Schacky[2], P. Angerer[3]. *[1]Julius Maximilians Univ. Würzburg, Cardiology, Würzburg, Germany; [2]Klinikum der Univ. München- Innenstadt, Cardiology, München, Germany; [3]Klinikum der Univ. München- Innenstadt, Institut f. Arbeits- u. Umweltmedizin, München, Germany*

Background: Intervention trials in postmenopausal women with coronary artery disease have failed to demonstrate beneficial effects of hormone replacement therapy (HRT) on the course of disease, potentially due to proinflammatory effects of conjugated equine estrogens (CEE). Novel hormone formulations might exhibit a more favourable balance between cardiovascular risk and benefit.
Subjects and Methods: We characterized the effects of 48 weeks of treatment with 2 17beta-estradiol based HRT regimens on nonspecific (high sensitivity C-reactive protein [CRP], blood sedimentation rate [BSR], fibrinogen) and specific (cell adhesion molecules: ICAM-1, VCAM-1, E-selectin) markers of inflammation. Healthy postmenopausal women with subclinical atherosclerosis (i.e., increased carotid artery intima-media thickness of >1mm) randomly received either no HRT (n=73), or 1 mg 17beta-estradiol daily plus 25 mg gestodene for the last 12 days of each 28 day cycle (=standard dose progestin; n=65), or gestodene added each third cycle only (=low dose progestin; n=65). CRP was assessed by high-sensitivity assay.
Results: Groups were comparable regarding all baseline characteristics. No effect of either HRT regimen was observed on CRP levels, leukocyte count and neutrophils. Both HRT regimens reduced levels of ICAM-1 (-9%), VCAM-1 (-9%), E-selectin (-11%), fibrinogen (-12%), BSR (-5%), FSH (-44%) (all $p<0.001$). A modest effect on total (-6%; p=0.003) and LDL cholesterol (-7%; p=0.001)was seen. Subgroups of smokers and subjects on antihypertensive or lipid lowering medication showed effects comparable to the whole cohort. Effects of low and standard dose progestin were not different.
Conclusion: Our data indicate that HRT based on 17beta-estradiol favourably influences markers of vascular inflammation without a concomitant rise in hs-CRP. This finding adds new data to the ongoing discussion of the risks and benefits of HRT.

3264 Role of AT1 receptors and calcium influx in enhancing oxidative stress in hypertension

V. Sanguigni[1], P. Pignatelli[2], G. Germanò[3], L. Lenti[2], F. De Vito[1], R. Lauro[4], F. Violi[3]. [1]*University of Rome Tor Vergata, Internal Medicine, Rome, Italy;* [2]*University of Rome La Sapienza, Experimental Medicine, Rome, Italy;* [3]*University of Rome La Sapienza, Internal Medicine, Rome, Italy;* [4]*University of Roma Tor Vergata, Internal Medcine, Rome, Italy*

Background: Recent studies provided experimental evidence that hypertension induces atherogenesis through enhanced oxidative stress and that angiotensin converting enzyme (ACE) system activation may play a pivotal role. AT1 receptors have been shown in vitro to enhance formation of superoxide anion (O2-). It has never been studied if this occurs also in human hypertension.
Methods: Forty-four hypertensive patients were randomly allocated to a treatment with ibesartan, an inhibitor of AT1 receptors, and life-style modification only. In each patients platelet platelet O2- production by chemiluminescience of lucigenin was studied before and after 4 weeks of treatment. Fourty healthy subjects matched for sex and age were also studied as control. To further analyse O2- production we performed an in vitro study using dihydroetidium as probe in a cytofluorimetric assay. The role of calcium in inducing angiotensin II mediated O2- production was analysed. Platelet suspension was added with dihydrothidium (160 μmol/L) and 50 μH calcium, incubated with or without irbesartan (1-3-10 nM 30 min 37C°), and stimulated with angiotensin II (2 μM).Calcium influx measurement was performed using the fluorescent indicator dye Fura-2 and the calcium surrogare Mn2+.
Results: Compared to healthy subjects, hypertensive patients had higher platelet production of O2- (2,68±0,57 vs 0,85±0,22) ($p<0.001$); there was not correlation between blood pressure and platelet O2- production. After treatment no changes of platelet O2- formation was observed in patients allocated to life-style modification; conversely in patients treated with ibesartan was demonstrated a significant decrease of platelet O2- production (2,69±0,63 vs 1,73±0,41) ($p<0,002$), that, however, was not correlated with blood pressure lowering. Platelet O2- production upon stimulation with angiotensin II (2 μM) in presence of calcium (50 μM) was 7.0+0.6. Irbesartan (1-3-10 nM) inhibited in a dose dependent manner the angiotensin II mediated O2- production (22%, 53% and 72% respectively, $p<0.005$). Angiotensin II (2 μM) induced calcium influx (80%). Irbesartan (1-3-10 nM) inhibited of 48%, 70% and 85% respectively the angiotensin II induced O2- production ($p<0.001$).
Conclusion: Patients with hypertension has enhanced formation of O2-, that is mediated by AT1 receptor upregulation.In vitro study demonstrated that AGII facilitates the influx of calcium into platelets and underscored the role of AT1 in eliciting such effect.This finding provides new insight to understanding the proatherogenetic activity of ACE system in humans.

LEFT VENTRICULAR REMODELLING AFTER MYOCARDIAL INFARCTION

3265 Prolonged activation of P38 MAPK following acute myocardial infarction; significance for myocardial remodelling

M.G. Berova[1], T.M. Behr[1], S.S. Nerurkar[2], C. Maniscalco[2], R.N. Willette[2], C.E. Angermann[1]. [1]*Med. Poliklinik, Cardiology, Wuerzburg, Germany;* [2]*GlaxoSmithKline, Cardiovascular Department, Philadelphia, United States of America*

Background: P38 MAPK is an important mediator for the signal transduction of major neurohumoral, inflammatory and mechanical stimuli relevant for the remodelling process following acute myocardial infarction (AMI). In vitro experiments have shown an activation of p38 mitogen activated protein kinase (MAPK) in states of acute ischemia and a role of this kinase in cardiomyocyte hypertrophy. So far, extent and time course of p38 MAPK activation have not been investigated in an in vivo model of myocardial infarction.
Methods: Left coronary artery ligation was performed in adult male Lewis rats. Sham operated animals served as controls. The AMI size was assessed in vivo by echocardiography and by visual inspection at organ harvesting. P38 MAPK activity in the left ventricular myocardium was detected by a non-radioactive MAP Kinase Assay and by Western Blot at 15 minutes, 1, 4 and 24 hours, 1, 3 and 6 weeks following AMI. Left ventricular expression of atrial natriuretic peptide (ANP) was measured by an ELISA technique, as ANP-expression is considered an established parameter of myocardial remodeling. At each time interval post AMI a minimum of 10 animals was sacrificed (4 sham-operated, 6 AMI).
Results: Compared with the sham operated hearts, P38 MAPK activation was found increased in AMI hearts at all time intervals. Two peaks of p38 MAPK activation were detected at 4 hours and at 1 week following AMI. At all time intervals post AMI higher p38 MAPK activity values were found in medium sized and large AMIs than in small ones. Expression of ANP was not detected in sham-operated, but in AMI hearts and was more pronounced in medium sized and large AMIs. However, the extent of p38 MAPK activation and the LV-expression of ANP did not closely correlate.
Conclusion: Investigating the first 6 weeks post AMI this study to our knowledge shows for the first time a long-term activation of p38 MAPK in vivo. The relationship between p38 MAPK activation and ANP expression with infarct size suggests a potential role of p38 MAPK in the remodeling following AMI.

3266 Up-regulation of CTGF following myocardial infarction in the rat and correlation with a1 (I) procollagen and TGFβ1 gene expression

A. Tzanidis, Y. Jun, S. Lim, H. Krum. *Monash University Medical School, Medicine, Prahran, Australia*

Background: One of the major mechanisms associated with adverse cardiac remodeling post-myocardial infarction (MI) is the pathological deposition of extracellular matrix material (fibrosis). Neurohormonal (NH) peptides e.g. angiotensin II (AngII) and endothelin (ET-1) have been implicated in this process, at least in part via down-stream activation of the profibrogenic peptide, transforming growth factor beta 1 (TGFb1). Connective tissue growth factor (CTGF) may be the final common mediator of fibrosis and in vitro data suggests that TGFb1 is a potent stimulus of CTGF. However, it remains uncertain whether similar interactions play a role in fibrotic processes in vivo. Therefore, the purpose of this study was to determine whether CTGF expression post-MI (i) is associated with parallel changes to collagen expression and (ii) whether this may be mediated via upstream TGFb1 expression.
Methods: Female Sprague Dawley rats underwent permanent ligation of the LAD to induce MI. Following confirmation of moderate-sized infarcts by ECG 24 hours post-MI, animals were randomised to 1-week treatment with either an AngII receptor antagonist (valsartan; ATRA, n=8), an ET-1 receptor antagonist (bosentan; ETRA, n=7) or combined treatment (AT/ETRA, n=8). Control animals received vehicle (n=8). Sham animals (n=8) underwent operation without ligation. Whole heart was harvested for total RNA extraction and Northern blot analysis of CTGF, TGFb1 and a1(I) procollagen mRNA transcripts.
Results: CTGF gene expression was increased by 137±28% in untreated MI animals compared to sham controls. Similarly, MI resulted in a 167±22% increase in TGFb1 ($P<0.01$) and a 862±22% increase in alpha (a)1(I) procollagen mRNA transcripts ($P<0.001$) compared to sham. NH blockade with ATRA, ETRA or AT/ETRA attenuated the increase in CTGF gene expression by 21±4%, 18±1% and 14±2% compared to vehicle post-MI. Importantly, there was a strong positive correlation observed between CTGF and a1(I) procollagen gene expression ($r=0.84$; $P<0.001$) amongst MI animals across all treatment groups. Furthermore, CTGF message correlated with TGFb1 mRNA transcripts ($r=0.76$; $P<0.001$). Conclusions: These data demonstrate a strong association between CTGF and (i) a1(I) procollagen message, supporting an important role for CTGF in mediating pathological fibrosis post-MI, and (ii) TGFb1 gene expression, suggesting that CTGF is regulated, at least in part, by endogenous activation of TGFb1 within the injured myocardium.

3267 Plasma BNP versus clinical, echo and angiographic variables for predicting early left ventricular remodelling and death after reperfused acute myocardial infarction and left ventricular dysfunction

G. Cerisano[1], L. Bolognese[1], P.D. Pucci[1], A. Migliorini[1], R. Valenti[1], M. Tommasi[2], S. Raspanti[2], D. Antoniucci[1]. [1]*Careggi Hospital, Division of Cardiology, Florence, Italy;* [2]*Dep. Clinical Physiopathology, Nuclear Medicine Unit, Florence, Italy*

Background: Plasma brain natriuretic peptide (BNP) is an independent predictor of long-term LV remodeling and survival in thrombolized AMI patients (pts). However, information on prognostic role of BNP as compared to well established clinical, echo and angiographic prognostic predictors in pts with reperfused AMI and LV dysfunction are still missing. OBJECTIVE: To assess whether BNP measured at 1 and 3 days can independently predict 30-day LV remodeling and cardiac death after a first AMI and LV dysfunction successfully treated with primary PTCA. METHODS: In 31 pts with first AMI and LV dysfunction (ejection fraction =EF <40%), venous blood samples for analysis of BNP were obtained on day 1 (about 16 hours after admission), and on day 3 after AMI. All pts underwent 2-D echo examination within 24 hours of admission and at 3 day to assess both systolic and diastolic LV function. Repeat 2-D echo examination, and coronary angiography were obtained at 30 days after the index infarction. An increase in end-diastolic volume index (EDVI) > 20% from baseline to 1-month was defined LV remodeling. RESULTS: Pts were divided in 2 groups according to the 75th percentile concentration of BNP (251 pg/ml), (Group 1: high BNP, n=11; Group 2: low BNP; n=20). Pts of Group 1 had significantly greater baseline end-diastolic and end-systolic volumes (72 ± 17 ml vs 56 ± 12 ml, p = 0.005 and 50 ± 9 ml vs 32 ± 9 ml, p < 0.0001, respectively), and lower LVEF (30 ± 7% vs 42 ± 6%; p < 0.0001) and Doppler-derived mitral deceleration time (DT: 147 ± 42 msec. vs 183 ± 42 msec; p = 0.03) than pts of Group 2. No other significant differences between the two groups were found regarding demographic, clinical and echo variables. Patency and restenosis rate at 1 month were similar in the two groups. At 1 month, 4 pts (13%) died, and LV remodeling occurred in 9 (33%) of 29 survived pts. All four deaths occurred in Group 1; the prevalence of LV remodeling (75% vs 25%; p = 0.03) was significantly greater in Group 1 than in Group 2. However, only BNP measured at day 3 was significantly related to 1-month LV remodeling and survival. Moreover, by logistic regression analysis of clinical, non-invasive and angiographic variables, only DT, but not BNP, was an independent predictor of LV remodeling and survival (p = 0.04). CONCLUSION: In pts with reperfused AMI and LV dysfunction plasma BNP at day 3, but not at day 1, is related to 30-day LV remodeling and survival. However, BNP does not provide any incremental prognostic information when compared to other simple echo prognostic indicators, such as Doppler DT.

3268 Correlation of plasma MMP-2 and MMP-9 with N-BNP and with left ventricular function and volumes after acute myocardial infarction

I.B. Squire[1], M. Thompson[2], I. Loftus[2], L.L. Ng[1], J. Evans[2]. [1]*University of Leicester, Medicine & Therapeutics, Leicester, United Kingdom;* [2]*Leicester Royal Infirmary, Vascular Surgery, Leicester, United Kingdom*

Following acute MI (AMI), plasma levels of N terminal pro BNP (NT) relate inversely to LV function and prognosis. Matrix metalloproteinases (MMP) may play a role in LV remodelling after MI and heart failure (HF). We investigated profiles of plasma MMP2 and MMP9 after MI and relationship with plasma NBNP and echo-cardiographic measures of LV dysfunction. Plasma NT and MMP levels were measured on each day 1-5 in 60 patients (45 male,mean age 64, range 36-87) after acute MI (39 anterior, 21 inferior). Echo studies for assessment of LV end systolic (ESV), end diastolic (EDV) volume and wall motion index (WMI) were performed during admission (ESV1,EDV1,WMI1) and at 6 weeks (ESV2,EDV2,WMI2; n=52). WMI1 (median=1.2) and WMI2 (1.5) correlated (p<0.0005). NT was elevated (Anterior median 1384 fmol/ml; Inferior 554 fmol/ml) and correlated with WMI1 (day 3 NT; r= -0.57,p<0.0005) and WMI2 (day 3 r=-0.37,p=0.04). MMP2 increased from day 1 (median 417,range 257-1800 ng/ml)- day 5 (501,310-2130) and on days 1-3 was higher in inferior compared to anterior MI (p<0.05). Plasma MMP9 showed a biphasic response, most prominent in anterior MI, with nadir on day 2 (median 4.55, range 0-111 ng/ml)and peak on day 4 (8.5, 0-641)(p=0.06).

Plasma NT correlated strongly with MMP9 after anterior (day4 MMP9 r=0.6, p=0.001; peak MMP9 r=0.57, p<0.001) but not inferior MI. There was borderline correlation of NT with MMP2 on days 3 (r=0.3, p=0.08) and 4 (r=0.37, p=0.054) after anterior MI.

For anterior MI, MMP9 correlated with EDV1 (r=0.72, p=0.004), ESV1(r=0.71, p= 0.005),and ESV2 (r=0.47,p=0.05).MMP2 correlated negatively with EDV1 (r = -0.64), ESV1 (r = -0.57), EDV2 (r = -0.56), ESV2 (r = -0.55)(All p<0.05). MMP9 but not MMP2 correlated with WMI1 (r=-0.70, p<0.0005). For inferior MI, there was borderline correlation of MMP2 and WMI1 and WMI2 (r=-0.4, p=0.07). Peak CK did not correlate with NT, MMP2 or MMP9.

Conclusion: After AMI,particularly anterior,there is a strong correlation between plasma MMP9 and NT. MMP9 correlates positively with LV volumes during, and 6 weeks after, admission. In contrast MMP2 correlates strongly but negatively with these parameters. Plasma MMP9 also correlates with LV function as assessed by WMI.This is the first evidence of differential relationship of plasma levels of individual MMPs with LV function and remodelling after AMI. Differential responses of MMPs may play a role in remodelling after AMI. Selective inhibition of MMPs may represent a therapeutic target in patients at risk of ventricular remodelling after AMI.

3269 Activated TGF-β1-TAK1-p38MAPK pathway in spared myocardium and its relation to ventricular remodelling after myocardial infarction in rats

Y. Takimoto, T. Aoyama, Y. Yui. *Kyoto University Hospital, Cardiovascular Medcine, Kyoto, Japan*

Background: It has been reported that TGF-beta1 alters myocardial gene expression resulting in myocyte hypertrophy. Two signaling pathways, Smad and TGF-beata1-activated kinase (TAK) 1, have been known in the signal transduction of TGF-beta1. However, its signal pathway in cardiomyocytes remains unknown.

Methods: We examined the changes of the TGF-beta1 signaling pathway in non-infarcted tissue by Western blotting and their relation to ventricular remodeling (n=6 for each group) after myocardial infarction (MI) in rats.

Results: The protein level of TGF-beta1 increased by 1.38±0.01-, 2.59±0.10-, 2.34±0.06-, 1.57±0.03-fold (p<0.01) compared with sham-operated rats(SR) 1, 3, 7 and 14 days after MI, and the TGF-beta1 receptor (TbetaR) II protein level increased 1.50±0.05-, 1.83±0.02-, 1.60±0.06- and 1.51±0.03-fold (p<0.01 compared with SR), respectively. The expression level of TbetaRI was significantly increased 3 and 7 days after MI (1.60±0.08- and 1.35±0.03-fold, p<0.01), respectively. The protein level of TAK1 was significantly (p<0.01) increased by 1.66±0.14-, 1.97±0.16- and 1.57±0.07-fold compared to that from SR at 1, 3, and 7 days post-infarct. There was no difference in the protein levels of MKK6 and p38MAPK among each group. However, phosphorylated MKK6 was increased by 2.20±0.19-, 2.55±0.47- and 3.29±0.32-fold (p<0.01), and phosphorylated p38MAPK was also increased by 1.90±0.03-, 2.03±0.06- and 2.35±0.06-fold (p<0.01) compared with SR 1, 3 and 7 days after MI. Immunoreactive staining of TGF-beta1, TbetaRI and TbetaRII was observed in cardiomyocytes, vascular smooth muscle cells and fibroblasts. In contrast, immunoreactivity of TAK1 was mainly localized to cardiomyocytes. mRNA levels of ANP and beta-MHC determined by competitive RT-PCR were significantly increased in ventricles after MI compared with SR (p<0.01 at each time point). Left ventricular diastolic and systolic dimensions determined by echocardiography were rapidly increased in the acute phase of MI, and additional changes were observed by 2 weeks (p<0.01 at each time point compared with SR). Posterior wall thickness was increased; however, relative wall thickness was decreased in the rats with MI.

Conclusion: The activated TGF-beta1-TAK1-MKK6-p38MAPK pathway paralleled the increased expression of ANP and beta-MHC during acute MI. Thus, this pathway in cardiomyocytes may play an important role in the ventricular hypertrophy of non-infarcted regions and in the ventricular remodeling after MI in rats.

3270 Impact of microvascular obstruction on left ventricular remodelling and long-term clinical outcome after reperfused acute myocardial infarction

L. Bolognese, N. Carrabba, G. Parodi, G.M. Santoro, P. Buonamici, G. Cerisano, D. Antoniucci. *Careggi Hospital, Division of Cardiology, Florence, Italy*

Background: The relation between microvascular obstruction (MO), left ventricular (LV) remodeling and long-term clinical outcome after AMI has still to be elucidated. We hypothesized that a preserved microvascular integrity in the area at risk (AAR) would favourably influence LV remodeling and prognosis.
Methods: One-hundred unselected patients (pts) with AMI successfully treated with primary PTCA underwent intracoronary myocardial contrast echocardiography (MCE) before and shortly after PTCA. Baseline (3±1 days), 1 and 6-month complete 2D-echo were obtained in 85 pts. Infarct zone wall motion score index (IZWMSI, from 1=normal to 4=dyskinetic), end-diastolic (EDV) and end-systolic (ESV) LV volumes, and ejection fraction (EF) were calculated. Repeat coronary angiography was obtained 6 months after AMI in 94 pts. Myocardial perfusion in the AAR was graded semiquantitatively as 0 (no visible contrast effect), 1 (patchy myocardial contrast enhancement), and 2 (homogeneous contrast effect). In each pts a MCE score index (MCESI) of AAR was derived by averaging the single segment score within the AAR. A pts was considered to have adequate reperfusion if MCESI was ≥1. Long term (3.4±1.9 years) clinical follow-up were collected for all pts.
Results: After PTCA 82 pts showed adequate myocardial reperfusion in the AAR (R), while 18 did not (NR). Baseline clinical and angiographic characteristics were similar between the 2 groups. However, NR pts had a higher peak creatine kinase (4126±2781 vs 2759±1771 U/L; p=.001), baseline IZWMSI (2.61±0.31 vs 2.24±0.43; p=.001), and a lower baseline EF (32±9 vs 40±7%; p=.001). At 6 month patency and restenosis rate were similar between the 2 groups. From day 3 on LV volumes progressively increased in the NR pts (n=13) and were larger than those of R pts (n=72) at 6 months (LV EDV: 171±61 vs 115±30 mL; LV ESV: 115±61 vs 59±26 mL; ANOVA p<.0001 for both). By stepwise multiple regression analysis MO was the most important independent predictor of late LV dilation (p=.0001) even adjusted for enzymatic infarct size. By Cox multivariate analysis MO represents the only strong predictor of cardiac death (p=.004) and combined events (cardiac death, nonfatal reinfarction, and hospitalization for heart failure; p=.01). Pts with microvascular integrity showed significantly better survival in terms of cardiac death (p=.0001, by log-rank) and combined events (p=.003, by log-rank).
Conclusions: In successfully reperfused AMI, MO within the risk area is an important predictor of both postinfarction LV remodeling and unfavorable long-term clinical outcome.

TRENDS IN CARDIOVASCULAR DISEASE IN EUROPE

3271 Are social gradients in cardiovascular risk factors widening or narrowing: ten-year trends in the Glasgow MONICA project?

J. Connaghan, H. Tunstall-Pedoe, C. Morrison. *Ninewells Hospital and Medical School, Cardiovascular Epidemiology Unit, Dundee, United Kingdom*

Introduction The MONICA inner-city population of Glasgow has high coronary event rates and high levels of social deprivation. Sociologists warn of polarization and alienation of deprived groups and the threat this poses to narrowing the social gradients in disease. We examined our survey data to see whether the risk factors that we measured showed evidence that social gradients widened or narrowed in the decade 1986-95.
Methods We examined data from surveys in 1986, 1989, 1992 and 1995, calculating age- standadized mean risk factor levels for men and women aged 25-64. A deprivation score was based on the postcode sector of residence of each person. We examined overall means and those in the least and most deprived quarters of each sex.
Results There were 2 859 men and 3 085 women aged 25-64. Response rates ranged from 60-65%. There were more social gradients in women than men overall. The following comments refer mainly to change in these gradients.
Cigarette smoking: no change in existing social gradients over time in either sex.
Systolic blood pressure: no gradient, no trend in men, gradient no trend in women.
Diastolic blood pressure: no change in women, paradoxical significant change in men from positive gradient (higher in more deprived group) to the reverse.
Total cholesterol: no gradient in men, no trend, no time trend in gradient in women.
HDL-cholesterol: no gradient in men, no change, gradient in women, no change.
Body mass index: no change in gradient in women, paradoxical significant trend in men from positive to negative gradient.
Consumption of fruit and green vegetables no change in gradient in either sex, but increasing gradient for skimmed milk in women.
The Dundee Coronary Risk Score: no change in existing strong gradient in either sex.
Conclusions Over ten years there was no consistent trend of widening social gradients in either sex. In men two related risk factors (diastolic blood pressure and obesity) showed significant reversal from positive to negative social gradient. For these factors there was no difference if all the survey results were averaged, but over ten years the the least and most deprived had changed places. Women, who showed many static social gradients, had a widening gradient for one dietary factor over the ten years of study. We therefore found no overall evidence of widening or narrowing of existing social gradients for risk factors, although there was an overall tendency to slow improvement.

3272 Age at hospital admission suggests delay in coronary heart disease presentation not prevention: trends over 20 years in 23,422 individual patients

C.J. Ellis, G.D. Gamble. *University Department of Medicine, Auckland Hospital, Auckland, New Zealand*

Background: There is increasing evidence that the decrease in age-adjusted coronary heart disease mortality is an artifact of age adjustment and does not represent a true reduction in the incidence of disease, rather a delay in the age of presentation.
Methods: This study examined the age at presentation in all patients with coronary heart disease: discharge diagnosis (ICD-9CM 410-414), during the years 1980 to 2000 who had been admitted to Auckland and Green Lane Hospitals (1200 bed tertiary referral centre). The unique patient identifier code was matched to a national mortality database and the vital status of each patient ascertained. The age/sex structure of the referring population was taken from national census figures. Years between the four yearly census cycle were estimated from linear interpolation.
Results: Between 1980 and 2000 there were 47, 875 discharges in 23,422 individuals. Using the first admission per patient (n=23,422), the average age at presentation in 1980 was 56 years (SD 12) rising to 72 years (SD 13) in 2000 at 0.65 years of age per year (P<0.0001 for linear trend). From 1980 to 1985 19% of all coronary heart disease admissions were in people aged 65 or greater compared with 28% in 1995 to 2000 (P< 0.0001). The proportion of women admitted increased in a linear manner from 31% in 1980 to 48% in 2000 (P<0.0001). Direct standardisation to the Auckland population produced age/sex adjusted admission rates of 0.4 per 1000 population in 1980 and 8.1 per 1000 population in 2000.
During the same time period, length of stay decreased at a rate of 0.25 days per year (P <0.0001 for linear trend) from a median 8 days (IQR 6-10) in 1980 to a median 4 days (IQR 2-8) in 2000.
Conclusion: The age at first presentation with coronary heart disease has increased by 13 years over 2 decades. In addition, more first coronary heart disease admissions are seen in the elderly than would be predicted by the aging New Zealand population, alone. These data suggest that coronary heart disease is delayed, not prevented.

3273 Atrial fibrillation and the ageing population: an emerging epidemic?

S. Stewart[1], J.J.V. McMurray[2]. [1]*The Queen Elizabeth Hospital, Cardiology Dept., Adelaide, Australia;* [2]*University of Glasgow, CRI in Heart Failure, Glasgow, United Kingdom*

Aims: Atrial fibrillation (AF) is the most common cardiac arrhythmia and an important cause of cardiovascular morbidity and mortality (particularly in relation to stroke and heart failure). This study examined the likely burden of AF in respect to its population prevalence among those aged 45 years or more, in addition to the number of hospital admissions associated with a principal diagnosis of AF in the UK for the period 2000-2020.
Methods: We applied contemporary UK-specific estimates of the population prevalence of AF and the rate of hospital admissions associated with a prinicpal diagnosis of AF (on an age and sex-specific basis), to projected changes in the UK population for the years 2000, 2005, 2010 and 2020. Using recent trends analyses, in addition to population changes alone, we also considered the likely (additional) impact of underlying increases in the prevalence of AF and related hospitalisations.
Results: We estimate that in the year 2000 there were approximately 290,000 men and 254,000 women aged 45 years or more being actively treated for AF in the UK: a combined total of 544,000 individuals representing just under 1% of the UK population overall. Based on population changes alone (i.e. stable prevalence rates) we estimate the number of men and women being treated for AF will have increased by 33% and 18%, respectively, by 2020. If combined with a modest 5% rate increase in the prevalence of AF every 5 years across all age groups (due to a greater burden of contributory cardiovascular disease states), these figures will increase by 54% and 33%, respectively, with about 1.3% of the UK population affected by 2020. In both models, the greatest increases are predicted to occur in the period 2010-2020 because of the ageing "Baby Boomer" population cohort. We also estimate that there were 37,500 male and 38,300 female admissions for AF (principal diagnosis) in the UK during the year 2000. Based on population changes alone, these admissions are predicted to rise by 31% and 16%, respectively, by 2020. If, however, current trends in the rate of increase of such admissions are maintained, these figures are predicted to rise by 395% and 325%, respectively. Once again, the greatest increases are likely to occur between 2010 and 2020.
Conclusions: In this unique study, we have shown that AF already represents a major health problem within the UK population. Furthermore, without substantial changes in relation to its prevention and treatment, the burden of AF (particularly as a precursor of stroke and heart failure)is likely to rise substantially in the next 20 years.

3274 Cardiovascular risk factors and therapeutic management of patients with stable coronary artery disease: a nationwide French survey

P. Gueret[1], N. Genes[2], G. Charpentier[3], L. Vaur[2], J.P Cambou[4], J. Amar[5] on behalf of the Investigators of the ESPOIR Coronaire Survey. [1]*Hôpital Henri Mondor, Cardiology, Creteil, France;* [2]*Laboratoire Aventis, Medical Department, Paris Cedex 12, France;* [3]*CH Sud Francilien, Internal Medicine, Corbeil, France;* [4]*INSERM U 518, Toulouse, France;* [5]*Hôpital Purpan, Internal Medicine and Hypertension, Toulouse, France*

Aims: To assess prevalence and control of cardiovascular risk factors as well as therapeutic management of French patients (pts) with stable coronary artery disease (CAD)in 2001.
Methods: The 6 first consecutive pts with CAD presenting to a cardiologist were included if they met the following criteria: prior acute myocardial infarction (AMI), prior PTCA or CABG or documented stable angina.The following data were collected: demographics, cardiovascular history, risk factors, blood pressure (BP), last record of LDL-cholesterol and cardiovascular therapeutics.
Results: 6349 pts (81% men) aged 67±10 years were included by 795 french cardiologists. Previous risk factors were: hypertension (50%), hypercholesterolemia (75%), current smoking within 3-months period(9%) and diabetes (16%). Previous AMI was observed in 51% of pts and previous angina in 59% of pts.The 140/90 mmHg BP goal was obtained in 56% of pts (41% in pts with treated hypertension vs 70% in pts not receiving antihypertensive drugs for hypertension). BP control in pts with diabetes was only 44%. The LDL-c goal less than 3.4mmol/l was obtained in 58% of pts (60% in pts treated by lipid lowering agents vs 53% in not treated pts).Aspirin or other antiplatelet agents were used by 84%, statins by 65%, beta-blockers by 64% and Ace-Inhibitors by 33% of pts respectively. In pts with prior AMI the use of beta-blockers rose to 68% and the use of ACE-inhibitors to 41%. In pts with diabetes the use of beta-blockers fell to 60% and the use of ACE-inhibitors rose to 47%.
Conclusion: ESPOIR was a nationwide study representative of french pts with stable CAD. Prevalence of modifiable risk factors remains high and blood pressure as well as cholesterol goal were not satisfactorily achieved. A slow incorporation of secondary prevention strategies was observed mainly regarding the use of ACE-inhibitors.

3275 The associations between climatological variations and cardiovascular mortality, in greater Athens area, during 15 years period (1987–2001)

D.B Panagiotakos[1], A.G. Paliatsos[2], P.T. Nastos[3], C. Chrysohoou[1], C. Pitsavos[1], C. Stefanadis[4], V.P. Tritakis[5], P.K. Toutouzas[4]. [1]*University of Athens, School of Medici, Cardiology Clinic, Athens, Greece;* [2]*Technological Educational Institute of, Department of Mathematics, Piraeus, Greece;* [3]*University of Athens, Department of Bioclimatology, Athens, Greece;* [4]*Veterans Affair Hospital, Cardiology Division, Washington, United States of America;* [5]*Academy of Athens, Research Institute of Astronomy, Athens, Greece*

Background: The fact that environmental conditions are associated with the pathogenesis of physical disease was known as early as the time of Hippocrates. The aim of this study is to evaluate the association between climatological variations, with cardiovascular mortality, on the greater Athens area inhabitants.
Methods: We studied mean monthly values of air temperature and relative humidity (data from the National Observatory of Athens) as well as the cardiovascular mortality (local registers), during 1987-2001. In order to evaluate the association between cardiovascular mortality and the climatological variations we applied a special, empirically determined temperature-humidity index (T.H.I.), suggested by E. C. Thom (T.H.I. = Ta - 0.55*(1 - 0.01 RH)*(Ta - 14.5), Ta = mean monthly dry-bulb air temperature in oC, RH = mean monthly relative humidity in %). Statistical analysis was based on Poisson regression models, after taking into account the effect of age group, seasonality, air pollution, and the number of holidays and strikes (confounders).
Results: An age-adjusted positive trend in CHD mortality was observed during the investigated period (+26% in all ages, $p < 0.001$ and +32% in >75 years old group, $p < 0.001$). Additionally, CHD mortality was positively related with relative humidity ($p<0.001$) and inversely associated ($p < 0.01$) with mean air temperature, during the studied period. Moreover, a consistent association between T.H.I. and CHD deaths was found (b=-0.72, $p < 0.001$), with more significant results in the elderly ($p < 0.0001$). In particular, a 10-unit decrease in the T.H.I. scale raises by 20% the monthly cardiovascular mortality ($p < 0.001$), while T.H.I. < 24 increase by 53% the risk (odds ratio = 1.53, $p < 0.05$) of observing the daily number of cardiovascular deaths in the upper quartile (i.e. > 42 deaths/day) compared to the lower quartile (i.e. < 29 deaths/day).
Conclusions: Our findings suggest that a strong association between climatological variations and CHD mortality seems to exist. The suggested cut-off point of 24 in the T.H.I. scale could be a useful tool in public health practice, in order to reduce mortality rates, especially in countries with extreme environmental phenomena. The previous findings are in accordance to the reports from other studies, especially, in the US, but it is hard to claim that they support evidence for causality. Thus, further research is needed in order to investigate the mechanisms by which environmental conditions affect CHD mortality.

3276 Plasma lipids and sex hormones among 366 men from France and Northern Ireland

V. Bataille[1], B. Perret[2], P. Ducimetière[3], A. Evans[4], P. Amouyel[5], D. Arveiler[6], J. Ferrières[1]. [1]INSERM U558, Department of Epidemiology, Toulouse, France; [2]La Grave Hospital, Laboratory of Biochemistry, Toulouse, France; [3]INSERM U258, Paul Brousse Hospital, Paris, France; [4]The Queen's University of Belfast, Dpt of Epidemiology and Public Health, Belfast, United Kingdom; [5]INSERM U508, Lille, France; [6]Faculty of Medicine, Department of Epidemiology, Strasbourg, France

Background The prevalence of coronary heart disease (CHD) is much higher in men than in women, even after adjustment on known independent cardiovascular risk factors. An explanation of these sex differences could be that sex hormones may play a role in the pathogenesis of CHD, probably through their associations with plasma lipids. The aim of this cross-sectional study was to assess the relationship between sex hormones and plasma lipids in a population-based sample.

Methods Subjects were 366 men, 50 - 59 years old, selected in France (Lille, Strasbourg and Toulouse) and Northern-Ireland (Belfast) and examined between 1991 and 1993. Socio-economic, tobacco consumption and physical activity data were obtained by questionnaire. Medical examination included blood pressure (BP) and anthropometric measurements. A blood sample was obtained for the measurement of biological parameters (triglycerides (TG), high-density-lipoprotein cholesterol (HDL-C), total testosterone (TT), estradiol (E2) and sex-hormone-binding-globulin (SHBG)). Low-density-lipoprotein cholesterol (LDL-C) was calculated using Planella's formula. Pearson correlation coefficients and student's t tests were used to identify factors associated with plasma lipids. Multiple linear regression models were used for multivariate analyses, using TG (log-transformed) and HDL-C as dependent variables. The effect of sex hormones on plasma lipids was estimated after adjustment for age, body mass index (BMI), systolic BP, smoking, alcohol intake and physical activity.

Results SHBG and TT were negatively correlated with TG ($p<0.0001$ and $p<0.04$, respectively) and positively correlated with HDL-C ($p<0.0001$ and $p<0.01$). E2 was positively correlated with TG ($p<0.03$). No significant association was found between sex-hormones and LDL-C. In multiple linear regression analyses, after multiple adjustment, SHBG and E2 remained significantly ($p<0.01$ and $p<0.05$, respectively) and independently associated with TG. SHBG remained also strongly associated with HDL-C ($p<0.0001$). The model including SHBG, E2 and adjustment variables explained 14.1% of TG variability, and SHBG and E2 accounted respectively for 16.4% and 7.0% of the model variation. The model including SHBG and adjustment variables explained 26.1% of HDL-C variability, and SHBG accounted for 29.0% of the model variation.

Conclusions After adjustment for confounders, SHBG was positively associated with HDL-C and negatively associated with TG, suggesting that SHBG may play an important role in the relationship between sex hormones and plasma lipids.

THE ROLE OF ASSIST DEVICES IN HEART FAILURE

3277 Early and mid-term results of the Harefield left ventricular assist device combination therapy for reversal of end stage heart failure

P. Tansley, E. Birks, M. Hipkin, C. Bowles, N. Banner, A. Khaghani, M. Yacoub. *London, United Kingdom*

We have previously described a strategy for reversal of end stage heart failure through induction of reverse remodelling using LVADs combined with pharmacological therapy, followed by induction of physiologic hypertrophy using the B2 agonist Clenbuterol. We present here the early and mid term results. From December 1999 to December 2001, 19 patients with idiopathic dilated cardiomyopathy (DCM) in end stage heart failure with deteriorating clinical status and evidence of secondary organ dysfunction were treated using this therapy. There were 15 males and 4 females aged 15 to 56 years. Diagnosis had been made a mean of 44 months before. None had histological evidence of myocarditis. Eighteen received HeartMate 1 and 1 received HeartMate II. There were 3 (15.8%) deaths in the peri-operative period and 1 late death due to infection. Patients underwent sequential echocardiographic, exercise capacity and oxygen consumption assessment with the pump switched off under full heparinisation at fortnightly intervals following the first month, and invasive haemodynamic investigation at 3 months. Duration of LVAD support ranged from 63 - 503 days, mean 276. During this period 11 (73.3%) of the survivors exhibited significant improvement as defined by a series of strict criteria. Of these 11, one was transplanted because of persistent native valve regurgitation, 1 is awaiting explantation and 9 (60% of survivors) have been successfully explanted. During a period of post explantation follow up ranging from 144 to 496 days, one patient developed lung carcinoma and is being treated by chemotherapy and radiotherapy. The remaining patients are completely asymptomatic and all have returned to their previous occupation. The mVO2 was a mean of 26mls/kg/min and ejection fraction was a mean of 69% at latest follow up. Invasive investigation performed at 6 monthly intervals showed a mean PA pressure of 15mmHg, PCWP of 9mmHg and cardiac output of 4.9 l/min at latest investigation. It is concluded that the combination therapy for reverse remodelling followed by induction of physiological hypertrophy gives encouraging early and mid-term results which may warrant extension of this form of therapy to less critically ill patients in a randomised trial.

3278 Six hundred patients supported by ventricular assist devices in Berlin

E. V. Potapov, M. Pasic, E. Hennig, M. Jurmann, T. Drews, Y. Weng, R. Hetzer. *Deutsches Herzzentrum Berlin, Cardiothoracic and Vascular Surgery, Berlin, Germany*

Background Since 1987 we have used seven different types of ventricular assist devices in more than 600 patients. The aim of this study is to present our experience.

Patients and Methods: Between April 1987 and January 2002, 620 ventricular assist devices were implanted in 604 patients [male, 498 (82%); female 106 (18%)]. The mean age was 48 years with a range of 3 days to 77 years [adults, n = 554 (92%), pediatric, n = 50 (8%)]. The indications for the use of a ventricular assist device were: a) profound cardiogenic shock [cardiomyopathy (ischemic = 37; dilative = 166; others 35 cases), or acute myocardial infarction (n = 41)], b) severe end-stage heart failure without cardiogenic shock [n = 160 (26%)] and c) inability to wean a patient from cardiopulmonary bypass (postcardiotomy heart failure) [n = 84 (14%)]. The intention was to support the patients as a bridge to heart transplantation, bridge to recovery or permanent support.

Results In 337 cases (55%) the ventricular assist device implanted was a biventricular, in 264 (43%) a left ventricular and in 19 (2%) a right ventricular support system. The pulsatile extracorporeal device Berlin Heart was implanted in 429 patients (69%) and an implantable left ventricular device of type Novacor in 113, HeartMate in 21, and LionHeart or Micromed DeBakey in 19 patients. The early mortality was significantly higher ($p<0.05$) in patients with preoperative profound cardiogenic shock (55%) and in the postcardiotomy group (74%) in comparison to patients with preoperative end-stage heart failure without shock (28%). One hundred and seventy-two patients (29%) were bridged to heart transplantation; there was no significant difference in long-term survival after heart transplantation in patients with and without previous ventricular assist device implantation. Removal of the device was performed in 43 (7%) patients after recovery of myocardial function. Thirty-three patients are currently on a device, 50% of them supported permanently.

Conclusion Implantation of a ventricular assist device may lead to recovery of the patients from secondary organ failure. When implanted in the situation without profound shock, the results are significantly better. Therefore, the patients with severe end-stage heart failure should be considered for possible implantation of a assist device before profound cardiogenic shock occurs.

3279 Long-term results with left ventricular assist devices as bridge to heart transplantation: the Niguarda experience

M. Lanfranconi[1], G. Bruschi[1], E. Ribera[1], C. Russo[1], T. Colombo[1], F. Oliva[2], M. Frigerio[2], E. Vitali[1]. [1]Niguarda Ca' Granda Hospital, Cardiac Surgery, Milan, Italy; [2]Niguarda Ca' Granda Hospital, Heart Failure and Transplant Program, Milan, Italy

Background: Congestive heart failure is the leading cause of death in western countries. Heart transplantation currently is the only accepted therapy for patients with end-stage heart failure but the supply of donor hearts is inadequate, and different mechanical circulatory support have been utilised as bridge to heart transplant.
Patients and Methods: Since April 1992, 53 patients (47 man, 6 women, 43,1±12,5 years) with end-stage heart failure were assisted with an LVAD as bridge to heart transplant. The causes of heart failure were: dilated idiopathic cardiomyopathy in 39 (73.6%) pts, ischemic cardiomyopathy in 11 (20.7%), acute myocarditis in 3 (5.7%). The devices utilised were: Novacor LVAS in 31 (58,5%) patients, DeBakey VAD in 11 (20,7%), Thoratec in 7 (13.2%), Medos LVAD in 3 (5,6%), Abiomemd BVS 5000 in 1 (1,9%).
Results: All patients survived the operation. Mean duration of LVAD support was 2.8±5.6 months (range 1 day-38 months). Three patients were assisted for more than 1 year and 1 patient for more than 3 years; the cumulative time of support was 156 months. Thirty-seven patients (71.1%) underwent heart transplantation. Twelve major bleeding episodes requiring rethoracotomy occurred in 9 pts (16.9%). Major neurologic events (defined as neurologic deficit permanent or persistent for more than 24 hours) occurred in 6 patients (11,3%). Abdominal pocket infection (defined as the presence of local signs of infection with purulent secretion and positive bacterial cultures necessitating irrigation and drainage) occurred in 2 patient (3.77%). Septic complication (defined as the presence of body temperature above 38.5 °C, white blood cell > 12.000 gm/dL, positive blood cultures) occurred in 3 pts (5.6%).
Ten patients (19,9%) assisted with the Novacor Wearable LVAS device were discharged at home while waiting for HTx. The mean follow-up of 34 discharged transplanted patients was 45.3±37 months. Actuarial survival of transplanted patients while on LVAD was 91.0±4.9% and 83.4±8.5% at 1 and 5 year respectively. No differences in post-transplant long term survival, rejection and allograft vasculopathy occurred between patients transplanted with or without LVAD assistance.
Conclusions: LVAD therapy proved to be effective in bridging patients with end stage heart failure to HTx. While on LVAD support patients assisted with implantable wearable devices could be discharged at home ameliorating their quality of life. The excellent survival rate after HTx is concomitant with a low incidence of rejection and cardiac allograft vasculopathy.

3280 Initial and prolonged haemodynamic effects of intraaortic balloon support in ventricular septal defect complicating acute myocardial infarction

H. Thiele[1], B. Lauer[2], E. Boudriot[1], G. Schuler[1]. [1]University of Leipzig - Heart Center, Internal Medicine/Cardiology, Leipzig, Germany; [2]Zentralklinik Bad Berka, Internal Medicine/Cardiology, Bad Berka, Germany

Background: Immediate surgical repair of ventricular septal defect (VSD) complicating acute myocardial infarction is associated with high mortality. Preoperative use of an intraaortic balloon pump (IABP) is routinely recommended to achieve hemodynamic stabilization, which permits preoperative diagnostic examinations or even delayed surgical repair. However, there is no clear evidence of the hemodynamic effects of short-term and prolonged IABP support.
Methods: An IABP was implanted preoperatively from 12/1997 to 02/2002 in 20 consecutive patients with infarct-related VSD (11 men, 9 women, mean age 70±11, range 46-89). Effective cardiac output (l/min), left-to-right-shunt (l/min) and the shunt flow ratio were calculated by the method of Fick pre and post intraaortic balloon counterpulsation and at daily follow-up with pump "on" and "off".
Results: Effective cardiac output improved from 3.6±1.3 l/min to 4.2±1.3 l/min ($p<0.001$). Left-to-right-shunt was reduced from 7.3±3.5 l/min to 5.6±.3.3 l/min ($p<0.001$) and shunt flow ratio decreased from 3.1±0.9 to 2.5±0.7 ($p<0.001$) with IABP support. In patients undergoing delayed surgical repair (n=8) hemodynamic improvements were sustained over time (pump "on" vs. "off" $p<0.05$). Mortality in patients with early (day 1-2) operation was 71% and with delayed surgery (day 8-25) 22%, respectively.
Conclusions: In patients with infarct related VSD IABP support provides an immediate and sustained hemodynamic improvement resulting in an enhanced effective cardiac output and a reduced left-to-right-shunt and shunt flow ratio, which results in hemodynamic stabilization in at least some patients.

3281 Functional status of patients with chronic angina treated with Enhanced External Counterpulsation

E.D. Kennard[1], S.F. Kelsey[1], G. Linnemeier[2] on behalf of the IEPR investigators. [1]University of Pittsburgh, Department of Epidemiology, Pittsburgh, United States of America; [2]HeartGen Inc, Indianapolis, United States of America

Introduction: Enhanced External Counterpulsation(EECP) is a non-invasive therapy, similar to the intra-aortic balloon pump, used for treatment of chronic angina in patients who are no longer considered suitable candidates for surgical or percutaneous revascularization. This study examined a group of patients both pre and immediately post a course of EECP treatment, to determine changes in functional status and factors affecting functional status.
Methods: The International EECP Patient Registry collects data on consecutive patients treated with EECP to determine safety and document both short and long term outcome. The functional status of a subgroup of 485 patients was assessed using the Duke Activity Status Index(DASI).
Results: Patients had a mean age of 67 ± 11 years, were mostly male(73%), and had long standing coronary disease (mean 12 ± 8 years, multivessel disease in over 70%). The majority had previous revascularization (71% PCI, 69% CABG) and 78% were no longer considered candidates for further revascularization. Severe (CCSC Class III/IV) angina was reported by 86% of patients, and 69% reported nitroglycerin use. Comorbidities were frequent: diabetes (43%), peripheral vascular disease (24%), congestive heart failure (25%). The mean DASI score pre-EECP was 12.8 ± 11.0, a very poor functional status similar to that previously reported for end stage coronary artery disease patients. Baseline factors associated with a low score were female gender ($p<0.01$),hypertension ($p<0.001$), hyperlipidemia($p<0.01$), congestive heart failure($p<0.01$), diabetes($p<0.05$),severe angina($p<0.001$) and unsuitability for further PCI or CABG ($p<0.001$). By multivariate regression analysis significant, independent factors predicting a low functional status pre-EECP were female gender, chf, diabetes, hypertension, severe angina and unsuitability for CABG. After a mean treatment course of 34 hours, 72% of patients reported a one or more class reduction in angina, and 47% of patients using nitroglycerin had discontinued its use. Mean DASI score post-EECP was 18.0 ± 13.4. Post-EECP DASI scores were significantly associated both with the score pre-EECP ($p<0.001$) and a reduction in angina class ($p<.001$).
Conclusions: Patients presenting for EECP treatment for chronic angina have a poor functional status. Functional status is dependent on severity of angina and presence of comorbidity and risk factors. Treatment with EECP not only reduces angina symptoms, but produces a concomitant increase in functional capacity similar to that seen 1 year after bypass surgery.

3282 Cardiogenic shock – Can mechanical circulatory support systems act as life-savers?

A. El Banayosy[1], D. Cobaugh[2], L. Kizner[1], L. Arusoglu[1], R. Koerfer[1]. [1]Heart Center NRW, Thoracic and cardiovascular surgery, Hattingen, Germany; [2]Heart Center NRW, Thoracic and Cardiovascular Surgery, Bad Oeynhausen, Germany

Background: Despite many advances in drug therapy and medical technology cardiogenic shock (CS) is still associated with a high mortality rate (80-90%). To improve survival chances of patients suffering from cardiogenic shock, it is often necessary, despite critical conditions, to transport these patients to a highly specialized center where mechanical circulatory support systems (MCSS) are available. In 1991 our clinic established a special emergency transportation team to transfer the critically unstable patients from peripheral hospitals. Their mission was to stabilize their condition and transport them to our facility using the most effective methods.
Methods: In a retrospective study we examined the data of 43 patients to determine if the mortality rate was different when compared to conventionally treated patients.
Results: Between 1998 and July 2001, 43 patients (31 male, 12 female) with cardiogenic shock refractory to conventional therapy were referred to our team. All of them were on high doses of inotropic support agents and on respirators. They showed signs of multi-organ failure and some of them were already on IABP or ECMO. Etiology for the CS was as follows: acute myocardial infarction (34%), decompensated DCM (30%), myocarditis (18%) and the rest had miscellaneous causes including valvular disease, toxic heart failure, etc. (18%). Prior to transportation we initiated IABP in 20 patients and a centrifugal pump in 7 patients.
All together, 21 patients were released from the hospital. Of those, 19 are currently still alive. During hospitalization, 12 of these had a LVAD and 5 others a BiVAD. In total 8 patients received heart transplantations.
Conclusion: The survival rate of almost 50% in these critically ill patients, in our opinion, justifies the high expenses (time, energy, costs) of treating these patients who, for a large part, would otherwise die. It is felt that the use of MCSS plays a significant role in the reduction of mortality in this group of patients. Furthermore, this significant mortality difference would justify the establishment of other transportation teams with similar capabilities.

MANAGEMENT OF CONGENITAL HEART DISEASE IN GROWN-UPS

3283 The echocardiographic, neurohormonal and exercise capacity changes post transcatheter closure of atrial septal defects

E. Mackie, A. McKenzie, K. Shields, W.S. Hillis. *University of Glasgow, Medicine and Therapeutics, Glasgow, United Kingdom*

Introduction: Atrial septal defects(ASD) are the commonest congenital cardiac abnormality presenting in adult life. The transcatheter closure of these defects has become increasingly common over the past few years,however little is known about the follow-up of this group.Methods: 58 patients had successful closure of ASDs using the amplatzer device. A Full Bruce protocol exercise test with continual expired gas analysis was performed pre closure and at 82 ±63 days post closure. 18 patients performed the protocol at 10.02±6.14 months post closure. Predicted VO2 was calculated. Transthoracic echocardiography and transcranial Doppler with injection of agitated saline was performed at both time points. Venous blood was taken for measurement of Brain Natriuretic Peptide (BNP).Results: Paired t-tests were performed on the data.(Mean(SEM)).The mean age of the patients was 43.8± 14.9 years. Exercise time increased from 513s pre (36.9) to 564s(32.4) post (p=0.01) VO2 max. increased from 23.89 (1.18) pre to 25.36 (1.04) post (p=0.0001). Despite the improvement in VO2 max, it remained significantly less than predicted. (actual 25.36 (1.04), predicted 30.09 (1.39) p=0.001). This reduction in VO2 was still evident in the group at 10.02±6.14mths. (24.84(SEM1.77), predicted 31.52 (2.1) p=0.001). Right ventricular(RV) dimensions were reduced post closure (3.3cm(0.13), 2.82(0.08) p=0.0001) as was pulmonary artery pressure(PAP)(29.09mmHg (1.77), 20.32 (0.69) p=0.0001). Transcranial Doppler produced positive embolic signals in 25% of patients post closure compared to echocardiography in which 8% demonstrated a right to left shunt. Two contrasting patterns of BNP secretion were observed. In the group with a reduction in BNP (86.5(27.9) to 58.0(18.3) p=0.043), RV dimensions decreased (3.16(0.3),2.63 (0.1), p=0.031), PAP decreased (24(2.49),15.6 (0.4) p=0.014) and VO2 max increased (23.7(3.26), 25.6(2.93),p=0.046). This was in contrast to the group with an increase in BNP(9.2(3.2) to 40.0(13.6) p=0.05). In this group RV dimensions (2.98(0.36), 2.88(0.29), p=0.377), PAP (19.17(1.54), 19.17(1.54) and VO2 max (24.5(1.93), 24.9(2.29) p=0.063) showed no significant change. Conclusion: The transcatheter closure of ASDs results in significant improvement in echocardiographic measurements and exercise capacity post closure. BNP appears to reflect resultant change in these indices. Transcranial doppler is a sensitive technique for detecting right to left shunts.In combination with echocardiography it can assess the need for continuing antiplatelet therapy and further investigation.

3284 Increased carotid arterial wall thickness as an indicator of cardiovascular risk in adult patients succesfully operated for aortic coarctation

J.W.J. Vriend[1], E. De Groot[2], H.W. Vliegen[3], G. Veen[4], B.E. Van Huizen[2], W.J. Stok[5], J.J.P. Kastelein[2], B.J.M. Mulder[1]. [1]*Academic Medical Center, Cardiology, Amsterdam, Netherlands;* [2]*Academic Medical Center, Vascular Medicine, Amsterdam, Netherlands;* [3]*Leiden University Medical Center, Cardiology, Leiden, Netherlands;* [4]*Free University Medical Center, Cardiology, Amsterdam, Netherlands;* [5]*Academic Medical Center, Physiology, Amsterdam, Netherlands*

Objectives: Despite succesful surgery of aortic coarctation cardiovascular mortality and morbidity, notably premature coronary artery disease and cerebrovascular accidents, are greatly increased in middle aged adult post-coarctectomy patients. This may be due to previous increased blood pressure in the pre-coarctatial arterial conduits. B-mode ultrasound imaging can describe status and changes in intima-media complex thickness (IMCT) of carotid and femoral arterial walls. IMTC is a non-invasive measure and considered a validated endpoint for atherosclerosis.

Methods:

Ultrasound investigations were done in 26 normotensive (31.7(SD9.1)years) and 22 hypertensive (34.2(9.6)years) adult post-coarctectomy patients, and in 26 age and sex matched controls (33.9(9.9)years). Mean age at operation was 9.5(range 0.8-22.1)years in normotensives and 8.5(0.1-26.9)years in hypertensives. A subject's IMTC was calculated as the averaged measurements of three right and three left carotid arterial wall segments. Hypertension was defined as the daytime mean systolic blood pressure above 140mmHg registered on 24 hour ambulatory blood pressure monitoring. Student's unpaired t-test was used to compare IMTC's of normotensive and hypertensive post-coarctectomy patients and controls.

Results: IMTC of the entire post-coarctectomy group (0.74(SD0.10)mm) was increased if compared to controls (IMTC=0.60(0.09)mm):DIMT=0.14mm, $p<0.0001$. Differences between normotensive (0.70(0.10)mm) and hypertensive (0.78(0.10)mm) patients and each of these groups with controls, were highly significant (all $p<0.0001$).

Conclusions: Normotensive as well as hypertensive post-coarctectomy patients showed increased carotid IMTC at relatively young age. The findings reflect increased vascular risk in all post-coarctectomy patients regardless of blood pressure and indicate the need for cardiovascular risk profile evaluation in all patients to improve vascular disease prevention.

3285 Late progression of pulmonary regurgitation in adults with repaired tetralogy of Fallot

A.A. Karatza[1], P. A. Davlouros[2], W. Li[2], M. Henein[3], A.G. Magee[1], D. Gibson[3], M. Mullen[2], M.A. Gatzoulis[2]. [1]*Royal Brompton Hospital, Paediatric Cardiology, London, United Kingdom;* [2]*Royal Brompton Hospital, Adult Congenital Heart Programme, London, United Kingdom;* [3]*Royal Brompton Hospital, Echocardiography, London, United Kingdom*

Background: Pulmonary regurgitation after repair of tetralogy of Fallot is associated with late morbidity and mortality. However, little is known about the rate of progression of pulmonary regurgitation.

Methods: Using cross sectional echocardiography we studied 60 consecutive adults with repaired tetralogy of Fallot (age 35±11 years, range 16-62 years, 23 females and 37 males). Severity of pulmonary regurgitation was assessed by the pulmonary regurgitant index (PRi: pulmonary regurgitant Doppler signal duration/total diastolic time). Patients with right ventricular outflow tract Doppler velocity >3m/s were excluded. Right ventricular end-diastolic diameter was measured using M-mode in the parasternal long axis view (RVDd) and at the inflow (RVDinflow) from the four-chamber view. Individual patients results were compared with corresponding indices derived from echocardiograms performed at least 30 months (mean 51±13, range 30-77 months) previously at this institution. Measurements were performed by a single blinded investigator.

Results: There was a significant decrease in PRi (0.85±1.4 vs 0.74±0.19, $p<0.0001$), denoting progression of pulmonary regurgitation. Forty (66%) patients had at least moderate pulmonary regurgitation at present compared to 26 (43%) at previous echocardiogram (Fisher's exact test, p=0.017). PRi correlated negatively with the color diameter of the pulmonary regurgitant jet both at current (r=-0.502, p=0.0002) and at initial echocardiogram (r=-0.643, $p<0.0001$). There was a tentative increase in RVDd (3.00±0.9cm vs 3.35±0.9cm, p=0.06) and RVDinflow (4.49±0.79cm vs 4.64±0.71cm, p=0.09) between the two echocardiograms.

Conclusions: Severity of pulmonary regurgitation progresses with time in adults with repaired tetralogy of Fallot. Early pulmonary valve implantation may therefore improve the very long-term outlook for these patients.

3286 Long-term outcomes up to 30 years after the Mustard or Senning operation: a nationwide multicentre study

P. Moons[1], M. Gewillig[2], T. Sluysmans[3], H. Verhaaren[4], P. Viart[5], M. Massin[6], B. Suys[7], A. Vliers[8]. [1]*Catholic University of Leuven, Centre for Health Serv. & Nursing Res., Leuven, Belgium;* [2]*University Hospitals of Leuven, Division of Congenital Cardiology, Leuven, Belgium;* [3]*Cliniques Universitaires Saint Luc, Department of Paediatric Cardiology, Brussels, Belgium;* [4]*Ghent University Hospital, Heart Centre, Ghent, Belgium;* [5]*Université Libre de Bruxelles, Department of Paediatric Cardiology, Brussels, Belgium;* [6]*University of Liège at CHR Citadelle, Division Paediatric Cardiology, Liège, Belgium;* [7]*University Hospital of Antwerp, Department of Paediatric Cardiology, Antwerp, Belgium;* [8]*Found. for res. in paediatric cardiol., Halle, Belgium*

Patients with transposition of the great arteries (d-TGA), corrected with the Mustard or Senning operation, present with multiple problems during follow-up. This frequently complicates the long-term management of this patient population. This multicentre study assessed mortality, morbidity, functional abilities and social integration of patients up to 30 years after Mustard or Senning repair. Long-term outcomes of both procedures were compared.

Methods: We performed a retrospective review of medical records of all patients with simple or complex d-TGA, operated on and/or followed-up in Belgium. Three hundred thirty nine subjects were included, comprising 124 patients after Mustard and 215 patients after Senning repair. About two-third of the sample was male (64.6%). Simple d-TGA was observed in 244 patients (72%), while in the remaining 95 patients (28%) other cardiac lesions were associated, such as large VSD, pulmonary valve stenosis, or coarctation of the aorta.

Results: Overall mortality was 24.2%. Early mortality (<30 days after operation) accounted for 16.5%, while late mortality was observed in 7.7%. The actuarial survival of early survivors at 10, 20, 25 and 30 years after operation was 91.7%, 88.6%, 87.5%, and 79.3%, respectively. The Senning operation showed a slightly, but not significantly, better survival than the Mustard operation. Yet, baffle obstruction occurred more frequently after Mustard repair (15.3%) than after Senning repair (1.4%)($p<0.001$). A difference between the two types of operation was also observed for atrial flutter (20.5% vs. 1.8%), although this difference was due to the longer postoperative course of patients after Mustard operation (OR: 1.18; 95%CI: 1.05 – 1.33). Systemic ventricular dysfunction (moderate=9.5%; severe=2%) and tricuspid valve regurgitation (moderate=27.5%; severe=7.5%) did not significantly differ between the two procedures. Survivors of the Senning cohort showed a significantly better functional status ($p=0.023$), and more engagement in sport activities ($p<0.001$).

Conclusions: This nationwide multicentre study indicated that long-term outcomes after the Mustard and Senning operation were relatively favorable in terms of mortality, morbidity, functional status and social integration. Although overall mortality in the Senning cohort did not differ from the Mustard group, patients after Senning repair showed better functional status, higher participation in sport activities, and less baffle-related problems.

3287 Right ventricular ischaemic dysfunction during dobutamine stress in patients with Mustard repair for transposition of great arteries

W. Li, T. Hornung, C. O'Sullivan, D. Gibson, M. Gatzoulis, M. Henein. *Royal Brompton Hospital, Cardiac Dept., London, United Kingdom*

Background: Despite good functional capacity in patients with Mustard repair for transposition of great arteries (TGA) they are known to have impaired right ventricular (RV) function, the mechanism of which is unclear.

Aim: To assess RV electrical and mechanical response to stress and to explore possible mechanisms that may explain late development of RV dysfunction in these patients.

Methods: Twenty five patients (age 30±7 years, 13 male) were studied 25±6 years after Mustard repair using Doppler echocardiography, 12 lead ECG at rest and peak conventional dobutamine stress protocol and compared them with 15 controls of similar age. RV free wall and septal amplitude were measured from M-mode recording of the tricuspid ring movement and systolic and diastolic velocities using tissue Doppler technique. Patient's cardiopulmonary (MVO2) exercise tolerance was also assessed in the same day of the echocardiogram.

Results: Fourteen patient were in NYHA class I and 11 in class II. No patient developed stress related symptoms although all but one had RV amplitude less than the 95% CI of normal, $p<0.001$ at rest. Fifteen patients dropped or failed to increase RV free wall amplitude with stress in contrast to controls who increased their RV amplitude by 20%. Eighteen patients developed RV and/or septal incoordination (post-ejection shortening), $p<0.001$, eleven of whom demonstrated significant anteroseptal ST depression and/or T wave normalization, $p<0.001$. RV free wall amplitude and systolic velocities and septal amplitude correlated with MVO2 (r values 0.5, 0.72 and 0.64, respectively, $p<0.001$) Septal amplitude also correlated with peak aortic velocity ($r= 0.5$, $p<0.01$).

Conclusion: Although patients with Mustard repair for TGA tolerated pharmacological stress with no symptoms 72% demonstrated significant electrical and mechanical signs of ischaemic right ventricular dysfunction. These abnormalities are related to their limited cardiopulmonary exercise. Thus, stress related ischaemic changes may contribute to perpetual deterioration of right ventricular function known in this condition.

3288 Neurohormonal activation and the chronic heart failure syndrome in adults with congenital heart disease

A P. Bolger[1], R. Sharma[1], W. Li[2], P. Kalra[1], A.J.S. Coats[1], S.D. Anker[1], P.A. Pool-Wilson[1], M.A. Gatzoulis[3]. [1]*National Heart and Lung Institute, Clinical Cardiology, London, United Kingdom;* [2]*Royal Brompton Hospital, Department of Echocardiography, London, United Kingdom;* [3]*Royal Brompton Hospital, Adult Congenital Heart Programme, London, United Kingdom*

Background: Neurohormonal activation characterises chronic heart failure, relates to outcome and is a principal target for pharmacotherapy. It is not known whether a similar pattern of neurohormonal activation exists in adults with congenital heart disease and if so whether it relates to common measures of disease severity or whether cardiac anatomy is a better discriminant.

Methods: Concentrations of atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), endothelin-1 (ET-1), renin, aldosterone, norepinephrine and epinephrine were determined in 53 adults with congenital heart disease, comprising 4 anatomical subgroups; fetralogy of Fallot, single ventricle physiology, right-sided systemic ventricle, miscellaneous (29 female; 33.5±1.5y, NYHA class 2.0 ± 0.1, mean ± SE) and 15 healthy control subjects (8 female; 32.3±1.3y). Systemic ventricular function was graded by a blinded, echocardiographer as being normal, or mild, moderately or severely impaired. Patients underwent cardiopulmonary exercise testing, and had chest x-ray, ECG and oximetry performed.

Results: Adults with congenital heart disease had elevated levels of ANP (56.6 vs 3.1 pmol/L), BNP (35.8 vs 5.7 pmol/L), ET-1 (2.5 vs 0.7 pmol/L, all $p<0.0001$), renin (147 vs 16.3 pmol/L), norepinephrine (2.2 vs 1.6 pmol/L, both $p<0.01$) and aldosterone (546 vs 337 pmol/L, $p<0.05$). There was a highly significant stepwise increase in ANP, BNP, ET-1 and norepinephrine according to NYHA and systemic ventricular function class (all ANOVA $p<0.001$ and <0.05 respectively). Even asymptomatic patients had evidence of significant neurohormonal activation. In contrast there was no direct relationship between the 4 anatomic subgroups and any of the neurohormones studied (all ANOVA $p>0.2$). Neurohormonal activation related to cardiothoracic diameter, atrial volume and peak oxygen consumption in a manner indistinguishable from chronic heart failure.

Conclusions: Neurohormonal activation in adult congenital heart disease bears the hallmarks of chronic heart failure, relating to symptom severity and ventricular dysfunction and not to anatomical substrate. Neurohormonal antagonism across this large and anatomically diverse population should be considered.

CONGENITAL HEART DISEASE: METABOLISM AND ARRHYTHMIAS

3289 Management of junctional ectopic tachycardia by hypothermia after cardiac operations in infants

I. Mosquera[1], F. Rueda[2], C. Abelleira[2], C. Medrano[2], F. Portela[2], C. Zavanella[2], A. Castro-Beiras[3]. [1]*Juan Canalejo Hospital, Cardiología, A Coruña, Spain;* [2]*Juan Canalejo Hospital, Area Infantil del Corazón, A Coruña, Spain;* [3]*Juan Canalejo Hospital, Area del Corazon, A Coruña, Spain*

Background Junctional ectopic tachycardia (JET) is a postoperative complication after repair of congenital heart disease, especially in infants. The high ventricular rate, the poor response to conventional antiarrhythmic drugs and the resistance to electrical cardioversion make it be associated with a high morbidity and mortality. The purpose of this study was to assess the safety and efficacy of moderate hypothermia in the treatment of postoperative JET in infants.

Methods The case notes of 12 infants (9 females, aged between 8 days and 7 months) with postoperative JET, diagnosed according to established criteria, who were treated with surface cooling by placing ice bags on the child's body surface, were reviewed. The patients were sedated, mechanically ventilated, and paralysed. Moderate hypothermia was defined as rectal temperature between 32° and 35°C. Atrial pacing was used as an adjunct to hypothermia, in order to restore atrioventricular synchrony.

Results Mean interval between diagnosis of JET and initiation of hypothermia was 1.5 ± 0.5 hours (mean ± SD). Moderate hypothermia was achieved in 10 patients. Hypothermia led to a reduction in heart rate in all patients within four hours (from 189 ± 17 to 166 ± 16 beats/minute, $p<0.001$), with rises in systolic blood pressure (from 69 ± 11 to 78 ± 21 mmHg, $p=0.14$) and hourly urine output (from 3.3 ± 2.3 to 5.0 ± 2.1 cc/kg/minute, $p=0.015$), and reduction in central venous pressure (from 14.3 ± 4.8 to 11.3 ± 3.3 mmHg, $p=0.027$). No direct adverse events were noted. Cooling was maintained for a period of 36 to 144 hours (74 ± 42 hours). All patients but one survived and, after a follow-up period of 15 ± 12 months, they stay alive and without neurological deficits.

Conclusions Early institution of moderate hypothermia, with atrial pacing as a complementary measure, was a safe and efficient method to control ventricular rate and improve haemodynamic condition in infants with postoperative JET.

3290 Long QT syndrome with syndactyly, a novel highly malignant variant of inherited arrhythmias in the normal heart

C. Napolitano[1], R. Bloise[1], M. Stramba Badiale[2], M. Lunati[3], M. Gasparini[4], C. Cavalli[5], P.J. Schwartz[6], S.G. Priori[1]. [1]*Salvatore Maugeri Fondation, Molecular Cardiology Dept., Pavia, Italy;* [2]*IRCCS, Auxologico Hospital, Milan, Italy;* [3]*Niguarda Hospital, Cardiology, Milan, Italy;* [4]*Humanitas Hospital, Cardiology Division, Rozzano, Italy;* [5]*Ospedale Civile, Verona, Italy;* [6]*IRCCS Policlinico San Matteo, Dept of Cardiology, Pavia, Italy*

The association between Long QT Syndrome (LQTS) and syndactyly defines a distinct clinical entity (LQTS-syn). Seven cases with this variant of LQTS have been reported and they were all sporadic forms leading to the suggestion that the disease is due to de novo mutations. Here, we report 5 patients affected with LQTS-syn including the first evidence of a familial form of this syndrome. In all cases cutaneous syndactyly involving the third to the fifth fingers was identified at birth. Markedly prolonged QT was evident (560±50 ms) and it was associated with episodes of functional 2:1 AV block in the majority of patients. In three out of five patients macroscopic T wave alternans was observed at Holter monitoring. Beta blocker therapy was implemented in all patients. After a follow up of 26±23 months 3/5 (60%) patients experienced cardiac events (two of them died after elective surgery). Given the unfavourable outcome of the previously reported cases despite beta-blockers and pacing, we implanted an ICD in the two living patients with QTc exceeding 600ms (age at implant 6 and 1 year, respectively). Eight months after implantation, the one year old child experienced a cardiac arrest while playing. The other patient has remained asymptomatic. We performed molecular screening on LQTS related genes and failed to demonstrate the presence of mutations in all probands. Based on the evidence of LQTS-synd in a female patient, the X-linked pattern of inheritance appears unlikely. On the other hand the presence of a family with two affected children and apparently unaffected parents supports the view that this variant may be inherited as an autosomal recessive trait. It is concluded that LQTS with Syndactyly is a clinically and distinct disease characterised by marked prolongation of QT interval frequently associated with T wave alternans and functional AV block. This variant of LQTS is highly malignant with inadequate response to beta-blockers: ICD should be considered in these patients.

3291 Novel mutation in the N-terminus of HERG channel causes long QT syndrome 2 with a marked variation in clinical phenotype

T. Rossenbacker[1], M. Gewillig[2], K. Devriendt[3], H. Heidbuchel[2]. [1]*KULeuven, Campus Gasthuisberg, CTG, Leuven, Belgium;* [2]*KULeuven, Campus Gasthuisberg, Department of Cardiology, Leuven, Belgium;* [3]*KULeuven, Campus Gasthuisberg, Centre for Human Heredity, Leuven, Belgium*

Background: HERG encodes for an alpha-subunit of a voltage-gated rapidly activating delayed rectifier potassium channel (IKr). HERG exhibits two distinct and physiologically significant gating characteristics: rapid inactivation and slow deactivation. Mutations in HERG cause LQTS subtype 2 (LQT2). The clinical phenotype of LQT2 patients is due to distorted myocardial repolarization and varies markedly within affected families. HERG channels are also molecular targets for widely used pharmacological agents.

Findings: We report on a large LQTS family. Three patients died suddenly in distinct circumstances at the age of 20,22 and 23 years, one patient, who was diagnosed earlier with "epilepsy", experienced cardiac arrest but was succesfully resuscitated and one patient developed torsades de pointes evoked by the combined intake of grapefruit juice and antifungal medication. Seven family members with lenghtened QT-interval on ECG are asymptomatic while on beta-blocker therapy. Mutation analysis (Denaturing High Performance Liquid Chromatography – D-HPLC) was performed and revealed an amino-acid change from lysine to glutamic acid at codon 28 of the HERG gene (K28E). All phenotypically affected patients carry this mutation. The mutation was introduced in the HERG cDNA using PCR overlapping fragments. HEK-293 cells were transiently transfected through the lipofectamine method with mutant channels and wild-type channels. GFP was co-expressed. Whole-cell patch-clamp experiments are being done and pharmacological challenges with IKr blockers are planned.

Conclusions: A novel mutation in the HERG gene has been isolated in a large LQTS family. The K28E mutation is located in the cytoplasmic amino (N)-terminus of the HERG channel. This terminus, containing a PAS domain, controls deactivation, by tightly associating with the body of the K^+ channel. There is a strong belief that the in vitro study of the K28E mutation will further explain the important regulatory role of the N-terminus in HERG channel gating. More-over the use of HEK-293 allows to perform pharmacological challenges with IKr blockers in contrast to transfections in Xenopus oocytes. This study will probably render more pathophysiological insights in acquired lengthening of the QT-interval, which predisposes to dangerous arrhythmias as shown in one of our patients.

Five patients in this LQT2 family have a severe phenotype and seven patients are asymptomatic. These findings stress again the variety in clinical presentation in the LQTS and points to the important role of modifier genes.

3292 High-Incidence of misdiagnosed epilepsy in children with syncope caused by malignant ventricular tachyarrhythmias

F.E.S. Cruz[1], I.G. Maia[2], M.L.A. Fagundes[1], C. Lace[1], L. Xavier[1], S. Boghossian[2], L. Vanheusden[2], R.S. Sa[1]. [1]*Instituto de Cardiologia Laranjeiras, Arritmia, Rio de janeiro, Brazil;* [2]*Pro-Cardiaco, Arritmia, Rio de Janeiro, Brazil*

Background: The vast majority of syncopal attacks in children are related to cardiogenic disease, however most cases are first referred to a neurologist. Consequently patients reach the cardiologist already under anticonvulsive therapy.

Methods: Out of 2.000 ambulatory 24-Holter recordings performed from 1998 to 2000, we analyzed the data of 610 pediatric patients. From these, we selected the malignant ventricular electrical rhythm disturbances which could be potentially responsible for syncope or sudden death. The data included: 1. History of previous use of anticonvulsive therapy. (AntiConvT). 2. Familial sudden death (SD) caused by "epilepsy" (FamEpSD). 3. Syncope Characteristics (SyncChar).Results: The study group included 21 patients, 12 females and 9 males, with a mean age of 11,7 ± 5,3 years. Twelve patients had Congenital Long QT Syndrome, among these, 05 (42%) had a history of syncope, 2/5 (40%) used AntiConvT, 1/5 (20%) had FamEpSD and all had undefined SyncChar. Seven patients had catecholaminergic bi-directional ventricular tachycardia, all with a history of syncope (100%), use of AntiConvT was noted in 3 (43%), FamEpSD in 2 (28.5%) and SincCar related to exercise or stress in all. Two patients presented the short coupled variant of torsade des pointes, both with syncopal episodes (100%), without previous use of AntiConvT, no FamEpSD or undefined SyncChar. Incidence of SD or aborted cardiac arrest was 21%, all under 12 years of age. Conclusions: 1. Pediatric patients with syncopal attacks and lethal arrhythmias, have a significant risk of being misdiagnosed as Epilepsy and treated with an anticonvulsive drug, 2- Primary prevention becomes necessary and includes an interaction among pediatric cardiologists and neurologists.

3293 High incidence of appropriate and inappropriate ICD therapies in children and young adults

T. Korte[1], H. Köditz[2], T. Paul[3], M. Niehaus[1], J. Tebbenjohanns[1]. [1]*Medical School Hannover, Cardiology Dpt., Hannover, Germany;* [2]*Medical School Hannover, Dept. of Pediatric Cardiology, Hannover, Germany;* [3]*Medical University of South Carolina, Pediatric Cardiology, Charleston, United States of America*

Background: Appropriate and inappropriate ICD therapies have a major impact on morbidity and quality of life in ICD recipients, but have not been systematically studied in children and young adults during long-term follow-up.
Methods: Incidence, reasons and predictors of ICD therapies were analyzed in 20 young patients (age: 16±6 years, congenital heart defect: 11 Pt, LQT-Syndrome: 4 Pt, idiopathic VF: 2Pt, ARVD: 1 Pt, ICM: 1 Pt, HOCM: 1Pt) after epicardial ICD implantation in 6 and transvenous implantation in 14 Pt during 51±31 months [18-132].
Results: There was a total 239 ICD therapies in 17 Pt (85%) with a therapy rate of 2.8 per patient-years of follow-up. 127 ICD therapies (53%) in 15 Pt (75%) were categorized as appropriate and 112 therapies (47%) in 10 Pt (50%) as inappropriate with a rate of 1.5 appropriate and 1.3 inappropriate ICD therapies per patient-years of follow-up. Time to first appropriate therapy was 16±18 months, caused by VF in 29 and VT in 98 episodes. Termination was successful by ATP in 4 (3%) and by shocks therapy in 123 episodes (97%). Time to first inappropriate therapy was 16±17 months, caused by AF/AFL or sinus tachycardia in 77 (69%), T-wave oversensing in 19 (17%) and electrode defect in 16 episodes (14%). Inappropriate therapies were shocks in 87 (78%) and only ATP in 25 episodes (22%). No clinical variable (age, gender, repaired congenital heart disease, history of supraventricular tachycardia, epicardial electrode system) could be identified as predictor of either appropriate or inappropriate ICD therapies.
Conclusions: There is a high rate ICD therapies in young ICD recipients, the majority of which occur during early follow-up. The rate of inappropriate therapies is as high as 47% and is caused by supraventricular tachycardia and electrode complications in the majority of cases.

3294 Pre-natal exposure to carbon monoxide delays post-natal electrophysiologic maturation of rat ventricular myocytes: a link to SIDS?

L. Sartiani[1], G. Lonardo[1], P. DePaoli[1], R. Cagiano[2], V. Cuomo[3], E. Cerbai[1], A. Mugelli[1]. [1]*University of Firenze, Dept. Pharmacology, Firenze, Italy;* [2]*University of Bari, Department of Pharmacology, Bari, Italy;* [3]*University "La Sapienza", Dept. Pharmacology and Gen Physiology, Rome, Italy*

Maternal smoking during pregnancy and prolongation of the QT interval on the electrocardiogram in the first weeks of life are considered as risk factors for Sudden Infant Death Syndrome (SIDS). In animal models, prenatal exposure to carbon monoxide (CO), a major component of cigarette smoke affects postnatal development of several organs; no data are available concerning cardiac electrophysiological development. In neonatal rat myocytes, the physiological cell growth is accompanied by a significant reduction of the action potential duration (APD), the cellular determinant of QT interval, due to an increased expression of the transient outward current. The aim of this study was to compare cell electrophysiological maturation in male Wistar rats born from mothers exposed to 0 (CTR) or 150 ppm CO during pregnancy, resulting in blood carboxyhaemoglobin levels comparable to those found in human smokers.
Methods: Action potential and ionic currents were measured in patch-clamped myocytes isolated at different ages after birth (1, 2, 4 and 8 weeks). Cells were superfused with a normal Tyrode's solution (to measure action potential, AP) or appropriately modified Tyrode's solutions (to measure transient outward current, TO and the L-type calcium current, CaL).
Results: Postnatal increase in cell size was similar in both groups; however, differences were observed in the electrophysiological parameters during growth. APD measured at -50 mV (APD50) progressively decreased in CTR from 131±24 ms at 1 week (n=14) to 78±8 ms at 4 weeks (n=14) and 67±7 ms at 8 weeks (n=10). This process was delayed in CO: at 4 weeks, APD50 remained significantly prolonged (148±24 ms, n=13) versus 4-week old CTR ($p<0.02$) and progressively shortened up to 92±12 ms (n=10) at 8 weeks. The ionic basis of APD shortening involved both calcium and potassium currents abnormalities. At 4 weeks, the density of CaL was significantly ($p<0.02$) higher in CO than in CTR (21±2 pA/pF, n=17, vs. 16±2 pA/pF, n=22) and normalized thereafter (at 8 weeks: 15±1 pA/pF, n=28 in CTR and 14±1 pA/pF, n=18 in CO). TO density progressively increased in CTR (in pA/pF, from 4±1 at 1 week to 13±2 at 4 weeks and 14±2 at 8 weeks, $p<0.01$), but it remained lower in CO at 4 and 8 weeks (respectively, 7±1 pA/pF, n=22, $p<0.01$ vs. 4-week old CTR; 8.5 pA/pF, n=13, $p<0.01$ vs. 8-week old CTR).
Conclusions: Prenatal CO exposure affects the physiological shortening of APD, thus favoring QT prolongation and related arrhythmias and possibly contributing to SIDS occurrence.

INTERVENTIONAL CARDIOLOGY IN CONGENITAL HEART DISEASE

3295 Long-term outcome of balloon aortic valvuloplasty in infants and children

M. Witsenburg[1], W.A. Helbing[2], M. Dalinghaus[2], R.M.F. Berger[2]. [1]*Erasmus MC/Sohia Children's Hospital, Paediatric Cardiology, Rotterdam, Netherlands;* [2]*Erasmus MC/Sophia Children's Hospital, Paediatric Cardiology, Rotterdam, Netherlands*

Objective: Evaluation of clinical outcome after balloon aortic valvuloplasty (BAV) in infants and children.
Methods: Retrospective analysis of patient files in a tertiary referral center.
Results: Since 1986 BAV was used as primary treatment in all consecutive patients (pts) with severe aortic valve stenosis (VAS) and in pts with residual stenosis after surgery. In a 15 year period 82 pts (58 boys, 24 girls, age range 3 days-15 yrs) underwent BAV for VAS. 38/82 pts were infants. 18/82 pts underwent earlier surgical valvulotomy. Follow up (mean 7 yrs) was complete in 80 pts. Mortality concerned 8 pts, of whom 7 during infancy. Two infants of these died during the intervention, caused by aortic regurgitation in one and arterial bleeding in the other. The other 6 pts died because of cardiac failure in 4, endocarditis in one and acute arrhythmia 11 yrs after BAV in one pt refusing surgery. Re-interventions were necessary in 40 pts during follow up: repeat BAV in 11 pts, surgical aortic valvulotomy in 3 and valve replacement in 26 pts. The indication for valve replacement (pulmonary autograft) in these 26 pts was valve stenosis in 44%, regurgitation in 33% and a both stenosis and regurgitation in the remaining pts. Of the 11 pts that underwent a repeat BAV 4 required subsequent valve replacement during follow up. At 5 yrs follow up 53% of pts were free from any re-intervention. During the study period up endocarditis occurred in 4 pts which was fatal in one.
Conclusion: In infancy mortality and the need for re-interventions after BAV for VAS is considerable. After infancy BAV for VAS is a successful and low risk therapy at longer term, postponing surgical intervention in the majority of pts.

3296 Long-term results of percutaneous balloon dilation for discrete subaortic stenosis. A 17-year study

J. Suarez de Lezo[1], J. Segura[1], A. Medina[2], M. Pan[1], M. Romero[1], D.J. Pavlovic[1], S. Ojeda[1], E. Hernández[2]. [1]*Reina Sofía Hospital, Cardiology Dept., Cordoba, Spain;* [2]*Dr Negrín Hospital, Cardiology, Las Palmas, Spain*

Transluminal balloon dilation (TBD) for thin discrete subaortic stenosis (DSS) is a useful alternative to surgical therapy. Better initial results are observed in patients with larger aortic annulus and a membrane further away from the valve. However, given the progressive nature of the disease, the long-term efficacy of this treatment remains unknown. This 17-year study describes the findings obtained in 66 patients with isolated DSS who underwent percutaneous TBD and were followed-up for a mean period of 7±5 years (range 2 months-17 years). The mean age at treatment was 17±15 years (range 2 to 56). The procedure evolved through time but was always oriented to transcatheter tearing of the membrane. One patient 56 years old died after emergency surgery for inferior wall rupture during dilation manoeuvres (1.5%). Immediately after treatment, the subvalvular gradient decreased from 67±27 mmHg to 17±11 mmHg ($p<0.001$). No significant progression of aortic regurgitation was observed after treatment; in 7 (11%), aortic regurgitation even decreased after treatment. None of the patients developed mitral insufficiency. Sixty-five patients were followed up closely and had serial echo-Doppler or hemodynamic studies. After a mean follow-up time of 7±5 years, 1 patient had a non cardiac death (1.6%), 8 pts (12%) developed restenosis (loss of 50% of initial gain), 2 (3%) progressed to muscular obstructive disease and one developed a new obstructive distant membrane. The age at treatment was significantly lower in patients who developed restenosis as compared with that from patients restenosis-free (7±4 vs 19±14 years, $p<0.001$). To date, no patient older than 13 years has had restenosis. Nine pts were redilated at a mean follow-up time of 4±1 years after first treatment. The peak gradient decreased again from 74±30 mmHg to 22±14 mmHg ($p<0.001$) and none had progression of aortic regurgitation. Two patients (3%) were surgically operated 9 months and 5 years after first treatment. Fifty-five patients (83%) remain free of re-dilation and/or surgery without progression of aortic insufficiency or muscular obstructive disease. The mean last residual gradient, either hemodynamic or Doppler, was 28±11 mmHg at a mean follow-up of 7±4 years.
Conclusions: TBD is an effective modality of treatment in patients with isolated thin DSS, mainly in those older than 13 years of age. More than 80% of patients persist with the initial benefit at long-term follow-up (mean 7 years). Redilation, when needed, is similarly effective to first-dilation and seems to provide persistent relief.

3297 Percutaneous closure of large PDA (diameter > 2.5 mm) with the ADO. Comparisons with the Rashkind, buttoned devices and coils in 116 patients

F. Godart, C. Rey, P. Devos, G.M. Brevière, C. Francart. *Paediatric cardiology, Paediatric Cardiology - Radiology, 59037 Lille cedex, France*

Design of previously employed devices is not ideal for transcatheter closure of moderate-to-large patent ductus arteriosus (PDA), and their use has been associated with several drawbacks.

Method and Results: This study was performed to compare results of transcatheter closure of PDA (diameter above 2.5 mm) using the Amplatzer Duct Occluder (ADO) and previous occluders. One hundred and sixteen patients (77 females, 39 males) underwent PDA closure with several devices: Rashkind double umbrella (n=23, group I), Sideris buttoned device (n=39, group II), detachable Cook coil (n=17, group III), and ADO (n=37, group IV) at a mean age of 74 ± 129 months (weight: 18.9 ± 15.5 kg). Duct diameter was 3.8 ± 1.22 mm. Implantation succeeded in all but 9 (3 in group I, 2 in group II, 3 in group III, and 1 in group IV). Time of fluoroscopy was shorter and full occlusion better on angiography (64%) in group IV despite larger ducts (respectively $p<0.0001$, $p=0.0003$ and $p=0.0015$). Complications included embolization (n=2, 1 in group I and 1 in group III) and hemolysis (n=3, 2 in group III and 1 in group IV). During follow-up, 12 patients had a second procedure because of residual shunting (5 in group I, 6 in group II, and 1 in group III). Complete occlusion was achieved earlier after implantation (mean 2.6 months, $p=0.0002$) and rate of complete occlusion was better in group IV (97%, $p=0.025$).

Conclusions-Transcatheter closure of PDA with the ADO is an effective and safe technique which provides better results than previous occluders. It could be highly recommended for closure of large ducts (> 2.5mm).

3298 Single center experience of transcatheter closure of atrial septal defects using different devices

J.I. Stein[1], A. Gamillscheg[1], P. Zartner[1], H. Schuchlenz[2], A. Beitzke[1].
[1]*Universitäts-Kinderklinik, Pädiatrische Kardiologie, Graz, Austria;*
[2]*LKH-Uniklinikum, Kardiologie,II.Med.Abteilung, Graz, Austria*

Percutaneous closure of secundum type atrial septal defects (ASD)as therapeutic approach is widely used not only in the pediatric patient group. A number of different technical specifications have been used. We report our single centre experience in a mixed population with the two most commonly used systems Amplatzer septal occluder (ASO) and Cardio Seal/Cardio Seal Starflex (CS/CSSTF).

In a 4 year period (1997 to 2001) 93 pts were scheduled for the procedure -aged 2 -71y, weight 10-91kg, 38% being <18 years and 15% > 50y. The procedure was performed under general anesthesia in all children and most adults, using TEE in all. Anticoagulation -heparine- was given for the procedure, antiplatelet therapy for the following 6 months. In 13 pts the procedure was stopped after balloonsizing. 81 devices were implanted, in one girl two defects were closed with two devices in the same session (CS).

There were 29 pts treated with CS/CSSTF and 51pts with ASO. We found no significant differences between the ASO and CSSTF group, although Qp:Qs and ASD- size were larger in the ASO group.There was also a tendency of smaller rims at the aortic border of the ASD in the ASO group. Procedure time und radiation time showed no significant difference (4.5 - 37 min, mean 10.2).

Successfull implantation was possible in all pts when attempted, in those rejected, the single defect was too large in comparison to the intraatrial septal length, and/or had no sufficient rim for either device. In the setting of multiple defects (3x) there was either no place for mutliple devices or insufficient rims too.

There was no early or late embolisation. We encountered only one serious complication. In a 4 year old girl with insufficient systemic anticoagulation a cerebral infarction with hemiparesis occurred within the first 12 hours after the procedure. Symptoms resolved qucikly and are almost gone three years after the implantation.

On follow up with TTE and TEE there are three trivial residual leaks;in 1 adult the initially well positioned device showed diffrent psoition and significant shunt at the 1 year followup.

CS/STF-devices are mainly used in smaller pts with defects upto 20 mm, although we also use now the 6-arm device where defects up to 26 mm can beclosed.ASO- devices were implanted also in defects exceeding even 30 mm.

In our experience ASD's in all ages can be addressed safely with transcatheter closure when the appropriate device for the pt and defect size is selected.

3299 Incidence and clinical outcome of thrombus formation on ASD and PFO closure devices in 900 consecutive patients

U. Krumsdorf, K. Horvath, S. Ostermayer, K. Billinger, E. Zadan, T. Trepels, H. Sievert. *Cardiovascular Center Bethanien, Cardiology, Frankfurt, Germany*

Purpose: The purpose of this study was to investigate incidence, morphology and clinical course of thrombus formation on atrial septal defect (ASD) and patent foramen ovale (PFO) closure devices.

Methods: Between August 1992 and January 2001 in 900 consecutive patients transcatheter closure of a patent foramen ovale (n=537) or an atrial septal defect (n=363) was performed. Routine transoesophageal echocardiography (TEE) was performed after 2-4 weeks and 6 months.

Results: Thrombus formation in the left (n=11) or the right atrium (n=6) or both (n=3) was found in 5/360 ASD patients (1.4%) and in 15/531 (2.8%) PFO patients. This was observed after 2-4 weeks in 14, after 6 months in 3, after 1 year in 2 and after 5 years in 1 patient. The diameter of the thrombus varied from 5 to 30 mm (12 ± 7). After 4 weeks the TEE revealed thrombus formation in 7% on the CardioSEAL, the STARFlex and the PFO-Star occluder, in 4% on the ASDOS occluder, in 1% on the Helex occluder and in 0% on the Sideris and the Amplatzer occluder. The difference between the Amplatzer on one hand and the CardioSEAL, the STARFlex and the PFO-Star occluder on the other hand was significant ($p < 0.05$).

Prethrombotic disorders were found in 2 PFO patients (thrombocytosis and hyperactivity of Factor VIII), post procedure atrial fibrillation in 4, persistent atrial septal aneurysm despite device implantation in 4, device arm fractures in 3 (N.S.).

Three minor strokes and one TIA occurred. In 17/20 patients the thrombus resolved following anticoagulation therapy with heparin or warfarin. In 3/20 patients the thrombus had to be removed surgically.

Conclusion: The incidence of thrombus formation on closure devices is low. In most of the patients the thrombus resolves under anticoagulation therapy without clinical consequences. Surgery is rarely needed and should not be recommended generally.

3300 Right ventricular size after device closure of atrial septal defects – Serial changes and factors affecting them

K.M. Krishnamoorthy, J.A. Tharakan, T. Titus, V.K. Ajithkumar, A. Bhat, S. Sivasankaran. *Trivandrum, India*

Introduction: Right ventricle (RV) will remodel and decrease in size when the volume overload due to atrial shunting is abolished. The time course of these changes and factors affecting the changes were studied in patients undergoing device closure of atrial septal defect (ASD) where the effect of anaesthesia and surgery are absent.

Methods: In 28 patients (17 females), RV size was measured before and 2 days (2d) after successful closure of ASD with Amplatzer device and at follow-up of 3 months (3m) and 1 year (1y).

Results: Mean age was 22.3±17 years and mean body surface area 1.31±0.32 m^2. Mean left to right shunt (Qp:Qs) was 2.08±0.53. RV dimension (RVD, in mm) before closure (RVD-pre) was 28.6±8.2. RVD 2d after closure (RVD-2d), at 3m follow-up (RVD-3m) and at 1y follow-up (RVD-1y) are shown in table 1. The decrease in absolute RVD, decrease in indexed RVD and percentage decrease in RVD are also shown in table 1. Significant correlations of Qp:Qs with decrease in RVD were seen for values at 2d and at 1y follow-up: (i) with absolute decrease at 2d: $r=0.72$, $p<0.005$; absolute decrease at 1y: $r=0.7$, $p<0.05$; (ii) with decrease in indexed size at 2d: $r=0.7$, $p<0.03$; decrease in indexed size at 1y: $r=0.78$, $p<0.02$; (iii) with percentage decrease at 2d: $r=0.69$, $p<0.002$; percentage decrease at 1y: $r=0.8$, $p<0.01$. There was a weak correlation of age with decrease in RVD at 2d: $r=0.49$, $p<0.008$.

	2 days	3 months	1 year
RVD after closure of ASD*	24.8±6.3	20.0±4.1	18.6±4.9
Decrease in absolute RVD	3.8±2.7	4.2±3.3	0.75±0.7
Decrease in indexed RVD	2.7±1.7	3.0±2.1	0.5±0.5
Percentage decrease in RVD	12.3±6.7	16.6±9.5	4.0±4.0

* $p<0.03$ between RVD-pre and RVD-2d, $p<0.05$ between RVD-2d and RVD-3m and $p<0.02$ between RVD-3m and RVD-1y

Conclusions: There is an immediate and a delayed decrease in RV size after device closure of ASD. The decrease is significantly related to the magnitude of the shunt prior to closure and weakly to the age of the patient. The early changes in RV size (unaffected by the morbidity of anaesthesia and surgery) are greater than the decrease in RV size at 1 year following ASD closure. Larger studies are required to clarify this.

PROGNOSIS OF ACUTE MYOCARDIAL INFARCTION: REGISTRIES VERSUS STUDIES

3301 Outcome of myocardial infarction in the unselected population is vastly different from samples of eligible patients in large-scale clinical trials

E. Björklund[1], M. Dellborg[2], B. Lindahl[1], K. Pehrsson[3], U. Stenestrand[1], E. Swahn[1], F. Van de Werf[4], L. Wallentin[5]. *[1]University Hospital, Dept. of Cardiology, Linkoping, Sweden; [2]University Hospital, Dept of Medicine, Gothenburg, Sweden; [3]Karolinska Hospital, Dept of Cardiology, Stockholm, Sweden; [4]Thoraxcentr, Rotterdam, Netherlands; [5]Uppsala University Hospital, Uppsala, Sweden*

Several large scale clinical trials of fibrinolysis in ST-elevation myocardial infarction (MI) have repeatedly demonstrated an impressively low mortality - 6% at 30 days and 9-10% at 1 year. It has, however, been questioned whether these results are representative for unselected patient populations.

Methods: The ASSENT-2 (A2) trial randomised ST-elevation MI patients to fibrinolytic treatment with tPA or TNK-tPA without any difference in outcome. Out of the 17005 patients 1070 were recruited in Sweden out of which 753 in hospitals simultaneously recording all CCU admissions in the national CCU registry RIKS-HIA. During the period for A2 recruitment another 2977 patients (Non-A2) with fibrinolytic treatment for acute MI were recorded in the RIKS-HIA. The data obtained in the RIKS-HIA registry and 1-year outcome, based on matching with the National registry for death, were used for the comparisons.

The Non-A2 population was significantly older and contained more women, diabetes mellitus, previous MI and used more anti-thrombotic and diuretic medication than the A2 patients. Further, in multivariate analysis, participation in the ASSENT-2 study was significantly ($p<0.001$) associated with improved 1-year survival adjusting for age, gender, diabetes mellitus, previous MI, congestive heart failure and medication at entry.

Results:

Results: Death at 1 yr	n/n	A2	Non-A2	p
Total	753/2977	9.0%	20.0%	<0.001
Age <65 years	314/1035	1.9%	5.2%	0.012
Age 65 - 75 years	260/861	7.3%	16.0%	<0.001
Age >75 years	179/1081	24.0%	37.4%	<0.001

Conclusion: The unselected acute MI population has considerably worse outcome than acute MI patients eligible for clinical trials. The natural course and the effects of different treatments in acute MI needs to be monitored also in broader patient populations than usually included in clinical trials.

3302 Study results did not represent real-life practice – Data from GUSTO-5 and ACSIS-2000

V. Guetta[1], J. Leor[1], H. Hod[1], S. Gottlieb[1], D. Freimark[1], A. Battler[1], Y. Hasin[1], S. Behar[2] on behalf of for the GUSTO-5 and ACSIS-2000 Trialists. *[1]Neufeld Cardiac Research Institute, Tel Hashomer, Israel; [2]Neufeld Cardiac Research Institute, Tel Hashomer, Israel*

Among the 16,588 patients (pts) who participated in GUSTO-5, 1973 were recruited in Israel. The study did not show a significant mortality difference between the two arms of the study (5.6 vs. 5.9%). The low 30-day mortality was suggested as the reason for the lack of difference between the two study groups. A national survey on AMI, ACSIS-2000, was performed during the conduction of GUSTO-5 in Israel and included 1,112 pts with ST elevation MI, of whom 473 (43%) were treated with thrombolysis. Two hundred and fifty pts were recruited to GUSTO-5 and 220 received routine thrombolysis in the same CCUs which recruited pts to GUSTO-5. The mean age of GUSTO-5 pts was lower (59 yrs) than that of patients included in the survey (controls) (62 yrs; $p<0.05$). The control group also included more diabetics (35%) and hypertensives (42%) than counterparts (23 and 32% respectively; $p<0.05$ for each). More pts included in GUSTO-5 presented with typical symptoms (96%) vs. controls (89%; $p<0.05$), while the latter group were more often in Killip class >2(18%) than the GUSTO-5 group pts (12%; $p<0.05$). In the GUSTO-5 group, all pts received tPA while among the control group, 82% received STK. Aspirin and beta-blockers were equally given to both groups. Coronary angiography was performed in 59% of GUSTO-5 cases versus 50% in the control group. The median time from pain onset to thrombolysis was similar in GUSTO-5 (165') and the control group (157'). Thirty-day mortality was 4.1% in the GUSTO-5 group versus 10.2% among controls ($p<0.05$). This study showed that only 43% of STE MI were treated with thrombolysis and only 50% of pts eligible for thrombolytic therapy were included in the trial. Pts included in GUSTO-5 exhibited a lower risk profile than counterparts treated with standard thrombolysis and therefore had different outcomes. This study emphasizes the importance of maintaining a registry when clinical studies are performed.

3303 Changes in in-hospital management and outcome of acute myocardial infarction in the late 1990s: the nation-wide French 1995 and 2000 registries

N. Danchin[1], H. Ghobrial[2], G. Hanania[1], P. Guéret[3], D. Blanchard[4], J.M. Lablanche[5], L. Vaur[2], J.P. Cambou[6]. *[1]Cardiology Dept., Paris, France; [2]Aventis, Paris, France; [3]CHU Mondor, Cardiologie, Créteil, France; [4]Clinique St Gatien, Cardiologie, Tours, France; [5]CHU Lille, Cardiologie, Lille, France; [6]Inserm U 518, Toulouse, France*

The hospital management of patients with acute myocardial infarction (AMI) has changed considerably in the last decade. In order to assess possible differences in "real world" management and outcome of AMI in the late 1990s, we conducted 2 nation-wide registries using a similar methodology in intensive care units representing more than 3/4 of all French ICUs in November 1995 and November 2000. A total of 2563 patients with AMI < 48 hours from symptom onset were included in 1995, and 2320 patients in 2000. Patients admitted in 2000 were significantly younger (65.4 ± 14 vs 66.6 ± 14 years, $p<0.05$), but the sex ratio and prevalence of risk factors were similar. Previous medical history was also similar (prior MI: 16% vs 18%, CHF: 9% vs 6%; stroke: 7% vs 5% and peripheral artery disease: 10% vs 9%). Intravenous thrombolysis was used less often in 2000 (24% vs 32%), while the use of early PTCA was more frequent (32% vs 13%); overall reperfusion therapy by either thrombolysis or PTCA was used as often in 2000 (43% vs 43%). The use of reperfusion therapy decreased with increasing age in both cohorts. In the younger patients (< 50 years) the use of early PTCA was half in 1995 (21%) compared with 2000 (45%); in older patients, also, early PTCA was used much more frequently in 2000 than in 1995 (patients 70–79 years: 25% vs 11%; patients 80 years and older: 12.1% vs 4.6%). Cardiogenic shock developed in a similar proportion of patients in the 2 cohorts (6.6% vs 7.0%) and ventricular fibrillation was also as frequent in the 2 cohorts (3.8% vs 3.5%). Five-day mortality, however, was lower in 2000 than in 1995 (5.8% vs 7.7%, $p = 0.01$), a difference that remained significant in multivariate analysis ($p<0.03$) The other independent factors of 5-day mortality were age, diabetes mellitus, previous stroke, and anterior location of MI; use and modality of reperfusion therapy were not significantly and independently related to early mortality.

Conclusion: patients admitted for AMI in France are sligthly younger in 2000 than in 1995; the use of reperfusion therapy is similar, with a dramatic shift from thrombolysis to PTCA. Early mortality has continued to decline from 1995 to 2000, but there is no evidence that this change is related to the changes in mode of reperfusion therapy.

3304 Predictors of in-hospital mortality in the global registry of acute coronary events (GRACE)

K.A.A. Fox[1], R.J. Goldberg[2], K. Pieper[3], C.P. Cannon[4], F. Van de Werf[5], S.G. Goodman[6], O. Dabbous[7], C.B. Granger[3] on behalf of The GRACE Investigators. *[1]The Royal Infirmary of Edinburgh, Cardiology, Edinburgh, United Kingdom; [2]U of Massachusetts Medical School, Department of Cardiology, Worcester, United States of America; [3]Duke University Medical Center, Department of Cardiology, Durham, United States of America; [4]Brigham and Women's Hospital, Cardiology, Boston, United States of America; [5]Universitair Ziekenhuis Gasthuisberg, Cardiology, Leuven, Belgium; [6]St. Michael's Hospital, Cardiology, Toronto, Canada; [7]U of Massachusetts Medical School, Center for Outcomes Research, Worcester, United States of America*

Background: Specific pharmacologic (e.g. glycoprotein IIb/IIIa inhibitors) and interventional strategies (revascularization), have most benefit in high risk acute coronary syndromes (ACS) patients. However, recent registry data suggest that clinical practice is not always based on trial evidence or current treatment guidelines. Robust and clinically applicable risk models are needed to guide routine practice, but prior risk models have been derived from restricted or trial populations and may be less widely applicable.
Methods: GRACE is the largest multi-national registry including patients with the full spectrum of ACS. We developed a multivariable logistic regression hospital death-prediction model in 11,380 patients (509 in-hospital deaths) and validated the model in a prospective cohort of 3,972 patients and also in 12,142 patients from the GUSTO IIb trial.
Results: Eight independent risk factors accounted for 90% of predictive information for the risk of in-hospital death in the model (Table). Two new independent predictors were identified: resuscitated cardiac arrest and serum creatinine. The model demonstrated excellent discriminant ability with a C statistic of 0.83 for the derived data set, 0.84 for the confirmatory data set and 0.79 for the external GUSTO IIb database.

Risk factors for in-hospital death

Risk factor	OR	Grace score
Resuscitated cardiac arrest	4.3	+39
ST-deviation	2.4	+28
Killip class	2.0 per class	0 - 59
Age	1.7 per 10 yrs over 30	1 - 100
Elevated initial cardiac markers (CRP, Troponin)	1.6	+14
Systolic BP	1.4 per 20 mmHg under 200	0 - 58
Heart rate	1.3 per 30 bpm over 50	0 - 46
Creatinine	1.2 per mg/dl under 4	0 - 28

Independent risk factors for in-hospital death (cumulative score predicts risk of death)

Conclusion: The GRACE registry has provided a robust risk model for the hazard of in-hospital death, regardless of whether the patient presents with ST-elevation MI, non-ST MI or UA. The GRACE cumulative score can be used in a nomogram or personal digital assistant (PDA) to predict death and hence guide clinical practice.

3305 Targeting improved adherence to the ACC/AHA guidelines for the management of non-ST-segment elevation acute coronary syndromes

M.T. Roe[1], E. Peterson[2], C.V. Pollack[3], S. Smith[4], R. Brindis[5], R. Christenson[6], W.B. Gibler[7], E.M. Ohman[4] on behalf of The CRUSADE Investigators. *[1]Duke Clinical Research Institute, Durham, United States of America; [2]Duke Clinical Research Institute, Cardiology Dept., Durham NC, United States of America; [3]Pennsylvania Hospital, Emergency Medicine, Philadelphia, United States of America; [4]University of North Carolina, Cardiology, Chapel Hill, United States of America; [5]Kaiser Permanente Health System, Cardiology, San Francisco, United States of America; [6]University of Maryland, Pathology, Baltimore, MD, United States of America; [7]University of Cincinnati, Emergency Medicine, Cincinnati, OH, United States of America*

Background: Despite publication of the revised ACC/AHA guidelines for the management of non-ST-elevation acute coronary syndromes (NSTE ACS) in 2000, implementation of the treatment recommendations from the guidelines in clinical practice has not been well-characterized.
Methods: The CRUSADE national quality improvement initiative has been developed to encourage adherence to the ACC/AHA guidelines for the management of high-risk patients with NSTE ACS in U.S. hospitals. A unique collaboration of Cardiologists and Emergency Medicine physicians has been established for CRUSADE to improve early risk stratification strategies and the quality of hospital-based care provided to patients with NSTE ACS.
Results: Since December, 2001, a total of 892 patients have been included in CRUSADE. Of these patients, 50.1% presented with ST-depression, 70.9% presented with elevated cardiac markers (CK-MB or Troponin I or T), the median age was 69 years (57,78 years), and 39.8% were female. Baseline use of acute and discharge therapies recommended by the ACC/AHA guidelines is displayed in the table. By August, 2002, projections indicate that approximately 8000 patients will be included in the CRUSADE database.

Acute and Discharge Medications

Medications*	Acute Use (1st 24 hours)	Discharge Use
Aspirin	89.6%	86.4%
Beta-Blockers	74.4%	82.7%
Heparin	83.7%	–
Glycoprotein IIb/IIIa Inhibitors	34.3%	–
ACE-Inhibitors	–	54.9%
Statins	–	56.2%

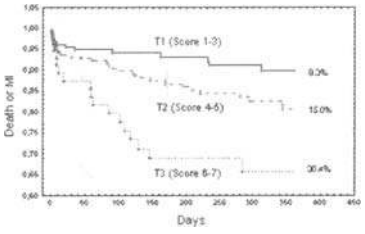
* Medication use reported for eligible patients without specific contraindications according to recommendations from the ACC/AHA guidelines; GP, glycoprotein;

Conclusions: Preliminary results from the CRUSADE quality improvement initiative demonstrate suboptimal adherence to the ACC/AHA guidelines for the management of NSTE ACS. These data provide targets for interventions designed to improve the quality of care for high-risk patients with NSTE ACS.

3306 Sustained prognostic value of TIMI risk score in acute coronary syndromes

P. Araujo Goncalves, J. Ferreira, C. Aguiar, M. Trabulo, J. Aniceto Silva, R. Seabra-Gomes. *H Santa Cruz, Cardiologia, Carnaxide, Portugal*

Background: TIMI Risk Score is a simple clinical score for short-term risk stratification and for therapeutic decision-making in patients (Pts) with non-ST-elevation acute coronary syndromes (ACS). Nevertheless, its value for long-term prognosis is unknown.
Objective: We sought to evaluate the prognostic value of TIMI Risk Score at 1 year after ACS.
Methods: We studied 433 consecutive Pts, admitted to our CCU with ACS (mean age 64±11 years, 21% female, 67% with unstable angina). The 7 variables of the TIMI Risk Score were applied at admission. Prognostic value was evaluated by the combined endpoint of death or myocardial infarction (MI) at 30 days and at 1 year.
Results: The incidence of death/MI at 30 days follow-up was 4.5% for Pts with TIMI Risk score 1-3 (T1, n=157), 6.8% for Pts with TIMI Risk score 4-5 (T2, n=220) and 14,3% for TIMI Risk score 6-7 (T3, n=56). Between 30 days and 1 year, the incidence of the combined endpoint was 4% for T1, 8.8% for T2 and 16.7% for T3 and at 1 year 8.3%, 15% and 30.4% respectively. The cumulative incidence of death or MI at 1 year was significantly higher in T2 or T3 versus T1 (p=0.006).



Cumulative incidence of death or MI.

Conclusion: Besides being a good prognostic indicator at 30 days, the TIMI Risk Score seems to keep it's prognostic value at one year follow-up.

PERICARDITIS

3307 Is two-dimensional echocardiography sensitive and specific enough to diagnose cardiac tamponade?

A.D. Ristic[1], A. Kusic-Pajic[1], P.M. Seferovic[1], B. Obrenovic-Kircanski[1], R. Maksimovic[1], G. Ristic[1], M. Ostojic[1], B. Maisch[2]. *[1]University Inst. for Cardiovasc. Dis., Belgrade, Yugoslavia; [2]Philipps University Marburg, Dept. of Internal Medicine-Cardiology, Marburg, Germany*

Echocardiographic prediction of cardiac tamponade is controversial. The aim of the present study was to evaluate sensitivity and specificity of two-dimensional (2D) echocardiographic signs of cardiac tamponade in comparison to the invasive hemodynamics.

Methods: In 50 pts with large pericardial effusions (PE) (58% males, age 54.2±9.6 yrs, PE> 2 cm anteriorly) echocardiography was performed immediately before cardiac catheterization and pericardiocentesis. Diagnosis of cardiac tamponade was established only if both clinical (jugular venous distention, tachycardia, hypotension, pulsus paradoxus) and hemodynamic signs were present (elevation and equilibration of intrapericardial and right atrial (RA) pressures).

Results: According to the clinical and hemodynamic criteria 8/50 pts (16%) undergoing pericardiocentesis for large symptomatic PE had cardiac tamponade. Average volume of PE evacuated by pericardiocentesis in pts with tamponade was larger but not significantly different in comparison to pts without tamponade (725±344 ml vs. 649±421 ml; p=0.317). Among the investigated 2D-echocardiographic parameters (table) RA collapse and sustained inferior vena cava (VCI) congestion had 100% sensitivity, but low specificity. Right ventricular (RV) diastolic collapse and "swinging heart" had high sensitivity, but low specificity. In contrast, left atrial (LA) collapse was highly specific, but had low sensitivity, with a positive predictive value of 42.9%. Sudden leftward motion of the interventricular septum (IVS) was the only parameter with both high sensitivity and specificity, and the positive predictive value of 80% for the diagnosis of cardiac tamponade.

N=50 pts	RA collapse (45 pts)	LA collapse (4 pts)	RV collapse (38 pts)	Swinging heart (29 pts)	Leftward IVS motion - inspirium (10 pts)	VCI congestion (29 pts)
Sensitivity (%)	100	37.5	75	75	100	100
Specificity (%)	11.9	90.5	23.8	45.2	95.2	50
Positive predictive value (%)	17.8	42.9	15.8	20.7	80	27.4

Sensitivity, specificity, and positive predictive value of the 2D-echocardiographic signs of cardiac tamponade. RA - right atrium, RV - right ventricle, LA - left atrium, VCI - inferior caval vein, IVS - interventricular septum.

Conclusion: Leftward IVS motion in inspirum is a valuable 2D-echocardiography sign of cardiac tamponade that should be systematically investigated in patients with large PE.

3308 Effect of cardiac tamponade in left ventricular pressure volume relations in humans

K.E. Vardakis[1], G.E. Kochiadakis[1], E.N. Simantirakis[1], N.E. Igoumenidis[1], E.I. Skalidis[1], M.I. Hamilos[1], P.E. Vardas[2]. *[1]Heraklion University Hospital, Cardiology Dept., Heraklion, Crete, Greece; [2]Heraklion University Hospital, Cardiology, Heraklion, Greece*

Background: In this study we use, for first time in humans, the analysis of left ventricular (LV) pressure-volume loops to estimate the influence of cardiac tamponade in LV performance. This method is considered independent from preload and afterload changes, which are extreme during cardiac tamponade.

Methods: We studied eight patients (4 men, mean age 53±6 years). All patients were free of previous cardiovascular events, with large pericardial effusion of neoplasmatic origin and were scheduled to undergo percutaneous balloon pericardiotomy. According to our protocol, we infused sucrose solution in the evacuated pericardial space (after successful percutaneous pericardiocentisis) until achievement of cardiac tamponade or strong patient discomfort. A conductance catheter was used to analyse LV pressure volume loops continuously and compute LV mechanics at baseline and after tamponade.

LV end-systolic elastance (EES), preload recruitable stroke work (PRSW), cardiac index (CI) and stroke work (SW) were derived as indexes of systolic performance while LV end-diastolic volume (LVEDV), LV end-diastolic pressure (LVEDP), LV chamber stiffness index (LVCSI) and time constant of isovolumic relaxation time (Tau) as indexes of diastolic function.

Results: Indexes of cardiac filling (LVEDV: 131.0±6.5 vs 90.4±5.0 ml, LVEDP: 10.3±1.3 vs 15.7±1.5 mmHg, $p<0.05$ for both) seemed to be impaired during tamponade as well as cardiac performance (CI: 3.5±0.3 vs 2.6±0.4 L/min.m^2, SW: 4818±626 vs 2410±283 mmHg.ml, p=0.028 for both) and LV diastolic function (LVCSI: 0.023±0.01 vs 0.037±0.02, Tau: 40.8±4.6 vs 32.3±2.8 sec, $p<0.05$ for all). In contrast, the preload-independent indexes of myocardial contractility showed no clear change at baseline and tamponade (EES: 1.08±0.19 vs 1.08±0.24 mmHg/ml, p=0.599, PRSW: 97.4±9.7 vs 94.9±14.6 mmHg, p=0.249).

Conclusions: Cardiac tamponade induces severe filling disturbances and impairs diastolic performance of the normal human heart but does not impair intrinsic myocardial contractility. Our results further support the concept that treatment should be focused in improving LV filling while the use of inotropic agents may be of limited value in the treatment of cardiac tamponade

3309 Tissue Doppler analysis of mitral annulus motion in patients with constrictive pericarditis

T. Butz[1], L. Faber[1], Y. Kim[1], C. Schaksmeier[1], N. Bogunovic[1], R. Koerfer[2], D. Horstkotte[1]. *[1]Heart Center North Rhine-Westphalia, Cardiology Dept., Bad Oeynhausen, Germany; [2]Heart Center North Rhine-Westphalia, Dept of Thorac Cardiovasc Surg, Bad Oeynhausen, Germany*

Background and Introduction: Clinical diagnosis of constrictive pericarditis (CP) is difficult. It has been suggested that tissue Doppler (TVI) analysis of mitral annulus (MA) motion might be a helpful tool to differentiate CP from diastolic myocardial dysfunction. In patients (pts.) without CP, early transmitral flow velocity (E) increases with higher filling pressure (PCW), while early diastolic MA velocity (E') is reduced, resulting in a positive linear correlation between E/E' and PCW. In contrast, E' has been reported to be normal despite high PCW in CP pts. We therefore studied the relationship between E, E' and PCW in pts. with documented CP who had undergone complete invasive hemodynamic assessment.

Results: From 14 CP pts. (mean age: 56±15 years), 9 were in sinus rhythm (SR), 5 in atrial fibrillation (AF). Coexistent mitral valve stenosis (MS) or replacement (MVR) was present in 3, aortic valve replacement (AVR) in 2, a cardiac post-radiation syndrome in 1, and coronary artery disease (CAD) in 5 pt(s). Systolic LV function was normal, mean pulmonary wedge pressure (PCW) 20±5, and LV enddiastolic pressure 22±5 mm Hg. Left atrial diameter was 50±13 mm. E was 112±55 cm/s, deceleration time of E 134±36 ms, and E' 13±6 cm/s. An E' <8 cm/s was only found in the pt. with post-radiation syndrome. After exclusion of the 3 pts. with MS or MVR, the E/E' ratio and PCW showed a significant inverse correlation (E/E' = 17.0 - 0.5 x PCW; r=0.78; $p<0.01$) opposed to that described in diastolic myocardial dysfunction.

Conclusion: TVI in combination with transmitral flow analysis is a helpful new tool to differentiate severe LV filling abnormalities, independent of cardiac rhythm, and especially for the peri-operative assessment of CP. The inverse correlation of E/E' and PCW may be impaired, however, if mitral valve or myocardial disease coexist with CP.

3310 Troponin I release in idiopathic acute pericarditis: clinical and prognostic value

M. Imazio, B. Demichelis, E. Cecchi, M. Giuggia, R. Trinchero. *Maria Vittoria Hospital, Cardiology Dept., Turin, Italy*

Background: Acute pericarditis has been recently reported as a possible cause of non-coronary heart disease systemic release of troponin I (Tn I). The prognostic value of this observation remains unknown.

Aim: To investigate the frequence of Tn I release in patients with idiopathic acute pericarditis and to evaluate its clinical and prognostic value.

Methods: 118 consecutive cases of idiopathic acute pericarditis (age 49,2 ± 18,4; 61 males) were included from January 2000. A highly sensitive colorimetric immunoassay was used to measure Tn I (lowest measurable concentration of 0,04 ng/ml, reference interval: 0,00-0,1 ng/ml and an acute myocardial infarction -AMI- threshold of 1,5 ng/ml). Creatine Kinase(CK)-MB enzyme release was measured using an immunoinhibition assay (lowest measurable concentration of 1,0 U/l, reference interval: 0,0-6,0 ng/ml).

Results: A Tn I rise was detectable in 38 patients (32,2% of cases). The following characteristics were more frequently associated with a positive Tn I test: younger age (31,9 ± 11,4 vs 57,3 ± 15,1 years, $p<0,001$), male gender (71,0 vs 42,5%, p=0,007), ST-elevation (97,4 vs 51,2%, $p<0,001$) and pericardial effusion (86,8% vs 60,0%, p=0,007) at presentation. Among patients with a positive Tn I test a borderline or mild increase of Tn I (<0,4 ng/ml) was detected in 29 cases (group I: 76,3%) without a CK-MB elevation. An increase beyond AMI threshold was present in 9 cases with an elevated CK-MB value and echocardiographic diffuse or localized abnormal ventricular wall motion (group II: 23,7%; mean Tn I: 11,6 ± 7,8 ng/ml; mean CK-MB peak 23,6 ± 19,0 U/l). Coronary artery disease was excluded by angiography and myopericarditis was diagnosed. In group II Tn I temporal pattern was similar to that seen in AMI with levels detectable for 5-6 days while in group I the temporal pattern was shorter (2-3 days). A mean follow-up of 18 months (range 3-24 months) was performed. A similar rate of complications was found in patients with a positive or a negative Tn I test (recurrent pericarditis: 13,2 vs 15,0%; constrictive pericarditis: 0 vs 1,3%, for all p=NS; no cases of cardiac tamponade or residual left ventricular dysfunction were detected).

Conclusions: In idiopathic acute pericarditis Tn I elevation is the biochemical evidence of myocardial inflammatory damage. It is commonly associated with young age, male gender, ST-elevation and pericardial effusion at presentation and sometimes is expression of myopericarditis. Unlike acute coronary syndromes Tn I is not a negative prognostic marker in idiopathic acute pericarditis.

3311 Pericardial friction rub and effusion in pericarditis

S. Natan[1], B.T.J Meursing[2], E.J.P Lamfers[2], A.J.M Oude Ophuis[2], F.W.A Verheugt[3]. [1]*University Medical Center Nijmegen, Heartcenter, Department of Cardiology, Nijmegen, Netherlands;* [2]*Canisius-Wilhelmina Hospital, cardiology, Nijmegen, Netherlands;* [3]*University Medical Center Nijmegen, Heartcenter, Nijmegen, Netherlands*

Background: In clinical pericarditis often a pericardial friction rub (PFR) is heard and pericardial effusion (PE) is seen on echocardiography. However, sometimes a rub is heard without PE and sometimes the other way around. The relationship between the presence of a rub and the amount of PE, if any, has hardly been studied in non-surgical pericarditis.
Methods: In 202 non-surgical patients (pts) a clinical diagnosis of pericarditis was made using history, fever, lab tests and ECG. The presence of a pericardial friction rub was scored and PE was quantitatively assessed by echocardiography: physiologic (<1mm), moderate (1-10mm), large (>10mm).
Results:

Amount of PE	Number of patients	Number of PFR	Percentage of PFR
Large	61	25	41
Moderate	48	27	56
Physiologic	93	50	54
Total	202	102	50

There was no relation between the amount of PE and the presence of PFR ($p>0.1$). However when the suspected aetiology was taken into account, there was a statistical significant relation with the presence of a rub ($p=0.0006$).
In 4/13 (31%) of pts with auto-immune disease as cause for pericarditis and in only 2/18 (11%) of pts with neoplasma PFR was heard. On the other hand, in 17/26 (65%) of post-infarction pts and in 37/64 (58%) of infectious pericarditis PFR was heard. Finally, a rub was heard in 40/78 (51%) of the idiopathic group. Taking into consideration that many cases of idiopathic pericarditis are infectious in origin and thus acute, it seems that acute pericarditis is more often correlated with a rub than the chronic one. Given the fact that fibrin deposition into the pericardial cavity is maximal at 24-48 hours after infection and that fibrinolysis occurs 6-8 days after it, we suggest that PFR is correlated with the presence of fibrin strands rather than with the amount of PE.
Conclusion: Although often suggested by clinicians, we could not identify a correlation between a PFR and the amount of PE in this large study. However, acute causes of pericarditis are more often associated with a rub suggesting that rather than the rough pericardial surfaces fibrin strings cause the rub, where they may serve as snares.

3312 Colchicine for recurrent pericarditis: influence of previous treatment with corticosteroids

J. Guindo[1], Y. Adler[2], A. Rodriguez de la Serna[1], A. Bayés Genis[1], C. Martin Riesco[1], Y. Finkelstein[2], A. Bayes de Luna[1]. [1]*Hospital de Sant Pau, Cardiology, Barcelona, Spain;* [2]*Rabin Medical Center, Cardiology, Petah Tiqva, Israel*

Objective: To determine the efficacy of colchicine in the treatment of recurrent pericarditis in patients refractory to corticosteroid therapy.
Background: Recurrence is one the major complications of acute pericarditis and its management is often frustrating. Corticosteroids are often attempted and frecuently unsuccessful and with significant side effects.
Methods: We included 51 patients (36 men; mean age 40.8 ± 18.7 years) with recurrent pericarditis. Prior treatment had included aspirin or other non-esteroidal anti-inflammatory drugs (n=47) and prednisone (n=29). Patients received colchicine (1-2 mg/day) for a median of 12 months (range (1-128) and were followed for a median of 36 (range 2-134 months).
Results: Patients receiving prednisone were older (42.2± 15.87 vs 39.0 ± 22.1 tears; p=0.028), had more often a secondary form of pericarditis (48.3% vs 18.2%; p= 0.027) and a greater number of relapses before colchicine was started (4.51±3.34 vs 2.54±0.67; p=0.0009). Fourteen of 29 patients who were receiving prednisone before colchicine was started (48.27%) presented with a total of 19 new recurrences. By contrast, only six of 22 patients (27.27%) who did not receive prednisone relapsed after colchicine was started (total, 7 recurrences). However, this difference was not statistically significant ($p = 0.139$). Interestingly, the benefitial effect of colchicine was greater in patients who were receiving prednisone before treatment was begun. Patients who were on prednisone before the initiation of colchicine had a significantly greater increment in the symptom-free periods during colchicine therapy (22.5±23.5 months vs. 4.6±4.7 months, p=0.0004), after colchicine was stopped (38.2±38.9 months vs. 14.4±15.7 months, p=0.0016), and for the total follow-up period (54.2±37.4 months vs. 21.3±19.2 months, $p <0.0001$).
Conclusions: Colchicine is highly effective in patients with recurrent pericarditis that are not properly controlled with corticosteroid therapy. These data suggest that colchicine should be added to succesfully withdraw corticoids and avoid adverse effects of prolonged corticosteriod therapy.

PROGNOSTIC FACTORS FOR CARDIOVASCULAR DISEASE IN HEALTHY POPULATIONS

3313 The prognostic value of the electrocardiogram in the west of Scotland coronary prevention study

P.W. Macfarlane[1], J. Norrie[2] on behalf of the WOSCOPS Executive Committee. [1]*University of Glasgow, Medical Cardiology Dept., Glasgow, United Kingdom;* [2]*University of Glasgow, Statistics, Glasgow, United Kingdom*

Introduction: The West of Scotland Coronary Prevention Study (WOSCOPS) recruited 6,595 men aged 45-65 years with moderate hyperlipidemia and no previous myocardial infarction (MI) who were randomised to treatment either by placebo or Pravastastin 40mg nocte. Patients were followed for a mean of 4.9 years and all events, cardiovascular or otherwise, were recorded over the period of the trial.
Aim: The objective of this sub study was to evaluate the prognostic value of the ECG with respect to the study endpoints, namely definite coronary heart disease (CHD) death and non fatal MI, as well as all cause mortality.
Methods: 12 lead ECGs were recorded using a computer assisted electrocardiograph and transmitted to a central core ECG lab. ECGs were recorded at baseline, annually and at the study run out phase. Minnesota Coding was undertaken in an automated fashion but all codes were reviewed manually. Clinical events were noted throughout the study and adjudicated by an endpoints committee. Minor ECG changes were defined as Minnesota Codes 4-2, 4-3, 5-2, and 5-3, as 4-1 and 5-1 were exclusion criteria. Ten second baseline ECG recordings were used to derive the standard deviation of normal RR intervals (SDNN) and to calculate an index of cardiac vagal tone. Left ventricular mass was calculated using an ECG based equation. Frontal plane T wave axis and the T amplitude in Lead I were also included in the analysis.
Results: An analysis of run out ECGs showed a highly significant reduction in incident T wave abnormalities (5-2) in the treated compared to the placebo group ($p=0.009$). With respect to the primary endpoint of definite fatal or non fatal MI, LV mass index ($p=0.026$), T axis ($p < 0.0001$), T amplitude ($p=0.0005$) and heart rate ($p = 0.006$) were all predictive in a multivariate analysis which included treatment, age, smoking history, use of nitrates,diabetes, Rose angina, family history of premature CHD death,widowhood, diastolic BP and cholesterol:HDL ratio. Similar results were found for the extended primary endpoint which included definite or suspect CHD death or non fatal MI. With respect to all cause mortality, minor ST-T changes ($p=0.0045$), SDNN ($p < 0.0001$) and T axis ($p < 0.0001$) were all significantly predictive of outcome in a multi variate analysis. Cardiac vagal tone was highly predictive of outcome ($p < 0.005$) in univariate analyses only.
Conclusion: These results indicate that the electrocardiogram is of significant prognostic value in a population of middle aged men who have not sustained a previous myocardial infarction.

3314 The cardiovascular life course of obese and overweight persons, compared to those with normal weight

A. Peeters[1], J.J. Barendregt[1], F.J. Willekens[2], A.A. Mamun[2], L. Bonneux[1] on behalf of NEDCOM. [1]*Erasmus University, Dept. of Public Health, Rotterdam, Netherlands;* [2]*University of Gronigen, Population Research Centre, Gronigen, Netherlands*

Background Overweight and obesity have been linked to an increased risk of mortality, disability and a number of diseases such as cardiovascular disease, cancer and other metabolic disorders. Their potential impact on life expectancy and lifetime experience of cardiovascular disease has not yet been fully described. Here we compare the total and cardiovascular disease specific life expectancies associated with overweight and obesity at age 40.
Methods We analysed individuals from the Original Framingham Heart study, aged 30-49 and grouped into normal weight, overweight or obese (based on body mass index) at baseline. Mortality and cardiovascular disease incidence rates specific for age and body mass index group were derived by survival analysis within sex and smoking status strata. From these we constructed multistate life tables describing the states free of cardiovascular disease and with cardiovascular disease for each body mass index group and estimated life expectancy and life years lived with cardiovascular disease over the life course. Confidence intervals were derived using a bootstrap procedure.
Results We found surprisingly large decreases in life expectancy associated with overweight and obesity, with forty year old non-smokers losing 3 years due to overweight and 6-7 years due to obesity. Obese smokers lost a striking 13-14 years compared to normal weight non-smokers. Cardiovascular disease caused approximately half of the years of life lost in obese subjects. Although obese people suffer a large decrease in total life expectancy they lived on average 0.6 years more with cardiovascular disease than those with normal weight.
Conclusions Obesity and overweight in adulthood are associated with large decreases in life expectancy, comparable to smoking. As with smoking, the loss of life due to obesity continues to occur decades after exposure. Even taking into account this shortened life expectancy, obese people spend a greater number of years with cardiovascular disease than those with normal weight: obesity both compresses healthy life and increases years lived with disease. The rising world-wide prevalence of obesity highlights the urgent need for more efficient prevention and treatment of overweight and obesity.

3315 Vitamin B6 is a predictor of long-term vascular events in a healthy population in addition to homocysteine and C-reactive protein levels

D. Vanuzzo[1], D. Gregori[2], L. Pilotto[3], P. Fioretti[3], M. Carluccio[4], S. Diviacco[5], M. Cattaneo[6], R. De Caterina[7]. [1]*Ospedale S. Maria della Miseridordia, Udine, Italy;* [2]*University of Trieste, Dept of Epidemiology, Trieste, Italy;* [3]*S.Maria della Misericordia Hospital, Udine, Italy;* [4]*University of Pisa, Cardiology Dept., Pisa, Italy;* [5]*Università di Udine, Dip di Scienze e Tecnologie Biomediche, Udine, Italy;* [6]*University of Milan, Milan, Italy;* [7]*Chair of Cardiology, Univ. of Chieti, Ospedale S. Camillo De Lellis, Chieti, Italy*

Background: Plasma total homocysteine (tHcy) has been recently proposed as a novel marker of cardiovascular risk. Plasma tHcy levels are affected by nutritional intake of vitamin B12, folate, and vitamin B6.
We assessed the predictive value of tHcy, vit. B12, folate and vit. B6 on the long-term occurrence of cardiovascular events in a prospectively recruited population in a nested case-control study with 12-years follow-up, out of the "Martignacco Project", an ongoing epidemiological and primary prevention trial on North-Eastern Italian middle aged men and women initiated in 1987.
Methods: Within 1,051 subjects (509 men and 542 women) recruited in 1987, 69 incident (15 fatal) coronary events (18 myocardial infarctions; 51 newly documented myocardial ischemia) and 40 incident (5 fatal) cerebrovascular events (27 definite strokes; 13 transient ischemic attacks) occurred, until June 1999, in subjects originally free of atherosclerotic cardiovascular disease (cases, n=109). 109 control subjects (subjects remained free of events in the same follow-up period) were matched to cases according to the following variables: age, sex, smoking, hypertension, dyslipidemia, and body-mass-index. On baseline serum samples, obtained from the initial cohort in 1987, tHcy plasma concentration, folate and vitamins B12 and B6, as well as C-reactive protein (CRP) levels, were measured.
Results: We found a significant graded association between tHcy levels and the risk of cardiovascular events (odds ratio, OR, for lowermost vs uppermost quartile = 1.32, 95% CI 1.01-1.73). Serum folate and vitamin B12 did not significantly differ between cases and controls, but were negatively ($P<0.01$) correlated with tHcy. Vitamin B6 did not show correlations with tHcy levels, but differed significantly between cases and controls: For subjects in the uppermost quartile vs the lowermost quartile of vit. B6, OR=0.68 (95% CI 0.49-0.95). For subjects in the lowermost quartile of vitamin B6 and the uppermost quartile of tHcy, the OR was 2.79 (95% CI: 2.06-3.77). Cases and controls were not different as to C-reactive protein levels.
Conclusion: These data confirm the role of tHcy as a long-term independent risk factor for cardiovascular events, but also support the additive importance of a "novel" marker, plasma vitamin B6, independent of tHcy and CRP.

3316 Prognostic risk factors for cardiovascular events, in subjects with familial hypercholesterolemia: 15 years follow-up (1987-2002)

J. Skoumas[1], C. Pitsavos[2], D.B Panagiotakos[2], N. Papaioannou[1], J. Skoumbourdis[1], M. Toutouza[1], C. Stefanadis[2], P.K. Toutouzas[2]. [1]*University of Athens, Hippokration Hospital, Athens, Greece;* [2]*University of Athens, School of Medici, Cardiology Clinic, Athens, Greece*

Background: It is estimated that 200 out of 100,000 individuals suffers from familial hypercholesterolemia, worldwide. However, the influence of several risk factors on all cause mortality, in this subgroup of subjects, has rarely been evaluated. In this work we evaluate the prognostic significance of several risk factors on the outcome of cardiovascular events, in subjects with familial hypercholesterolemia.
Methods: During a 1987-2002, we studied 639 individuals (230 males 49 ± 11 years old and 409 females, 52 ± 9 years old) with defined familial hypercholesterolemia. Baseline measurements of arterial blood pressures, fibrinogen levels, glucose concentration, total cholesterol levels, high and low density lipoprotein cholesterol, Apo A-I & B, Lp(a), and triglycerides were evaluate for their prognostic significance, with respect to age, sex and the prevalence of the common cardiovascular risk factors (body mass index, smoking, hypertension, diabetes mellitus) as, potential, confounders. All laboratory measurements were quality controlled and a detailed database was developed. Cox proportional hazards models were applied in order to evaluate the investigated associations.
Results: During the follow up period 87 cardiovascular events were observed in familial hypercholesterolemic patients. Fifty-three (61%) of the events were observed in males and the rest of them in females (39%). The application of the log-rank test raised the superiority of women compared to men in the events free survival ($p = 0.005$). The age adjusted 15-year event rate was 3% (87 events/2915 person-years). The multivariate analysis showed that smoking (hazard ratio=2.28, $p = 0.023$), LDL/HDL ratio (HR=1.23, $p = 0.041$) and presence of hypertension (HR=3.18, $p = 0.036$), were independently associated with 15-year cardiovascular events in the investigated sample. The applied sensitivity – specificity analysis showed that LDL values 8-times than HDL constitute a cut-off point that predicts with accuracy an adverse cardiovascular outcome. No associations were found between the outcome and the other investigated factors in the long-term assessment of our patients.
Conclusions: With the power of the 15 years of prospective evaluation our analysis showed that increased smoking habits, presence of hypertension and LDL levels 8-times more than HDL predicts an adverse cardiovascular event, in patients with familial hypercholesterolemia. No associations were found between the outcome and the other investigated clinical and biochemical factors.

3317 Triglycerides as predictor of late mortality in healthy hyperlipidemic men

E. Hjerkinn[1], L. Breivik[2], L. Sandvik[2], H. Arnesen[3], I. Hjermann[1]. [1]*Ullevaal University Hospital, Div. of Cardiology,Dpt. of Prev. Card., Oslo, Norway;* [2]*Ullevaal University Hospital, Research Forum, Oslo, Norway;* [3]*Ullevaal University Hospital, Division of Cardiology, Oslo, Norway*

Objective: The aim was to study cholesterol, triglycerides (TG), smoking and blood pressure as potential predictors of 24 years mortality in hyperlipidemic middle aged men.
Background: We studied 104 healthy men aged 40-49 years with start values of total serum cholesterol > 7.75 mmol/l and fasting triglycerides >2.95 mmol/l within the randomised diet and smoking cessation trial of the Oslo study (n=1232).
Results: 33 subjects died during the 24 years observation period.
Only triglycerides and smoking were significantly related to mortality.
Analysis for trend through quartiles of triglycerides (table I) showed statistical significance (p= 0.049).
Subjects in the lowest TG quartile (2.95-3.18 mmol/l) had 70% reduction in mortality compared to the remaining subjects (>3.18 mmol/l) (RR= 0.30, 95% CI 0.10-0.90, p= 0.014). Non-smokers had 60% reduced mortality compared to smokers (RR=0.40, 95%CI 0.17-0.94, p=0.019).
When TG and mortality were studied in a Cox regression analysis, with age and smoking as independent variables, TG was significantly related to mortality, 1.quartile vs 2.,3. and 4th quartile: RR=0.24, (95% CI 0.07-0.77), p=0.02. For smoking the Cox analysis showed a RR=0.39 (95%CI 0.15-1.02) p= 0.054.

Triglycerides	1.quartile	2.quartile	3.quartile	4.quartile
mmol/l	2.95 - 3.18	3.18 - 3.8	3.8 - 4.5	4.5 - 13.6
Dead (n)	3	9	12	9
Mortality % p=0.049	11.5	34.5	46.2	34.6

Triglycerides (mmol/l), quartiles vs Mortality

Conclusion: This study indicates that high levels of fasting triglycerides (>3.2 mmol) are associated with 3-fold increased late mortality in healthy men with combined hyperlipidemia.

3318 Conventional risk factors underestimate subclinical coronary artery disease in younger asymptomatic subjects

J. Shemesh[1], S. Segev[2], D. Haratz[3], M. Motro[1]. [1]Cardiac Rehabilitation Institute, [2]Institute of Medical Screening, [3]Lipid Research Institute, Sheba Medical Center, Ramat Gan, Israel

Background: The incremental value of coronary artery calcification (CAC) as compared to conventional risk factors in identifying subjects with subclinical coronary artery disease (CAD) has been unclear. We defined subclinical CAD as the presence of CAC, detected by multi-row detector spiral computed tomography (MDCT), and sought to compare its presence with the conventional coronary risk factors in relation to age.
Methods: We studied 445 participants (mean age 55±7 years old, 89% male) in the annual check-up program at our institute. Subjects over 40 years without known CAD were included. All underwent routine physical examination, ECG stress test, blood analysis and MDCT with prospective ECG triggering. Subjects were divided into a younger age group below 50 years (n=123, mean age 46±4) and an older one over age 50 (n=322, mean age 58±6).
Results: The prevalence of CAC was 27% in the youngers and 60% in the older group (p<0.01). Median (Q1,Q3) of total calcium score were 22 (13,73) and 54 (13,128) respectively (p<0.01). Prevalence of risk factors are given in the table.

Age group:	40-50 years	51-75 years
Hypertension	16%	31% **
Smoking	11%	18%
Diabetes Mellitus	3%	9% *
Hypertrigliceridemia	27%	20%
LDL>160mg%	10%	10%
HDL<40mg%	55%	38% *

*p<0.05, **p<0.01

Logistic regression analysis for the prediction of CAC presence was not significant in the younger group for all the risk factors while in the older subjects hypertension, smoking and hyperlipidemia (all types) were significant independent predictors of CAC with O.R. (95% C.I.) of 2.53 (1.35 - 4.1,p=0.025), 1.42 (1.1-1.8, p=0.025) and 1.26 (1.1-1.9, p=0.049) respectively.
Conclusions: In this cohort, conventional risk factors failed to predict the presence of subclinical CAD in asymptomatic subjects younger than 50 years, supporting the potential of CAC detection as a screening tool for this age group.

BENEFITS OF CARDIAC REHABILITATION

3319 Reduction of absolute coronary risk following a combined lifestyle intervention programme in patients with coronary heart disease

L. Sommervoll[1], K. Peersen[1], T. Holthe[1], T. Liodden[1], L. Johnson[1], I. Ford[2], J.E. Otterstad[1]. [1]Centralhospital of Vestfold, Cardiac rehabilitation, Tønsberg, Norway; [2]University of Glasgow, Robertsons Institute, Glasgow, United Kingdom

Objective: In order to evaluate the prognostic impact of a multidisciplinary lifestyle intervention programme (IP) we included 162 males with documented coronary heart disease (CHD) for a 2-year follow-up study. They were randomised into two groups: 1. IP group (n=79) with regular physical exercise (physiotherapist), dietary advice (dietician) and general lifestyle measures including smoking cessation (study nurse). A research physician was responsible for their medical treatment in accordance with recent guidelines for secondary prophylaxis. 2. Usual care group (UC, n=83), which included regular follow-up in our outpatient clinic or by their general practitioner.
Method: The absolute CHD risk at baseline and during follow-up was based upon the Cox proportional hazards model applied in the estimation of 5-year risk of fatal CHD and non-fatal myocardial infarction in the placebo group of WOSCOPS. All our patients were categorised as having angina pectoris according to the Rose questionnaire. The following cluster of risk factors were put into the model: Age, blood pressure, history of hypertension, family history of CHD, total cholesterol/HDL ratio, smoking status, minor ST-T changes in the ECG and fasting blood glucose.
Results: 5-year risk of fatal CHD and non-fatal myocardial infarction(% ± 1SD)at baseline: IP-group=15.3±9.0, UC-group=14.0±8.6, at 6 months: IP=11.7±9.0, UC=12.9±10.2, at 2 years: IP=12.2±11.9, UC=13.7±11.8. p=0.008 for difference in change from baseline to 6 months, p=0.023 for difference in change from baseline to 2 years. The use of statins, betablockers, aspirin and ACE-inhibitors was identical in both groups. During the study there were 35 cardiovascular hospitalisations in the IP group and 52 in the UC group.
Conclusions: The CHD risk was reduced by approximately 20% in the IP group versus no change in the UC group in spite of the fact that both groups had comprehensive and identical medical prophylaxis.

Group	Baseline	6 months*	2 years**
IP (n=79)	15.3 + 9.0	11.7 + 9.0	12.2 + 11.9
UC (n=83)	14.0 + 8.6	12.9 + 10.2	13.7 + 11.8

3320 Two-year benefit of cardiac rehabilitation program on quality of life and cost-effectiveness in patients with coronary artery disease

C.M. Yu[1], J. Chau[1], L.S.W. Li[2], S.L. Kong[1], S. McGhee[3], B.M.Y. Cheung[1], C.P. Lau[1]. [1]Queen Mary Hospital, Department of Medicine, Hong Kong, Hong Kong; [2]Tung Wah Hospital, Cardiac Rehabilitation Centre, Hong Kong, Hong Kong; [3]University of Hong Kong, Department of Community Medicine, Hong Kong, Hong Kong

Background: With the changing paradigm of managing patients with coronary artery disease (CAD) in the last decade and the relatively few randomized, controlled studies, it is uncertain if a cardiac rehabilitation program (CRP) could be cost-effective and lead to improvement of quality of life (QOL). This study evaluated the effect of CRP on QOL and its cost-effectiveness upon completion of the program at 2-year.
Methods: A prospective, randomized, controlled study was performed in 269 patients (mean age of 64±11 years, 76% male) with recent acute myocardial infarction (AMI, n=193) or after elective percutaneous transluminal intervention (PCI, n=76). They received either an 8-week CRP (n=181) or conventional therapy (control group, n=88) at a ratio of 2 to 1. QOL assessment (SF-36 and Symptoms Questionnaire) was performed in all the 4 phases. Direct healthcare cost was calculated while cost-utility of CRP was estimated as money spent (in US$) per quality adjusted life-year (QALY) gained. The prescription rates of statin and angiotensin converting enzyme inhibitor (ACEI) were 62% and 64% respectively. In the CRP group, 6 out of 8 SF-36 dimensions were significantly improved by phase 2, i.e. physical functioning (<0.001), physical role (<0.001), vitality (<0.001), social functioning (<0.001), emotional role (<0.001) and mental health (0.003); and were maintained at phase 4. Patients were less anxious and depressed, and were more relaxed and contented. In the control group, none of the SF-36 dimension was improved by phase 2, and was only 4 in phase 4 (physical functioning [p=0.002], physical role [p<0.001], vitality [p=0.04] and emotional role [p=0.01]) while bodily pain was increased. Symptoms were unchanged except increased hostility score. There was a significant gain in net time trade-off in the CRP group at phase 2 (CRP:0.031±0.028, controls: -0.049±0.031, p<0.005). The direct health care expenses in the CRP and control groups were $15,292 and $15,707/patient respectively. Therefore the cost-utility calculated was $640 saved/QALY gained in the CRP group. Saving attributable to CRP was primarily explained by the lower rate (13% Vs 26% of patients, X^2=3.9, p<0.05) and cost of subsequent PTCA (p=0.01).
Conclusions: In the contemporary era of managing patients with CAD where a high rate of statin and ACEI was used, a short-course CRP was highly cost-effective in the provision of better QOL in patients with recent AMI or PCI. In addition, the improvement of QOL is faster and sustained for at least 2 years after CRP.

3321 Activation of vagal reflexes, exercise training and long-term survival after a myocardial infarction

M.T. La Rovere[1], C. Bersano[2], M. Gnemmi[1], G. Specchia[2], P.J. Schwartz[3]. [1]Fondazione "S.Maugeri", IRCCS, Cardiology Dept., Montescano, Italy; [2]Policlinico di Monza, Cardiology, Monza, Italy; [3]Policlinico San Matteo, IRCCS, Cardiology, Pavia, Italy

We have previously shown that exercise-induced increase in Baroreflex Sensitivity (BRS) improves survival at the experimental level; such evidence is still lacking in patients after myocardial infarction (MI). We studied 95 consecutive male patients (pts) surviving a first uncomplicated MI who were randomly assigned to a 4-week endurance training period (T) or to no training (NT). Age (51±8 vs 52±8 years), site of MI (anterior 41% vs 43%), left ventricular ejection fraction (52±13 vs 51±14%), and BRS (7.9±5.4 vs 7.9±3.4 ms/mmHg) did not differ between the two groups. After 4 weeks training, BRS - as a marker of vagal reflexes - increased by 26% (from 7.9±5.4 to 9.9±6.4 ms/mmHg, p=0.04) in T, while it did not change in NT patients. During a 10-year follow-up, cardiac mortality was 12% in T and 26% in NT (p=0.07), while revascularization procedures were performed in 13% and 18% (NS) and beta-blockers were used in 16% and 13% (NS) in T and NT pts respectively. When T pts were grouped according to an exercise-induced increase in BRS > 3 ms/mmHg, cardiac mortality was strikingly lower compared to that of the T patients without such a BRS increase plus the NT patients (0/16 vs 18/79, p=0.04). Age, ejection fraction, anterior MI, myocardial revascularization and beta-blockade did not differ also between these two groups.
Conclusion: Post-MI exercise training can favourably modify long-term survival, provided that is associated to a clear shift of the autonomic balance toward an increase in vagal activity.

3322 The effect of exercise training on baroreflex control of heart rate and sympathetic activity in patients after acute myocardial infarction

J. Mimura[1], F. Yuasa[1], R. Yuyama[1], A. Kawamura[1], M. Iwasaki[1], T. Sugiura[2], T. Iwasaka[1]. [1]*Kansai Medical University, Cardiovascular center, Moriguchi-city, Japan;* [2]*Clinical Laboratory Medicine, Kochi Medical School, Kochi, Japan*

Autonomic imbalance has been found in patients after acute myocardial infarction (AMI) and have been associated with an increased risk of cardiac mortality. Although exercise training (ET) is associated with reduction in sympathetic tone, it is unknown whether ET improves sympathetic nerve traffic in patients after AMI. The aim of this study was to examine the effects of ET on baroreflex control of heart rate and muscle sympathetic nerve activity (MSNA) in patients after AMI.

Methods: Twenty patients with an uncomplicated AMI were prospectively randomized to training group (60% of peak heart rate, 40min/day, 4days/week, n=10, LVEF52±6%) or to control group (n=10, LVEF50±9%). Arterial blood pressure, heart rate and MSNA (microneurography at a peroneal nerve) were measured at baseline and after 4 weeks. Measurements were performed at baseline, and during baroreceptor stimulation (phenylephrine infusion) and baroreceptor deactivation (nitroprusside infusion).

Results: There were no significant differences in baseline data between the 2 groups. Peak oxygen consumption increased 9.0±6.6% with ET. Resting MSNA reduced from 31±13 to 24±8 bursts/min in training group but not in control group. Arterial baroreflex sensitivity did not change in both groups after 4 weeks. MSNA response to baroreceptor stimulation increased significantly in training group (%change of integrated activity from -43±23 to -70±23) but not in control group. In contrast, MSNA response to baroreceptor deactivation was similar in the 2 groups.

Conclusion: Exercise training lowers sympathetic nerve traffic in patients after AMI. This is accompanied by a restoration of baroreflex restraint on sympathetic nerve drive.

3323 Is coaching a substitute for cardiac rehabilitation in the management of cardiac risk factors?

M.V. Jelinek[1], M.J. Vale[1], D.L. Hare[2], J.D. Best[3] on behalf of COACH study group. [1]*St Vincent's Hospital, Department of Cardiology, Melbourne, Australia;* [2]*Austin & Repatriation Medical Centre, Department of Cardiology, Heidelberg, Australia;* [3]*The University of Melbourne, Department of Medicine, St Vincent's Hospital, Australia*

Background: We have shown that personalised coaching over the telephone (The Coach Program) is highly effective in improving risk factor (RF) status in patients with coronary heart disease (CHD). The COACH study has allowed us to contrast the effectiveness of coaching (TCP) with cardiac rehabilitation (CR) in its impact on RF.

Methods: Retrospective analysis of a multicentre RCT performed by cardiac units of six teaching hospitals in Melbourne, Australia. 679 (86%) of 792 patients with CHD completed a randomised trial of TCP vs usual care (UC) to improve RF status. CR was performed by 176 (53%) of 331 TCP patients and by 199 (57%) of 348 UC patients. Outcome measures included: changes in total cholesterol (TC), plasma triglyceride (TG), HDL-C and LDL-C, body weight (BW), fasting glucose (FBG), blood pressure (BP), cardiac depression score (CDS), Spielberger State (STAI) for anxiety, from baseline (in-hospital) to 6 months post-randomisation. In addition, 6 month post-randomisation levels of smoking, physcial activity, symptomatic status and general well-being were measured. Four groups were thus created: TCP/CR, TCP/No CR, UC/CR, and UC/No CR. The variables were compared by appropriate parametric and non-parametric statistics.

Results: Both TCP and CR produced a highly significant effects on the change in TC and LDL-C ($P<0.0001$). Neither intervention resulted in change of TG or HDL-C. Both TCP and CR resulted in large impacts on BW ($P<0.0001$). TCP/CR had a greater impact on regular walking patterns than either CR of TCP alone and all were superior to UC ($P<0.0001$). TCP/CR was more effective than either CR or TCP alone in reducing anxiety levels and all were superior to UC ($P=0.0045$). Both TCP and CR were effective in reducing the prevalence of chest pain and breathlessness and dyspnoea and in improving general health at 6 months post-randomisation ($P<0.0001$).

Conclusion: Retrospectively both TCP and CR were highly effective improving RF status. TCP is an alternative approach for the large proportion of patients not able or willing to attend CR.

3324 Evaluation of the immunoregulatory role of physical training in chronic heart failure: a randomized crossover study

S. Adamopoulos[1], J.T. Parissis[2], D. Karatzas[1], C. Kroupis[1], G. Karavolias[1], J. Paraskevaidis[1], A.J.S. Coats[3], D. Kremastinos[1]. [1]*Onassis Cardiac Surgery Center, Dept. of Cardiac Medicine, Athens, Greece;* [2]*"Amalia Fleming" Hospital, 1st Department of Cardiology, Athens, Greece;* [3]*Royal Brompton Hospital, Cardiology Dept., London, United Kingdom*

Objectives: To investigate the effects of physical training on peripheral immune responses expressed by circulating proinflammatory cytokines and soluble apoptosis mediators Fas (sFas) and Fas Ligand (sFasL), in chronic heart failure (CHF) patients and healthy controls.

Background: Recent investigations have shown an overexpression of circulating proinflammatory cytokines and soluble apoptosis mediators in patients with CHF, which may be related to their exercise intolerance and clinical deterioration.

Methods: Plasma levels of tumor necrosis factor-a (TNF-a), soluble TNF receptors I and II (sTNF-RI and sTNF-RII), interleukin-6 (IL-6), soluble IL-6 receptor (sIL-6R), sFas and sFasL were measured in 24 patients with stable CHF (New York Heart Association class II-III; left ventricular ejection fraction: 23.2±1.3%) and in 20 normal control subjects before and after a 12-week program of physical training in a randomized crossover design. Functional status of CHF patients and healthy controls was evaluated by using cardiorespiratory exercise test to measure peak oxygen consumption (VO2max).

Results: In CHF patients, physical training produced a significant reduction in plasma levels of TNF-a (7.5±1.0 vs 4.6±0.7 pg/ml, $p<0.001$), sTNF-RI (3.3±0.2 vs 2.7±0.2 ng/ml, $p<0.05$), sTNF-RII (2.6±0.2 vs 2.3±0.2 ng/ml, $p=0.06$), IL-6 (8.3±1.2 vs 5.9±0.8 pg/ml, $p<0.005$), sIL-6R (34.0±3.0 vs 29.2±3.0 ng/ml, $p<0.01$), sFas (5.5±0.7 vs 4.5±0.8 ng/ml, $p=0.05$) and sFasL (34.9±5.0 vs 25.2±4.0 pg/ml, $p<0.05$), as well as a significant increase in VO2max (16.3±0.7 vs 18.7±0.8 ml/kg/min, $p<0.001$).

Good correlations were also found between training-induced increase in VO2max and training-induced reduction in levels of proinflammatory cytokine TNF-a ($r=-0.54$. $p<0.01$) and apoptosis inducer sFasL ($r=-0.57$, $p<0.005$) in CHF patients. On the contrary, no significant difference in circulating cytokines and apoptotic markers was found with physical training in normal subjects.

Conclusions: Physical training modulates beneficially circulating proinflammatory cytokines and sFas/sFasL system in patients with CHF. These immunomodulatory effects may be related to the training-induced improvement in functional status of CHF patients.

GROWTH FACTOR REGULATION OF CARDIAC SIZE

3333 Variation at the beta-1 adrenoceptor gene locus affects left ventricular mass

T. Stanton[1], S. Padmanabhan[1], A. McConnachie[2], M. Upton[2], G. Watt[2], A.F. Dominiczak[1], A.G. Jardine[1], J.M.C. Connell[1]. [1]*University of Glasgow, Medicine & Therapeutics, Glasgow, United Kingdom;* [2]*University of Glasgow, General Practice, Glasgow, United Kingdom*

Aims: Left ventricular (LV) mass is an important cardiovascular risk factor. Beta-1 adrenoceptors (B1AR) are predominately located in the heart and their variation may, therefore, affect LV mass. A known polymorphism of the B1AR changes the amino acid at position 389 from glycine to arginine within an area critical for G-protein coupling and so cell signalling. The arginine-form of the receptor has been demonstrated to have increased GTP binding and cAMP generation. We therefore examined the relationship between this variation in the B1AR gene and the effect on LV mass in two contrasting populations.

Methods and Results: The first population studied consisted of 249 patients attending a renal clinic, 37% of whom were on renal replacement therapy (RRT). LV mass index (LVMI) was calculated by echocardiography. Individuals were categorised CC if both alleles encoded for arginine at position 389 and GG if both alleles encoded glycine. The GG group had a significantly higher LV mass index when compared to the other 2 groups, CG:GG $p= 0.02$ and CC:GG $p=0.01$ (see table). This relationship strengthened further when patients on RRT were omitted (CC:GG $p <0.001$).

	Number	% of 249	Mean LVMI
CC	127	51	130.1
CG	103	41	132.5
GG	19	8	160.8

Frequency of different B1AR genotypes and LVMI

In a second study, the effect of B1AR genotype on electrocardiographically measured LV mass was studied. 2280 subjects were genotyped for the B1AR polymorphism. No significant difference was found between LVMI and genotype after correction for age, BP and height and analysing separately for sex.

Conclusion: Genetic variation of the beta-1 adrenoceptor may well be important in defining LV mass in pathological circumstances.

3334 A specific type 4 cAMP phosphodiesterase isoform regulates beta-adrenoceptor signalling in neonatal rat cardiac myocytes

A. Sood[1], G. Baillie[2], T. McSorley[2], S.M. Cobbe[3], M.D. Houslay[2]. [1]Medical Cardiology/ Biochemistry Depts, Glasgow, United Kingdom; [2]University of Glasgow, Biochemistry, Glasgow, United Kingdom; [3]University of Glasgow, Medical Cardiology, Glasgow, United Kingdom

The large multigenic superfamily of phosphodiesterases (PDEs) provides the sole means of degrading the ubiquitous second messenger cyclic AMP (cAMP) within cells. Over 30 cAMP hydrolysing PDE isoforms are known and it is thought that this multiplicity allows discrete intracellular pools of cAMP to be maintained, thus enabling differential activation of the many targets of cAMP signalling.

We closely defined the PDE activities present in a neonatal rat cardiac myocyte culture model with particular focus on type 4 PDE (PDE4) where the precise isoforms present were defined by Western blotting and RT-PCR. We then investigated PDE control of beta-adrenoceptor (B-AR) mediated cAMP signalling in these cells. Stimulation with 10μM isoproterenol in the presence of PDE4 inhibitor (but not PDE3 or PDE2 inhibitor), caused a 5.5-fold increase in cAMP concentration compared to agonist alone ($p<0.001$), indicating that PDE4 activity was responsible for controlling B-AR mediated cAMP generation. Selective immunoprecipitation of PDE4 subclasses showed that PDE4D activity increased upon isoproterenol stimulation (16±0.7 to 25±2 pmol/min/mg at 20 minutes, $p=0.0011$), suggesting a particular role for this subclass. Immunoprecipation of the beta2-adrenoceptor co-precipitated PDE4 activity and Western blotting confirmed that this activity was due to PDE4D isoforms. Attenuation of specific PDE4D isoforms was achieved by adenoviral overexpression of catalytically inactive mutants and this potentiated the phosphorylation of B-AR linked cAMP targets without affecting other PKA controlled processes.

In summary, we have shown that in rat cardiac myocytes, beta-adrenoceptor cAMP signalling processes appear to be selectively controlled by a specific receptor bound PDE4 isoform. This has clinical implications as assignment of cellular targets to specific PDE isoforms may ultimately allow the design of highly selective pharmacological agents. An example in cardiac myocytes might be the development of inotropic agents without membrane destabilising arrhythmogenic effects.

3335 The role of PKCz and cPLA2 in the negative regulation of IGF-1 signaling and cardiac growth

S. Haq[1], H. Kilter[1], M. Andreucci[2], A. Michael[1], T. Force[1]. [1]MCRI New England Medical Center, Cardiomyocyte Biology Room 1311, Boston, United States of America; [2]Massachusetts General Hospital, Renal Department, Boston, United States of America

Cytosolic phospholipase A2 (cPLA2) releases arachidonic acid (AA) from phospholipids. Since AA is converted to eicosanoids, cPLA2 plays a critical role in many cellular processes. We report 3 novel functions of cPLA2-regulation of normal, stress-induced hypertrophic growth of the heart, and of IGF-1 signaling. Studies in cPLA2-deficient mice (-/-) demonstrated differential organ growth and increased heart/body wt.ratio in (-/-) mice. Both groups had identical myocardial function and physiology. The (-/-) mice had significantly thicker ventricles from increased cardiomyocyte size. Pressure-overload (PO) caused exaggerated hypertrophy in (-/-) mice. Both Akt and ERK1/2 were constitutively activated in the unstressed hearts of (-/-) mice. PO lead to significantly greater activation of PI3-K, Akt, GSK-3b, p70S6 kinase and ERK1/2 in the hearts of (-/-) mice. It has been shown that IGF-1 plays a pivotal role in mammalian postnatal cardiac growth. Studies in cells derived from mice with a cPLA2 deletion demonstrated that exogenous IGF-1 activated these intracellular mediators in a similar pattern to the PO exposed (-/-) group. IGF-1 administered in vivo lead to a similar profile of activation in (-/-) hearts. The "hyper-responsiveness" of IGF-1 signaling in (-/-) mice was not due to increases in endogenous IGF-1 production. Additionally, PDGF caused more enhanced activation of these signaling mediators in (+/+) and not in (-/-) cells, excluded a generalized growth factor response. The enhanced responsiveness of IGF-1 signaling was specific to cPLA2, and was confirmed by pharmacological inhibition of cPLA2 using inhibitors; AACOCF3 and MAFP in (+/+) cells, or conversely, rescuing the phenotype by gene transfer with adenovirus encoding cPLA2 in (-/-) cells. We found that cPLA2 negatively regulated IGF-1-dependent signaling via effects at the level of the IGF-1 receptor and IRS-1. The enhanced binding of IRS-1 to the IGF-1R was due to a failure to recruit PKCz, a recently described negative regulator of IRS-1. PKCz was not activated by PDK1 at Thr410 in vitro or in vivo in (-/-) mice. However, in the presence of arachidonic acid, PDK1 was able to phosphorylate (Thr410) and fully activate PKCz, "rescuing" the (-/-) phenotype. The disruption of this negative input in the cPLA2-deficient mouse leads to enhanced activation of the growth-regulatory PI3-K and ERK1/2 pathways, resulting in exaggerated normal and pathologic growth of the heart. These studies add the regulation of growth of the heart and modulation of IGF-1 signaling to the list of processes regulated by cPLA2.

3336 Calcineurin and protein kinase C are involved in insulin-like growth factor-1-induced hypertrophy of cultured adult rat ventricular myocytes

T. Miyashita, Y. Takeishi, H. Takahashi, T. Miyamoto, S. Kato, I. Kubota. Yamagata University School of Medicine, The First Department of Internal Medic, Yamagata, Japan

It has been recently reported that insulin-like growth factor-1 (IGF-1) increases intracellular calcium levels in cardiomyocytes. Thus, we examined the roles of calcineurin and protein kinase C in IGF-1-induced hypertrophy in adult rat ventricular myocytes. Primary cultures of adult rat ventricular myocytes were prepared from the ventricles of 14-16 week-old male Sprague-Dawley rats. First, we studied effects of IGF-1 on the morphology of adult rat ventricular myocytes. Myocyte surface area was significantly increased by IGF-1 (2268 ± 571 to 3018 ± 836 μm^2, $P < 0.01$). This hypertrophic effect of IGF-1 was blocked by genistein (tyrosine kinase inhibitor) and PD98059 (MEK inhibitor). These data suggest that IGF-1 produces adult rat ventricular myocyte hypertrophy by a tyrosine kinase-MEK mediated pathway as reported in neonatal cardiomyocytes. IGF-1-mediated adult rat ventricular myocyte hypertrophy was also attenuated by cyclosporine A (calcineurin inhibitor), staurosporine and chelerythrine (protein kinase C inhibitors). IGF-1 markedly increased calcineurin activity (8.7 ± 1.2 to 98.0 ± 54.3 pmol/hr/mg, $P < 0.01$), and this activation was completely blocked by the pre-treatment with cyclosporine A (8.5 ± 11.4 pmol/hr/mg, $P < 0.01$) and chelerythrine (2.3 ± 2.7 pmol/hr/mg, $P < 0.01$). These data suggest that IGF-1 activates calcineurin by a protein kinase C-dependent pathway. Increased mRNA expression of atrial natriuretic factor by IGF-1 was inhibited by cyclosporine A ($P<0.01$). Our data indicate that IGF-1 induces adult rat ventricular myocyte hypertrophy by protein kinase C and calcineurin-related mechanisms. IGF-1 activates calcineurin through protein kinase C. The fact that elevated calcineurin activity and induced atrial natriuretic factor mRNA expression by IGF-1 were blocked by cyclosporine A further supports the notion that calcineurin is critically involved in IGF-1-induced adult rat ventricular myocyte hypertrophy.

3337 Myocardial regulation of IGF binding proteins in two models of hypertension

M. Brink[1], B. Mottironi[1], J. Chrast[1], P. Delafontaine[2], F. Eberli[3], A. Anwar[1]. [1]Medical Research Foundation, Division of Cardiology, Geneva, Switzerland; [2]University of Kansas Medical Center, Division of Cardiovascular Diseases, Kansas City, United States of America; [3]University Hospital, Swiss Cardiovascular Center Bern, Bern, Switzerland

Background: GH treatment has been shown to increase cardiac mass, a response that is most likely mediated by insulin-like growth factor-I (IGF-I). In several rat models such treatment was associated with improved cardiac function, supporting a beneficial role for IGF-I. The biological activity of IGF-I is modulated by several highly specific IGF binding proteins (IGFBPs). Very little is known about the cardiac expression and regulation of these proteins in response to pressure overload.

Methods: We measured cardiac mRNA levels of the IGFBPs in two different models of hypertension, namely in rats infused with angiotensin II (ang II) through osmotic minipumps, and in salt-fed Dahl salt-sensitive (S) rats. The different mRNAs were detected by Northern blotting using radiolabeled specific probes. All signals were normalized for GAPDH.

Results: As expected, in both models increased blood pressure was associated with increased cardiac mass and increased tissue levels of the growth factor IGF-I. Ang II infusion (500 ng/kg/day) decreased cardiac IGFBP-3 mRNA by 54±9% and 41±5% at day 3 and 7, respectively ($P<0.05$). In this model the inhibitory IGFBP-4 was increased by 79±19% ($P<0.05$) at day 3, but returned to levels of control animals after 7 days. IGFBP-5 mRNA was not changed. After 4 weeks of high salt diet, hypertensive Dahl S rats had significantly higher IGFBP-4 levels (63% increase) compared with normotensive Dahl salt-resistant (R) rats ($P<0.05$). In this model no changes were observed for IGFBP-3 or IGFBP-5.

Conclusions: The increase in IGFBP-4 in both models suggests that this protein is important in regulating IGF-I activity in cardiac tissue under conditions of pressure overload. In addition, the combination of high cardiac IGF-I and low IGFBP-3 in ang II-infused rats likely facilitates development of cardiac hypertrophy in response to ang II, since IGFBP-3 is generally thought to inhibit IGF-I activity. This decrease in IGFBP-3 was not observed in hypertensive Dahl rats, and is therefore probably due to a blood-pressure independent mechanism.

3338 Different growth factor activation between right and left ventricle in experimental volume overload

G. Polidori, I. Bertolozzi, S. Vanni, F. Burberi, G. Costanzo, A.M. Perna, P A. Modesti. *University of Florence, Clinica Medica Generale e Cardiologia, Florence, Italy*

Cardiac overexpression of angiotensinogen (AGT) and insulin-like growth factor (IGF)-I genes has been reported in experimental volume overload. Different hemodynamic response to volume overload in left and right ventricles might influence the local expression of cardiac growth factors. Therefore we investigated AGT, IGF-I, and prepro endothelin (ppET)-1 mRNAs in right and left ventricles of 15 adult pigs (30+5 kg) after the creation of aorta-cava fistula distal to the renal arteries causing a 50% increase in cardiac output. Six animals were sham-operated.

At baseline, 2 weeks, 1, 2 and 3 months after surgery hemodynamic and echocardiographic measurements were recorded. Animals were then euthanized and myocardial specimens were taken for RT-PCR studies.

In the left ventricle volume overload did not cause significant changes in ventricular pressure and contractility (Vcf). RT-PCR revealed a selective overexpression of IGF-I mRNA at 2 weeks (2-fold) which remained elevated at following times in a close association to the increase in left ventricular mass (from 59±9 to 92±7 and 254±23 g at 2 weeks and 3 months respectively, $p<0.05$ for both). Conversely, in the right ventricle both systolic and end-diastolic pressure significantly increased at 2 weeks ($p<0.05$ vs baseline for both) and remained elevated vs baseline throughout the study. RT-PCR analysis showed overexpression of AGT and IGF-I mRNAs at 2 weeks ($p<0.05$ for both) and ppET-1 transcript at 1 month (24-fold). All genes remained overexpressed at the following experimental times ($p<0.05$).

In conclusion: a differential pattern of growth factor response to volume overload is detectable in left and right ventricle: 1) AGT and ppET-1 mRNA expression are restricted to right ventricular myocardium which had to face both pressure and volume overload, 2) IGF-I gene is overexpressed in both ventricles independently on AGT gene activation 3) in left ventricle IGF-I expression is associated with marked hypertrophy without impairment of myocardial contractility.

NOVEL MECHANISMS IN THE CONTROL OF CARDIAC FUNCTION

3339 Acute mechanical stretch of rabbit myocardium regulates expression of SERCA2a via the calcineurin pathway

P. schott, H. Kögler, P. Nguyen, F. Schaub, E. Domeier, G. Hasenfuß. *University of Goettingen, Cardiology, Goettingen, Germany*

Introduction: The regulation of gene expression of calcium cycling proteins in the myocardium is poorly understood so far. In this study we investigated the effect of a 6-h-stretch period on the expression of SERCA2a and NCX in non-failing rabbit myocardium. Both are key proteins for the regulation of cytosolic Ca^{2+}-concentration and show different patterns of expression in cardiac hypertrophy and failing myocardium. There is evidence for a wall tension-dependent regulation of SERCA2a in the published literature.

Methods: Right ventricular trabeculae from non-failing rabbit myocardium were dissected and mounted in a culture chamber in tissue culture medium (1.75 mM Ca^{2+}) at 37°C and electrically stimulated at 1 Hz. The trabeculae were stretched to obtain a resting tension of 95% Lmax and kept stretched for 6 h in culture.

Control preparations remained at slack for 6 h. SERCA2a and NCX1 mRNA levels were measured by competitive NASBA reaction. Protein levels were measured by Westernblot analysis. Calsequestrin served as the house-keeping gene.

Results: We observed a significantly higher expression of SERCA2a mRNA in stretched trabeculae compared to slack preparations (stretch (n=9) 1.08xe8 ± 6.0xe7 vs. slack (n=9) 4.23xe7 ± 2.5xe7, $p < 0.02$). RNA data were confirmed by western blotting with regard to protein expression of SERCA2a, which showed a significantly higher expression on protein level as well (stretch 0.85 ± 0.06 vs. slack 0.49 ± 0.15, $p < 0.01$). After addition of Cyclosprin A (CsA) for inhibition of calcineurin activity we observed a significant decrease of the stretch-induced SERCA2a upregulation (stretch without CsA (n=9) 1.08xe8 ± 6.0xe7 vs. stretch with CsA (n=9) 4.21xe7 ± 2.5xe7, $p < 0.02$). For NCX1 neither RNA nor protein data showed significant differences.

Conclusion: Our data show, that the expression of SERCA2a depends on the wall tension (load). Acute stretching of rabbit myocardium leads to an upregulation of SERCA2a expression, which may be useful in controlling stretch-induced increase of cytosolic Ca^{2+}. This regulation appears to be mediated via an activation of calcineurin activity by acute stretch. So acute inrease of wall tension leads, in contrast to the decreased expression of SERCA2a in chronic failing myocardium or chronic hypertrophy, to an upregulation of SERCA2a.

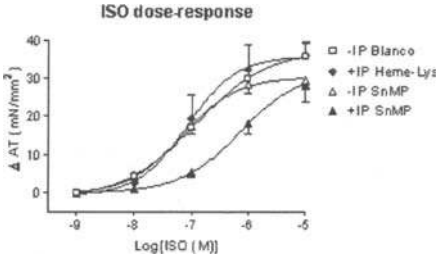
3340 Heme oxygenase modulates response of cardiac muscle to beta adrenergic stimulation

V.F.M Segers, P. Fransen, J. Hendrickx, S.U. Sys, D.L. Brutsaert. *University of Antwerp, Pharmacology, Antwerp, Belgium*

Introduction: Heme oxygenase (HO) catalyzes the first and rate limiting step in heme metabolism, producing equimolar quantities of carbon monoxide (CO), biliverdin and free iron. HO-1 (also known as 'Heat shock protein' 32) is the inducible isoform (induced by heme, heavy metals, heat shock, cytokines and endotoxin), which plays a major role in the defence against oxidative and cellular stresses.

Methods: HO-1 was induced by intraperitoneal injection (IP) of 75μg/kg hemin in New Zealand White rabbits 24 and 48 hours before measuring isometric contractions of right ventricular papillary muscles. Muscles were randomly assigned to a group (n=7) with heme-lysinate (HO substrate, 10μM) and a group (n=8) with stanneous-mesoporphyrin (SnMP, HO inhibitor, 30μM). A dose-response to isoproterenol (ISO, 10^{-9} to 10^{-5} M) was done in both groups, and all experiments were done with L-NMMA to block NO-synthase activity. The same dose-response was repeated in two groups of muscles (with or without SnMP) of control rabbits without previous induction of HO-1.

Results: Maximal inotropic response to ISO was not significantly affected by HO-1 induction or HO-1 inhibition. However, log(EC50) of ISO dose-response for active tension (AT) shifted from -6.9 ± 0.2 in muscles with induced HO-1 to -6.0 ± 0.2 in muscles with induced but inhibited HO-1. On the other hand, log(EC50) was not affected by inhibition without induction or induction without inhibition.



ISO dose-response.

Conclusion: Our results indicate that inhibition of HO decreases sensitivity of cardiac muscle contraction to beta adrenergic stimulation. However, the effect of inhibition appears only after induction of HO-1. This effect might be explained by a decrease in cGMP content by inhibition of CO production.

3341 The positive inotropic effect of endothelin-1 depends on Na^+/H^+ exchange in failing human myocardium

C. Luers, E.J. Metz, D. von Lewinski, L.S. Maier, B. Pieske. *University of Goettingen, Cardiology and Pneumology Dept., Goettingen, Germany*

Introduction: Endothelin-1 (ET-1) exerts direct positive inotropic effects in the human heart. However, it is controversial whether these inotropic effects are Ca^{2+}-dependent or result from intracellular alkalinization with enhanced Ca^{2+}-responsiveness of the myofilaments secondary to activation of the Na^+/H^+ exchanger (NHE-1). We tested the effects of NHE-1 inhibition on intracellular pH-changes and developed force after ET-1 in isolated failing human myocardium.

Methods: Isolated left ventricular trabeculae (n=25) were electrically stimulated (basal stimulation rate 1 Hz, 370C, isometric contractions). The muscles were loaded with the fluorescent pH-indicator BCECF-AM (15μM for 45 min). ET-1 (0.1 μM) was added under steady-state conditions in either bicarbonate-containing (Tyrode) or bicarbonate-free (HEPES) buffer. In a subgroup of experiments HOE-642 (3 μM) was added 20 min before the application of ET-1. PH and force-parameters were recorded for 60 min. PH-signals after each experiment were calibrated with the "high-K^+-Nigericin"-method. Average values are given as means ± SEM, analysed by the unpaired students t-test. Values of $p<0.05$ were considered significant.

Results: In bicarbonate-free HEPES buffer, HOE-642 resulted in a decline in force (by -57.3±2.7%, $p<0.05$) and an increase in pHi from 7.20±0.04 to 7.33±0.04 ($p<0.05$). ET-1 increased force by 23.1±7.9% ($p<0.05$) associated with a slight decline in pHi. HOE-642 prevented the effect of ET-1 on force and pHi in HEPES buffer. In bicarbonate-containing buffer the inotropic response to ET-1 was larger (42.6±2.3%, $p<0.05$) without significant changes in pHi. HOE-642 only partially prevented the inotropic response to ET-1 in Tyrode's solution (22.8±5.7%, $p<0.05$).

Conclusion: NHE-1 is activated under basal experimental conditions in failing hearts and contributes to force generation possibly by induction of reverse-mode Na^+/Ca^{2+} exchange. ET-1 exerts positive inotropic effects which are related to NHE-1 activation but are largely independent from changes in pHi.

3342 Spontaneous calcium release from SR is caused by increased intracellular sodium due to increased activity of Na/H-exchanger in failing myocytes

A. Baartscheer[1], M.M.G. v Borren[2], C.A. Schumacher[1], C.N.W. Belterman[1], R. Coronel[1], J.W.T. Fiolet[1] on behalf of Cardivascular Research Institute Amsterdam. [1]*Exp. and Molecular Cardiology Group,* [2]*Physiology, Academic Medical Center, Amsterdam, Netherlands*

Background: Spontaneous release of calcium from SR is increased in failing myocytes causing a higher incidence of calcium after-transient, which underlies delayed after potentials (DAD'S) and arrhythmias. We hypothesize that increased sodium ($[Na^+]_i$), secondary to up-regulated Na^+/H^+-exchange (NHE) activity, underlies the increased incidence of calcium after-transients and DAD's.
Methods: Heart failure is induced by combined volume and pressure overload in rabbits. $[Ca^+]_i$ and $[Na^+]_i$, were measured with the fluorescent probes indo-1 and SBFI in myocytes from control (n=5) and in failing rabbit hearts (n=12). DAD's were measured with the voltage sensitive fluorescent probe annepp. Calcium after-transient and DAD's were elicited after cessation of rapid pacing (3Hz) in the presence of 100 nM noradrenaline.
Results: $[Na^+]_i$ and $[Ca^+]_i$ were higher in failing myocytes 9.8±0.4 mM and 184 ±13.3 nM compared to control 6.2±0.3 mM and 84±8.9. Inhibition of NHE-activity with cariporide, a specific inhibitor resulted in a decrease of both $[Na^+]_i$ and $[Ca^+]_i$ in failing myocytes to almost control values without effect in control myocytes. In none of the myocytes (n=15) of control rabbits, but in most of the myocytes (32 out of 36) of failing rabbits calcium after-transients and DAD's could be evoked. The incidence of calcium after-transient and DAD's as well as their amplitudes were positive related to the $[Ca^+]_i$ just before the onset of the calcium after-transients. After inhibition of NHE with cariporide the incidence of calcium after-transient and DAD's in these myocytes was significantly reduced (4 out of 36). The four myocytes with after-transient and DAD's had significantly reduced amplitudes. Washout of cariporide increased the incidence to previous values (30 out of 36) an increased their amplitudes.
Conclusion: Disturbed sodium handling in failing myocytes causes an increase of cytosolic calcium resulting in an increase of the incidence of calcium after-transient and DAD's.

3343 Transgenic overexpression of the cardiac EF-hand Ca^{2+} binding protein S100A1: a novel strategy to increase myocardial contractile performance

P. Most[1], W.J. Koch[2], E.K. Löffler[1], P. Ehlermann[1], S.T. Pleger[1], H.A. Rockman[3], H.A. Katus[1], A. Remppis[1]. [1]*University of Luebeck, Internal Medicine II, Luebeck, Germany;* [2]*Duke University Medical Center, Department of Surgery, Durham, United States of America;* [3]*Duke University Medical Center, Department of Cell Biology, Durham, United States of America*

Background: Heart failure, an important public health problem with high morbidity and mortality is functionally characterized by impaired contractile force, diminished intracellular Ca^{2+} cycling and dampened responsiveness to catecholamine stimulation. S100A1, a cardiac Ca^{2+} binding protein of the EF-hand type has been found to be significantly down-regulated in the failing myocardium but S100A1 protein overexpression in vitro has recently been shown to improve cardiac contractile performance. Thus, to prove the therapeutic potential for the concept of S100A1 gene-transfer in vivo, we assessed cardiac function and morphology in S100A1 transgenic mice (TG S100A1).
Methods/Results: C57/B6 TG S100A1 mice were generated by the use of the alpha-MHC promotor and hemodynamics were assessed in 6±1 month old TG S100A1 mice by cardiac catherization and echocardiography compared to non-transgenic littermate controls (NLC's). Contractility and whole-cell Ca^{2+} transients in isolated transgenic cardiomyocytes were investigated by edge-detection and FURA2-AM loading, respectively. Expression levels of S100A1, Ca^{2+} cycling proteins and β-AR were examined by Western-blotting. Adenylylcyclase(AC)activity was carried out in crude membrane preparations. A nearly 4-fold cardiac-restricted S100A1 protein overexpression significantly raised basal and isoproterenol-stimulated systolic and diastolic cardiac function in vivo as well as in isolated cardiac myocytes. In accordance, intracellular Ca^{2+} transients at baseline and in response to isoproterenol were found to be significantly enhanced by S100A1 overexpression while cardiac protein expression levels of DHPR, RyR, SERCA2a, PLB, NCX, CSQ and β1/2 receptors as well as cardiac AC activity remained unchanged. Despite the marked increase in cardiac performance, echocardiographic and biometric measurements revealed that S100A1 gene-tranfer did not lead to cardiac hypertrophy.
Conclusion: Our study clearly demonstrates for the first time that cardiac S100A1 gene-transfer in vivo is feasible and causes significantly increased cardiac contractile force at baseline and in response to β-adrenergic stimulation. No cardiomyopathic consequences occurred during the study period and cardiac response to β-adrenergic stimulation was preserved. These data are in line with our recent data of cAMP-independent increase in contractility in S100A1 overexpressing cardiomyocytes. Thus, cardiac S100A1 gene delievery may reverse impaired cardiac peformance of the failing heart and appears therefore as a novel inotropic strategy to treat symptomatic heart failure.

LEFT VENTRICULAR DYSFUNCTION: INSIGHTS FROM TRANSGENIC MICE

3344 Overexpression of phosphatase inhibitor-2 rescues the cardiac function defect of PP1c transgenic mice

L. Fabritz[1], P. Kirchhof[1], N. Bruechert[2], W. Haverkamp[1], U. Kirchhefer[2], P. Boknik[2], A. DePaoli-Roach[3], J. Neumann[2]. [1]*Dept. of Cardiol. and Angiol.,* [2]*Inst of Pharmacol. and Toxicol., University Hospital Münster, Münster, Germany;* [3]*Indiana University, School of Medicine, Dept. Biochemistry & Molecular Biology, Indianapolis, United States of America*

Background: In failing human myocardium, increased activity of protein phosphatases (PP) contributes to decreased phosphorylation of myocardial regulatory proteins resulting in impaired calcium handling and contractile dysfunction. The protein phosphatase 1 (PP1) has been implicated in the control of major regulators of cardiac function. However, the effect of cardiac specific overexpression or inhibition of the protein phosphatase has not been fully explored.
Methods: Mice with cardiac specific overexpression of the catalytic subunit of PP1 (PP1c OE) were crossed with mice overexpressing inhibitor-2 (PPI2 OE), an endogenous inhibitor of PP1c. Wild type (WT; n=6), PP1c OE (n=6), PPI2 OE (n=6) and PP1c/PPI2 OE (n=6) littermates six months of age were analyzed by biplane echocardiography and cardiac doppler using a 15 MHz transducer.
Results: PP1c OE mice showed decreased ventricular contractility. The fractional shorting (FS) and the velocity of circumferential shortening (Vcf) were lower in PP1c as compared to WT, PPI2 or PP1c/PPI2 OE mice (See Table). Ventricular contractility in PPI2 OE mice and in PP1c/PPI2 double transgenic mice was not significantly different from WT. Dilated cardiomyopathy was clearly present in PP1c OE mice. Left ventricular end-diastolic (LVEDd) and end-systolic (LVEDs) diameters were increased in PP1c OE vs. WT, PPI2 or PP1c/PPI2 OE animals. Left ventricular diameters in PPI2 OE and in double transgenic mice were not different from WT.

	WT	PPI2 OE	PP1cOE	PP1c/PPI2
LVEDd (mm)	4.8±0.2	4.5±0.1	5.6±0.3**	4.3±0.1
LVEDs (mm)	3.3±0.3	3.0±0.2	4.4±0.4**	2.9±0.1
FS (%)	31.4±2.5	34.8±2.1	22.9±2.5**	31.9±1.3
Vcf (circ/s)	5.1±0.4	4.9±0.4	3.6±0.4**	4.8±0.4

Values are given as mean ± SEM, n = 6 per group, ** indicates p<0.005)

Conclusions: 1) Overexpression of PP1c results in cardiac dilatation and impaired function and 2)additional overexpression of PPI2 rescues the PP1c defective phenotype. These results suggest that inhibition of protein phosphatases could provide a new target for therapeutic approaches in the prevention of heart failure.
(Supported by the SFB556 B2 and Z2)

3345 Cardiac dilatation and impaired ventricular contractility in mice overexpressing protein phosphatase 2 (PP2A)

L. Fabritz[1], P. Kirchhof[1], L. Fortmüller[1], W. Haverkamp[1], J. Neumann[2], P. Boknik[2], W. Schmitz[2], U. Gergs[2]. [1]*Dep of Cardiol and Angiol,* [2]*Inst of Pharmacol and Toxicol, University Hospital Muenster, Muenster, Germany*

Background: Impaired catecholamine-induced protein phosphorylation is a major determinant of cardiac function in heart failure. An increased activity of protein phosphatases has been described in failing human myocardium. Protein phosphatase 2A (PP2A) specifically targets e.g. to the cardiac ryanodine receptor and may therefore directly influence cardiac function.
Methods: We generated transgenic mice with cardiac specific overexpression of the catalytic subunit of PP2A. Age (16 weeks) and sex matched (10 female, 10 male) littermates were studied in sedation (ketamine and xylazine) via biplane echocardiography and cardiac doppler using a 15 MHz transducer.
Results: Heart rate (PP2A 334±14 vs. WT 317±13 bpm) and aortic flow (PP2A+ 10.1±1 vs. WT 8.9±0.6 ml/min) were maintained in PP2A+ mice. Left ventricular enddiastolic and endsystolic diameter, in contrast, were enlarged by 32%* and 55%* in PP2A+ mice. Cardiac contractility was depressed as evidenced by decreased fractional shortening (FS, 31% decrease*) and reduced velocity of circumferential shortening (Vcf, 25% lower*, *p<0.005). Values are given in mean±SEM.

Echocardiographic parameters

	WT	PP2A+
LVEDd (mm)	4.1±0.1	5.4±0.2*
LVEDs (mm)	2.7±0.1	4.1±0.3*
FS (%)	36±1	25±2*
Vcf(circ/s)	5.1±0.2	3.8±0.3*

Values are given in mean and SEM, n=10 per group, *=p<0.005.

Conclusions: Cardiac-specific overexpression of PP2A results in ventricular dilatation and reduced cardiac contractility in vivo. Increased activity of PP2A may contribute to impaired cardiac function in end stage human heart failure.

3346 Impaired SR Ca^{2+} uptake by a phospholamban mutant PLB/N27A is a sufficient primary cause of progressive left ventricular dysfunction and heart failure

A. Schmidt[1], J. Zhai[2], M. Gerst[2], J. Lorenz[2], B. Hoit[3], E.G. Kranias[2]. *[1]Medizinische Klinik Univ. Göttingen, Kardiologie und Pneumologie, Göttingen, Germany; [2]University of Cincinnati, Pharmacology and Cell Biophysics, Cincinnati, OH, United States of America; [3]Case Western Reserve University, Cardiolology, Cleveland, OH, United States of America*

Increases in diastolic Ca^{2+} and impaired relaxation are associated with depressed sarcoplasmic reticulum (SR) Ca^{2+} uptake in end-stage failing hearts. However, the role of SR dysfunction in the onset and progression of heart failure is controversial. The present study tests the hypothesis that impairment of cytosolic Ca^{2+} sequestration by the sarcoplasmic reticulum via increased phospholamban inhibition, is a sufficient primary cause for left ventricular (LV) dysfunction and its progression to heart failure. A phospholamban Asn27 to Ala mutant (PLB/N27A), exhibiting a defined alteration in its three dimensional structure, as revealed by NMR analysis, was introduced in the cardiac compartment of the PLB null mouse. PLB/N27A expression (1-fold) resulted in a supershift of the EC50 value of the SR Ca^{2+} uptake (0.52±0.04* vs. 0.21±0.01 in wild-types: WT). Isolated cardiac myocytes and Langendorff-perfused hearts demonstrated preserved shortening fraction and peak systolic pressure development respectively; the rates of contraction (70%) and relaxation (53%) were significantly depressed compared to WTs. Furthermore, analysis of Ca^{2+} transients in Fura-2 loaded isolated myocytes showed significantly prolonged times for 80% Ca^{2+} signal decline (0.85±0.07*s vs. 0.52±0.07s in WT). Echocardiography revealed preserved fractional shortening (FS), but the isovolumic relaxation time was prolonged (48.2±6.7* ms vs. 25.8±1.9 ms in WT) and LV diastolic filling measured by the ratio of early to late LV filling (E/A) on transmitral Doppler was significantly impaired (1.09±0.09* vs. 1.76±0.1 in WT) in 12 week old PLB/N27A. Furthermore, a blunted force-frequency relation and an attenuated response to beta-agonist stimulation were observed in PLB/N27A hearts by LV-catheterization. Upon aging to 12 months, the predominantly diastolic dysfunction progressed to congestive heart failure, characterized by induction of a fetal gene program, cardiac remodeling, lung congestion and LV systolic dysfunction (FS %: 22.5±1.3* in N27A vs. 35.2±2.0 in WT). These findings suggest that changes in SR Ca^{2+} handling may be a primary causative factor rather than a compensatory response in the development of left ventricular dysfunction and the transition to heart failure. (* $P<0.05$.)

3347 Evaluation of left ventricular diastolic function from spectral and color M-mode Doppler in genetically altered mice

A. Schmidt[1], J. Zhai[2], M. Gerst[2], E.G. Kranias[2], B.D. Hoit[3]. *[1]Medizinische Klinik Univ. Göttingen, Kardiologie und Pneumologie, Göttingen, Germany; [2]University of Cincinnati, Pharmacology and Cell Biophysics, Cincinnati, OH, United States of America; [3]Case Western Reserve University, Cardiolology, Cleveland, OH, United States of America*

Heart failure cause by abnormal diastolic function is far more common than previously recognized and its underlying cellular mechanisms are still poorly understood. Echocardiographic techniques have proven useful in determining the interplay between altered gene expression and physiological cardiovascular function in genetically altered mouse models. However, the role of non-invasive assessment of left-ventricular (LV) diastolic function in the intact mouse is unsettled. The objective of our study was to characterize patterns of LV diastolic function in two genetically altered mouse models using Doppler- and Color-M-mode echocardiography. Phospholamban (PLB) reversibly inhibits the sarcoplasmic reticulum Ca^{2+} ATPase (SERCA) and is a key regulator of myocardial relaxation. 12-week old PLB knock-out mice (PLB/KO) were examined in parallel with age-matched transgenic mice expressing a mutant form of PLB (PLB/N27A) that exhibited superinhibition of SERCA and compared to controls expressing wild-type PLB (WT) (n=14/group). LV-systolic function was preserved in PLB/N27A mice compared to WT as assessed by fractional shortening (FS) (see table). However, transmitral Doppler flow indexes, including isovolumic relaxation time (IVRT), the ratio of peak early-to-late filling velocities (E/A), and deceleration time of peak early transmitral velocity (DT) indicate impaired diastolic filling in the PLB/N27A mutants, but improved LV diastolic function in the PLB/KO mice. Additionally, a relatively load-independent parameter of LV relaxation measured by color M-mode Doppler, the propagation velocity of early flow into the LV cavity (Vp), was established in the mouse and used to confirm the observed differences. Inter- and intraobserver variability was very good.

Echo-parameters of LV function

	FS (%)	IVRT (ms)	E/A	DT (ms)	Vp (cm/s)
PLB/KO	41,9 ±2,3	17,2 ±2,1*	2,0 ±0,1*	24,9 ±1,7	70,8 ±10,8
PLB/WT	39,4 ±2,3	27,0 ±1,0	1,6 ±0,1	22,3 ±2,5	49,1 ±1,7
PLB/N27A	38,9 ±2,3	45,6 ±4,5*#	1,0 ±0,1*#	45,6 ±4,5*#	22,8 ±1,8*#

* $p<0,05$ vs. WT; # $p<0,05$ vs. PLB/KO

We conclude that transmitral filling patterns and color M-mode flow propagation velocity have the sensitivity to detect changes in myocardial relaxation in mice with genetically altered levels or activity of phospholamban and may be useful tools to characterize LV diastolic function in other mouse models of disease.

3348 Phospholamban ablation rescues intrinsic contractility but does not prevent remodelling in myosin-binding protein-C mutant mice

A. Schmidt[1], A.N. Carr[2], B. Frank[2], L. Pater[2], H. Hahn[3], J.G. Seidman[4], B.D. Hoit[5], E.G. Kranias[2]. *[1]Medizinische Klinik Univ. Göttingen, Kardiologie und Pneumologie, Göttingen, Germany; [2]University of Cincinnati, Pharmacology and Cell Biophysics, Cincinnati, OH, United States of America; [3]University of Cincinnati, Division of Cardiology, Cincinnati, OH, United States of America; [4]Howard Hughes Medical Institute, Department of Genetics, Boston, MA, United States of America; [5]Case Western Reserve University, Cardiolology, Cleveland, OH, United States of America*

Homozygous mice bearing mutated alleles of myosin-binding protein-C (MyBP-C/Neo) that encode a truncated peptide analogous to that found in human hypertrophic cardiomyopathy exhibit early dilated cardiomyopathy. To test the hypothesis that enhanced Ca^{2+}-cycling through the SR by phospholamban (PLB) ablation may improve cardiac dysfunction and prevent the progression of remodeling, we crossbred the PLB knock-out model (PLBKO) with the homozygous MyBP-C/Neo mouse and characterized the resulting double mutants (CROSS) (n=6/group). Isolated cardiac myocytes (table) from MyBP-C/Neo exhibited significantly depressed maximal rates of contraction (+dL/dt,μm/s), relenghtening (-dL/dt) and cell shortening (SF,%) compared to wild-type (WT), which was accompanied by a significantly prolonged Ca^{2+}-transient decay (time to 50% decay: T50, ms). Ablation of PLB (Cross) resulted in a full restoration of all depressed contractile and Ca^{2+} cycling parameters to levels even higher than those observed in WT littermates. However, PLB-ablation failed to significantly improve cardiac function in the intact animal, as assessed by echocardiography (fractional shortening (%); WT: 43,3±2,4; MyBP-C/Neo: 25,9±1,9*; CROSS: 30.8±2,7*) and LV-catheterization (-dP/dt (mmHg); WT:-9844±575; MyBP-C/Neo: -4367±64*; CROSS: 5536±167*). Furthermore, gravimetric analysis of myocardial hypertrophy, fetal gene markers and histopathological changes (myofibrillar disarray, fibrosis) show a similar degree of cardiac remodeling in MyBP-C/Neo and CROSS animals.

Isolated cardiomyocytes

* $p < 0,05$	+ dL/dt	-dL/dt	%SF	Ca^{2+}-Ampl.	T50
WT	128 ± 9	93 ± 14	11,7 ± 0,4	0,36 ± 0,02	326 ± 17
MyBP-C/Neo	86 ± 13*	45 ± 4*	8,8 ± 0,4	0,32 ± 0,02	410± 20*
CROSS	255 ± 28*	230 ± 29*	16,3± 2,3*	0,58± 0,05*	201 ± 15*

These results indicate that increased SR Ca^{2+} cycling by PLB ablation is able to rescue intrinsic contractility but not remodeling in MyBP-C/Neo mice, suggesting that deficits in force transmission may serve as the primary signaling-mechanism.

3349 Diastolic dysfunction and stress-induced cardiac decompensation in transgenic mice expressing the human troponin T (I79N) mutation

C. Tschoepe[1], D. Westermann[2], B. Knollmann[3], J.D. Potter[4], P. Stenjiik[5], H.-P. Schultheiss[2]. [1]Benjamin Franklin Univ.-Hospital, Dept. of Cardiology, Berlin, Germany; [2]Benjamin Franklin Univ. Hospital, Cardiology Dept., Berlin, Germany; [3]Georgetown University, Pharmacology, Washington, United States of America; [4]Univ. Maimi, Pharmacology, Maimi, United States of America; [5]Univ. Medical Center, Cardiology, Leiden, Netherlands

The cardiac troponin T (TnT) I79N mutation is linked to familial hypertrophic cardiomyopathy and sudden death. To investigated LV pressure-volume relationships in transgenic mice expressing human wild type (Wt), human mutant TnT (I79N) and controls.. A micro-conductance catheter was introduced in the LV of anaesthetized (thiopental) and ventilated closed chest mice n =-8/group). During V. cava occlusion endsystolic and enddiastolic pressure volume relationships were obtained (ESPVR; EDPVR) under basal and stress conditions (0.25 mg/kg isoproterenol i.p.)

Basal: I79N mice showed increased systolic function compared to controls: EF: 63.3±.4.3* vs. 41.3±4.8%; SV: 35±3.2* vs. 26.5±2.3µl; CO: 16950±1300* vs. 10924±908 µl/min; Volume endsystolic: 26.55±2.3* vs. 43.6±5.6 µl; *p<0.05 without differences in HR, LVP and ESPVR-slope (Ees). LVEDP, Tau and PHT were unchanged, but the EDPVR-slope was increased (0.50±0.1* vs. 0.28±0.06; *p<0.05), indicating increased LV stiffness.

Stress: HR (654±21 vs. 675±12 bpm) and LVP (159.9±8.6 vs. 191.0±8.1* mmHg; *p<0.05) response was similar in all groups, but the systolic function of I79N mice decreased compared to controls (EF: 25.1±5.5* vs. 51.2±9.8%; SV: 13.97±3.28* vs. 23.13±1.76 µl; CO: 8916±1832* vs.14861±2887 µl/min; Ves: 42.22±3.67* vs. 26.57±7.21 µl and ESPVR-slope 2.35±0.57* vs. 4.3±0.78; *p<0.05). Diastolic indices demonstrate diastolic dysfunction in I79N compared to controls: LVEDP: 17.07±2.16* vs. 3.84±1.28 mmHg; *p<0.05 and PHT: 6.37±0.35* vs. 5.01±0.31 ms; *p<0.05. Increased EDPVR (1.12±0.34* vs. 0.47±0.09; *p<0.05) indicates cardiac stiffness worsened under b-adrenergic stimulation.

I79N TnT mice show an increased cardiac stiffness and diastolic dysfunction leading to decompensation under stress. These mice are a valuable model to study the mechanisms involved in humans with TnT mutations.

MOLECULAR MECHANISMS OF MYOCARDIAL ISCHAEMIA

3350 Involvement of free radicals and mitochondrial K+ATP channels in ischaemic preconditioning depends critically on the preconditioning stimulus

D.A. Liem, A. Heinen, W.E.M. Bos, R. van den Heuvel, P.D. Verdouw, D.J. Duncker. *Erasmus University, Thoraxcenter, Rotterdam, Netherlands*

The involvement of adenosine, mitochondrial ATP-sensitive potassium (KATP) channels and reactive oxygen species (ROS) in ischemic preconditioning remains incompletely understood. We previously observed in the in vivo rat heart, that adenosine contributes to ischemic preconditioning (IPC) produced by a single 15-min coronary artery occlusion (CAO) followed by 10 min of reperfusion (15-min CAO), but not to the cardioprotection afforded by 3 cycles of 3-min CAO interspersed by 5 min of reperfusion (3x3-min CAO). Adenosine-induced cardioprotection in the rabbit has recently been reported to be independent of ROS formation and mitochondrial KATP channel activation. Consequently, we investigated the involvement of mitochondrial KATP channels and ROS in the cardioprotection by the 15-min CAO and 3x3-min CAO preconditioning stimuli. Infarct size (IS) was determined measured after 120 min of reperfusion following a 60-min CAO in pentobarbital-anesthetized rats using trypan blue (negative staining of the area at risk) and nitro-blue-tetrazolium for vital staining. In control hearts IS comprised 70±1% (n=7) of the anatomical area at risk. IPC with a single 15-min CAO or 3x3-min CAO reduced IS to 47±3% (p<0.05, n=18) and 25±4% (p<0.05, n=16) respectively. The ROS scavenger MPG (1mg/kg/min iv), which had no effect on IS produced by 60-min CAO (IS = 68±2%, n=4) or on the cardioprotection afforded by 15-min CAO (IS = 39±7%, n=9), blunted IPC with 3x3-min CAO to 55±6% (n=10; p<0.05 vs 3x3-min CAO). In contrast, a high dose of the selective mitochondrial KATP channel blocker 5-hydroxydecanoate (5-HD, 20 mg/kg iv, followed by 20 mg/kg/h iv), which by itself had no effect on IS produced by a 60-min CAO (IS = 70±2%, n=3) or on IPC with 3x3-min CAO (34±8%, n=9), abolished IPC with a single 15-min CAO (71±3%, n=3).

In conclusion, a preconditioning stimulus consisting of a single 15-min CAO conferred cardioprotection via adenosine and mitochondrial KATP channels but did not involve the formation of reactive oxygen species. In contrast, 3 cycles of 3-min CAO, which afforded even more potent cardioprotection, involved increased formation of reactive oxygen species, but did not require adenosine or mitochondrial KATP channels. These findings indicate that preconditioning stimuli produce cardioprotection via markedly different signal transduction pathways.

3351 Cardioprotection and hypertrophy: role of STAT3 in a murine model of ischaemia and reperfusion

M. Fuchs[1], A. Hilfiker[1], D. Hilfiker-Kleiner[1], K. Kaminski[1], A. Schaefer[1], M D. Schneider[2], V. Poli[3], H. Drexler[1]. [1]Medical School Hannover, Cardiology and Angiology, Hannover, Germany; [2]Baylor College of Medicine, Dept. Of Medicine, Houston, United States of America; [3]University of Dundee, Dept. of Biochemistry, Dundee, United Kingdom

Myocardial stress, such as pressure overload, ischemia and reperfusion, cause production of cytokines of the IL 6 family, which stimulate the JAK/STAT and the MAP kinase signal transduction pathways via the common receptor gp130. Overexpression of STAT3 in the heart leads to myocardial hypertrophy. However, the role of STAT3 in the heart can only be clarified by a conditional knock out, since the general STAT3 k.o. results in early embryonic mortality.

By crossing the aMHC-Cre transgene into the STAT3flox background a heart specific STAT3 k.o. mouse was generated. In this mouse the recombinase Cre is expressed under the control of the aMHC-promoter, which is only active in postnatal cardiomyocytes, thereby eliminating most of the function of the STAT3 gene in the adult heart (12 weeks of age) but not in other organs.

Under basal conditions aMHC-Cre;STAT3flox (STAT3-/-) mice do not show significant differences concerning mortality, bodyweight, heart morphology and function compared to wild type controls (WT). After ischemia/reperfusion (1h/7d) LV function as determined by echocardiography was significantly reduced in STAT3-/-animals compared to WT (FS 19% vs. 30%, p<0,05), and showed a significantly reduced hypertrophy (septum thickness +5% v.s. +32%, p<0,01; myocyte cross sectional area -11% v.s. +20%, p<0,01) as determined by morphometry. After 1h of ischemia followed by 24h of reperfusion, the STAT3-/- mice showed a 1,6 fold increase in infarct size as determined by Evans blue and TTC staining (p<0,01) associated with a 4 fold increase in TUNEL positive cells compared to WT (p< 0,001).

In conclusion cardiomyocyte specific knock out of STAT3 in mice shows no pathological phenotype under basal conditions. However, ischemia/reperfusion leads to subsequent LV dysfunction in STAT3 k.o. mice. This is possibly due to significant increase in infarct size with a marked elevation of apoptotic cells and is augmented by the lack of LV hypertrophy.

3352 Recombinant P-selectin glycoprotein ligand-Ig versus abciximab in conjunction with tenecteplase in a non-human primate model of thrombolysis

A. Kumar[1], M.P. Villani[2], G.D. Shaw[1], R.G. Schaub[1]. [1]Wyeth Genetics Institute, Inflammation Biology, Cambridge, United States of America; [2]DaVinci Biomedical Research Products, South Lancaster, United States of America

We have shown that recombinant P-selectin Glycoprotein Ligand-Ig (rPSGL-Ig) with alteplase, reteplase or streptokinase accelerates thrombolysis and reduces acute reocclusion in porcine and canine models. In this study we evaluated rPSGL-Ig in conjunction with tenecteplase (TNK) and compared its efficacy to abciximab (abx). An occlusive thrombus was induced by placing a copper coil in the left femoral artery of 5-7 kg, male cynomolgus monkeys. All animals received aspirin and heparin was administered as follows: 70 U/kg bolus + 15 U/kg/hr in control and rPSGL-Ig animals, 60 U/kg bolus + 7 U/kg/hr in abx and abx + rPSGL-Ig animals. Animals received TNK 15 min post-occlusion as a 1.1 U/kg IV bolus followed by: (1) vehicle (2) rPSGL-Ig (500 µg/kg IV bolus) (3) abx (0.25 mg/kg IV bolus + 0.125 µg/kg/min infusion for the duration of the experiment) or (4) both rPSGL-Ig and abx. Antegrade blood flow was monitored by angiography every 10 min for 3 hr following TNK administration, and was scored on a scale 0-3. Bleeding times were measured on the forearm of the animals at baseline, 10 min after administering TNK and one of the 4 treatments above, and again prior to termination. Surgical and bleeding time site blood loss was recorded. In control monkeys, thrombolysis was achieved in 70±18.8 min (n=6). Both rPSGL-Ig and abx accelerated time to lysis by 64% (n=6; p=0.02) and 57% (n=5; p=0.05) respectively. The percentage of time that post-lysis blood flow was near-normal (score 2 or 3) was increased from 43.2±12.1% in control animals to 80±16.3% (p=0.05) and 83.6±14.7% (p=0.03) by rPSGL-Ig and abx respectively. The combination of rPSGL-Ig and abx was comparable to either agent alone. Bleeding times and surgical blood loss in rPSGL-Ig-treated animals were no different from control. Despite the lower dose of heparin, bleeding times in abx animals were significantly prolonged to greater than 10 min (when bleeding time measurement was terminated) at all times following abx administration. Surgical blood loss was increased from 16±7.4 g in control monkeys to 55.8±7.2 g in abx monkeys (p=0.002). Blood loss in monkeys receiving both rPSGL-Ig + abx (52.5±13.8 g) was no worse than with abx alone (p=0.85). These results suggest that rPSGL-Ig modulates platelet-leukocyte mediated thromboinflammatory events that result in tissue factor release, fibrin accretion, and contribute to thrombus amplification and stabilization. P-selectin blockade with rPSGL-Ig is as effective as platelet GPIIb/IIIa inhibition with abx in enhancing the efficacy of TNK, but without increasing bleeding complications.

3353 Aspirin prevents superoxide generation in acute myocardial ischaemia

A.C.P. Chagas, C.V. Serrano, M. Venturinelli, A. Carniatto, P.L. Luz. *Heart Institute, Univ. São Paulo, Cardiology, São Paulo, Brazil*

Background: Normal vascular homeostasis depends on endothelial elaboration of paracrine factors that prevent both platelet adhesion to the endothelial surface and inappropriate vasospasm. In vivo, .NO is subject to rapid inactivation by the superoxide anion, an obligate product of normal oxidative metabolism. Polymorphonuclear leukocytes (PMN) are integrated into the acute inflammatory response to tissue injury and possess the capacity to produce oxygen-derived free radicals such as superoxide anion, when activated by appropriate stimuli. It has been hypothesized that the protective anti-ischemic effects of aspirin (ASA), may be do not only to its anti-platelet, but to its anti inflammatory properties. To elucidate if ASA affects O2 generation - traces of PMN activity -18 anesthetized dogs were studied.
Methods: 18 dogs were subjected to 60 min of myocardial ischemia (MI) (LAD occlusion) and 30 min of reperfusion (RP). 9 dogs were pretreated with 500 mg of ASA, and were compared with 9 control (CT) dogs without ASA. We determined the risk/infarct area and relate it to the and to the .O2- generation (cytochrome c reduction/nmol/106 cells) of ex vivo phorbol ester-stimulated whole blood from both sets of dogs. Blood samples collected from the coronary sinus before LAD occlusion and 1,5,and 30 min after R.
Results: CT and ASA dogs presented similar infarcted areas (% risk areas): 38+4% and 35+1%, respectively. Results in the table are expressed as mean+SEM; *p<0.01, vs pre-occlusion; #p<0.04, CT vs ASA

	Pre-occl	1 min RP	5 min RP	30 min RP
.O2./CT	7+2	22+5*	30+4*,#	8+1
.O2./ASA	134+4	33+13*	51+8*	14+4

.O2./CT - superoxide anion generation in control dogs.O2./ASA - superoxide anion generation in aspirin trated dogs

Conclusion: Ex vivo O2 generation decreased significantly in stimulated cells suggesting in vivo activation. ASA, in addition to its anti-thrombotic effect, possesses an anti-oxidant effect.

3354 Effect of ischaemic preconditioning on oxygen radical production in myocardium: a microdialysis study with salicylate

E. Ruuge[1], E.I. Kalenikova[1], E.A. Gorodetskaya[1], O.S. Medvedev[2].
[1]*Cardiology Research Center, Institute of Experimental Cardiology, Moscow, Russian Federation;* [2]*Moscow State University, Faculty of Basic Medicine, Moscow, Russian Federation*

There is evidence that oxygen-derived free radicals play an essential role in the irreversible injury of cardiac cells associated with prolonged periods of ischemia. The aim of this study was to examine the effect of ischemic preconditioning on myocardial oxygen radical production using rat heart model of regional ischemia.
Methods: Experiments were carried out on anaesthized artificially ventilated open-chest male Wistar rats. The linear microdialysis probe was inserted in the left ventricle wall and perfused with Ringer solution containing sodium salicylate. 2,3-dihydrobenzoic acid (2,3-DHBA) produced in the reaction of oxygen radicals with salicylate was measured in dialysis samples by high-performance liquid chromatography. Before 30 min of coronary artery occlusion and 60 min of reperfusion, the hearts were either subjected or not subjected to preconditioning, which was achieved with three cycles of 5 min of ischemia followed by 5 min of reperfusion.
Results: In the control group, the regional prolonged ischemia induced a considerable increase of the 2,3-DHBA level (143±11% vs baseline) with maximum on 20-30 min of ischemia. Following reperfusion resulted in further extended rise of 2,3-DHBA level up to 214±18% (maximal level) after 20 min of reperfusion and 165±11% vs baseline value after 60 min of reperfusion. Preconditioning eliminated the increase of 2,3-DHBA level during prolonged ischemia and essentially restricted the elevated rate of oxygen radical production during reperfusion, which was observed only for the first 15 min of reperfusion. The changes in the kinetics of oxygen radical production were related to the limitation of the infarct size in preconditioned hearts – 5.4±1.4% vs 30.8±3.3% in control group. A worth mentioning finding of this study was the significant increase of the 2,3-DHBA level in preconditioned hearts during the second and third brief episodes of reperfusion (equal to 130±9% and 144±14% vs baseline level, respectively).
Conclusions: The results suggest that preconditioning significantly reduces the rate of oxygen radical production in myocardium during regional prolonged ischemia and reperfusion. It may play an important role in improvement of postischemic myocardial function. Oxygen radicals generated in cardiac myocytes during brief episodes of reperfusion may be involved in triggering of the cascade of protective mechanisms of ischemic preconditioning.

3355 Vascular stunning without myocardial stunning

V.J. Pomblum[1], S.C. Garcia Pomblum[1], T. Hohlfeld[2], E. Gams[3], J.D. Schipke[1]. [1]*University Hospital Duesseldorf, Research Group Experimental Surgery, Duesseldorf, Germany;* [2]*University Duesseldorf, Institute of Pharmacology, Duesseldorf, Germany;* [3]*Dept of Thoracic and Cardiov Surgery, Clinic of Surgery I, University Hospital Düsseldorf, Germany*

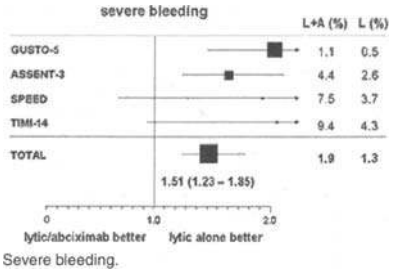
Background: Myocardial and vascular stunning coexist, but seem to represent relatively independent phenomena. For example, injury of endothelial cells precedes dysfunction of the cardiomyocytes.
Methods: To investigate uncoupling between myocardial and vascular stunning, experiments were performed on 31 isolated, blood-perfused rabbit hearts. Protocol: 30 min normoxia, 20 min no-flow ischemia, 60 min reperfusion. To assess vascular dysfunction, either placebo, an endothelium-independent NO-donor (SIN-1: 100 μM) or the endothelium-dependent vasodilator substance P (SP: 5 nM) was administered. This protocol was repeated in control hearts without ischemia/reperfusion.
Results: In the placebo group, ventricular function and coronary resistancec at the end of the protocol were not different from baseline. In the control hearts, SIN-1 and SP decreased coronary resistance by 35 and 39%, respectively. In the ischemic/reperfused hearts, the SIN-1-induced dilatation was almost maintained but the SP-induced dilatation was reduced to 9% (p<0.05 vs controls). In the three groups, postischemic/reperfused systolic ventricular function was not significantly reduced compared with baseline.
Conclusions: Our results convincingly show that brief global ischemia and reperfusion in isolated rabbit hearts can induce vascular (endothelial) stunning without impairing myocardial function (myocardial stunning). Thus, the absence of a postischemic contractile dysfunction does not ensure the absence of postischemic injury.

THROMBOLYTIC "COCKTAILS" – BENEFICIAL OR DANGEROUS

3356 Half dose lytic plus abciximab compared to full dose lytic in acute myocardial infarction: a meta-analysis

F.W.A. Verheugt, M.A. Brouwer. *University Medical Center Nijmegen, Heartcenter, Departmenf of Cardiology, Nijmegen, Netherlands*

Background: Angiographic trials have shown improved 60 and 90 minutes coronary patency with half-dose lytic plus abciximab versus lytic alone in ST-elevation MI (STEMI). These strategies have recently been evaluated in 2 phase III megatrials for efficacy and safety.
Methods: Rates of 30-day mortality, intracranial hemorrhage (ICH), severe extracranial bleeding and transfusions were collected from the half-dose lytic plus abciximab arms and the lytic alone arms of TIMI-14 and SPEED, and the megatrials GUSTO-V and ASSENT-3.
Results: In total 23,322 patients were randomized in these 4 published trials: 10,713 in the half-dose lytic plus abciximab groups and 12,609 in the lytic alone groups. 30-day death was similar in both groups: 5.8% vs 5.8% (RR 0.99, 95%CI 0.81-1.10, p = 0.88) as was the rate of ICH: 0.7% vs 0.7% (RR 0.98, 95%CI 0.49-1.96, p = 0.96). But, severe extracranial bleeding was very significantly increased by half-dose lytic plus abciximab (L+A) compared to lytic alone (L, figure), as was the need for transfusion: 5.6% vs 3.9% (RR 1.46, 95%CI 1.30-1.64).



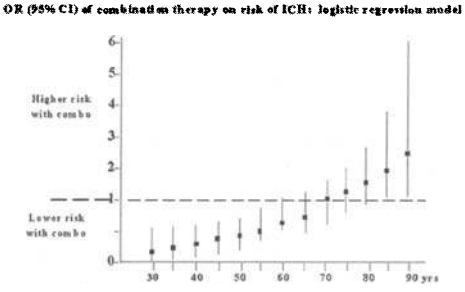
Severe bleeding.

Conclusion: In comparison to a fibrinolytic alone, reduced dose fibrinolytic combined with abciximab for STEMI significantly increases severe bleeding and transfusion with 50% without reducing mortality or hemorrhagic stroke. This costly combination should be avoided as a routine, and trial designs evaluating the combination for facilitated primary PCI or for prehospital/ER use prior to primary PCI should be reconsidered.

3357 Age and risk of intracranial haemorrhage with abciximab and half-dose reteplase in acute myocardial infarction: dichotomous response in the GUSTO V trial

S. Savonitto[1], D. Ardissino[2], A.M. Lincoff[3], J. Booth[3], P.F. Terrosu[4], J. Gang[3], E.J. Topol[3] on behalf of the GUSTO V Investigators. [1]*Ospedale Niguarda Ca' Granda, Divisione di Cardiologia I°, Milano, Italy;* [2]*Ospedali Riuniti di Parma, Divisione di Cardiologia, Parma, Italy;* [3]*Cleveland Clinic Foundation, Department of Cardiology, Cleveland, Ohio, United States of America;* [4]*Ospedale SS Annunziata, Divisione di Cardiologia, Sassari, Italy*

By reducing the dosages of the fibrinolytic agent and heparin, combination therapy with a GPIIb/IIIa blocker, half-dose lytic and reduced-dose heparin has the theoretic potential for reducing the risk of intracranial hemorrhage (ICH) associated with thrombolytic treatment of acute MI. We evaluated the relation between univariate and multivariate predictors of ICH and the efect of treatment with either abciximab and half-dose reteplase (combination therapy) or reteplase alone in the 16588 patients randomised in the GUSTO V trial. Overall, the incidence of ICH was similar in the two groups (0.6% vs 0.6%: OR 1.05, 95% CI 0.71, 1.56). Among the multivariable predictors of ICH, only age showed a significant interaction with treatment effect (age per treatment interaction Chi-square 7.103, P=0.008). When the age per treatment interaction is not included in the logistic regression model (C statistic 0.828), treatment with combination therapy is nonsignificant in predicting ICH. However, when the interaction term is included (C statistic 0.822), combination therapy becomes a significant predictor (Chi-square 6.953, P=0.008). The relationship between age and the odds ratio of having an ICH for patients randomised to combination therapy compared to reteplase alone is shown in the figure: a significant lower risk of combination therapy is observed for people of age <57, and a significantly higher risk for people >82.



ICH and age.

Thus, although no additional risk of ICH exixts with combination therapy in the whole population, a significant age per treatment interaction exixts, with a protective effect from combination therapy in younger patients and a higher risk in the elderly.

3358 Combination eptifibatide and reduced-dose tenecteplase in acute ST-segment elevation myocardial infarction: final results of a phase II angiographic trial (INTEGRITI)

U. Zeymer[1], F. Van de Werf[2], R.P. Giugliano[3], C.M. Gibson[4], M.M. Kitt[5], J.T. Strony[6], R.A. Harrington[7], E. Braunwald[3] on behalf of the INTEGRITI Investigators. [1]*Kliniken Kassel, Cardiology, Kassel, Germany;* [2]*Universitair Ziekenhuis, Cardiology, Gasthuisberg, Belgium;* [3]*Brigham and Women's Hospital, Cardiovascular Division, Boston, United States of America;* [4]*Harvard Medical School, Harvard Clinical Research Institute, Boston, United States of America;* [5]*COR Therapeutics, Inc., South San Francisco, United States of America;* [6]*Schering Plough Research Institute, Kenilworth, United States of America;* [7]*Duke Clinical Research Institute, Durham, United States of America*

Background: Prior studies suggest combination glycoprotein IIb/IIIa inhibition and reduced-dose fibrinolytic may restore infarct artery patency and tissue perfusion more effectively than fibrinolytic monotherapy.
Methods: 438 patients with STE-MI (median age 58y, 77% men, 33% anterior MI) were treated with aspirin and heparin. In dose-finding 189 patients received one of three combinations of eptifibatide (ept) and tenecteplase (TNK): 1)ept 180/2/90 + 50%TNK, 2)ept 180/2/90 + 75%TNK, 3)ept 180/2/180 + 50%TNK. In dose confirmation, 249 patients received either ept 180/2/180 + 50%TNK vs. full-dose (0.53 mg/kg) TNK monotherapy. The primary endpoint was the rate of TIMI 3 epicardial flow at 60 min as determined by a blinded angiographic core laboratory.
Results: TIMI 3 flow rates with the three combinations of ept+TNK in dose confirmation were similar (64-68%), while arterial patency was highest (96%) with ept 180/2/180 + 50%TNK. In dose confirmation, ept 180/2/180 + 50%TNK compared to TNK alone achieved higher rates of TIMI 3 epicardial flow (59% vs 49%, p=0.15), arterial patency 85% vs 77% (p=0.17), and faster median corrected TIMI frame count (36 vs 40 frames, p=0.54). Myocardial perfusion was improved with combination therapy as determined by median ST-segment resolution (71% vs 61%, p=0.08), and rate of TIMI myocardial perfusion grade 3 flow (49% vs 45%, p=0.59). At 48 hours and 30 days, combination therapy tended to have lower rates of death (48h: 1.7% vs 4.2%, p=0.25; 30d: 3.4% vs. 5.1%, p=0.51) and of the triple composite death+MI+urgent target vessel revascularization (48h: 3.4% vs. 11.0%, p=0.02; 30d: 10.9% vs. 14.4%, p=0.42). More major hemorrhage (7.6% vs. 2.5%, p=0.14) was seen with combination therapy, however this was all non-cerebral bleeding.
Conclusions: Ept 180/2/180 + 50%TNK improves epicardial and myocardial reperfusion, although it may also increase non-cerebral bleeding. This combination is being evaluated in a phase III study (ADVANCE-MI), with minor modifications aimed at reducing bleeding.

3359 TNK with reduced dose unfractionated heparin associated with similar efficacy and less bleeding: results from ASSENT-2 and ASSENT-3

J. Alexander[1], R.H. Tuttle[2], C.B. Granger[1], L. Wallentin[3], F.W.A. Verheugt[4], P.W. Armstrong[5], F.J. Van de Werf[6]. [1]*Duke University Medical Center, Medicine/Cardiology, Durham, United States of America;* [2]*Duke Clinical Research Institute, Durham, United States of America;* [3]*University of Upsala Hospital, Cardiology, Upsala, Sweden;* [4]*Catholic University, Cardiology, Nijmegen, Netherlands;* [5]*University Of Alberta, Edmonton, Canada;* [6]*University of Leuven, Herestraat, Belgium*

Background: ACC/AHA guidelines for management of acute MI call for weight-based, reduced-dose unfractionated heparin (UFH) with fibrinolytic therapy, however, this regimen has never been prospectively tested. We compared outcomes of patients receiving TNK-tPA and the current ACC/AHA-regimen UFH in ASSENT-3 and the former standard UFH regimen in ASSENT-2.
Methods: The ASSENT-2 and ASSENT-3 trials had similar inclusion criteria. In ASSENT-3, 2038 patients received TNK, a 60 U/kg bolus (max. 4000 U), and 12 U/kg/hour (max. 1000 U/hr) initial infusion of UFH. In ASSENT-2, 8461 patients received TNK and UFH. Those weighing >67 kg received a 5000 U UFH bolus and 1000 U/hour initial infusion and those weighing <67kg received 4000 U bolus and 800 U/hour initial infusion. In both trials, UFH was adjusted to an aPTT of 50-70 seconds. In ASSENT-3, a 3 hour aPTT was added to allow early adjustment for aPTT >70 seconds. We compared outcomes before and after adjusting for baseline predictors of 30-day mortality (age, systolic BP, heart rate, MI location, Killip class) and major bleeding (age, gender, weight, diastolic BP, HTN, region).
Results: ASSENT-3 and ASSENT-2 patients had similar baseline characteristics. Those in ASSENT-3 underwent less CABG (5.2% vs. 5.5%) and more PCI (31% vs. 24%) than those in ASSENT-2. Outcomes are shown in the Table. Adjusted 30-day mortality was similar in ASSENT-3 and ASSENT-2 (OR 0.96, p=0.73) but the adjusted risk of major bleeding in ASSENT-3 was lower (OR 0.45, p<0.001).

Outcome	ASSENT-3 (n=2038)	ASSENT-2 (n=8461)	p-value
Death (30d)	6.0%	6.2%	0.77
Death (30d)/MI	9.6%	9.5%	0.96
Death (30d)/MI/RI	17.5%	17.0%	0.60
ICH	0.93%	0.93%	0.88
Major Bleeding	2.2%	4.7%	0.001
Transfusion	2.3%	4.3%	0.001

Conclusion: These data support the use of ACC/AHA guideline recommended weight-based, reduced-dose UFH regimen with fibrinolytic therapy. This regimen results in less systemic bleeding but similar ICH compared to more aggressive UFH dosing, with no loss of efficacy.

3360 Combination therapy with reduced-dose tenecteplase and eptifibatide results in faster and more stable reperfusion for acute myocardial infarction

M.T. Roe[1], C. Green[2], K. Trollinger[2], S. Crater[2], K. Loeffler[2], R.P. Giugliano[3], R.A. Harrington[2], M.W. Krucoff[2] on behalf of The INTEGRITI Investigators. [1]*Duke Clinical Research Institute, Durham NC;* [2]*Duke Clinical Research Institute, Cardiology Dept., Durham NC;* [3]*Brigham and Womens Hospital, Cardiology, Boston, MA, United States of America*

Background: Despite improved infarct-artery patency with reduced-dose fibrinolytics and glycoprotein (GP) IIb/IIIa inhibitors, combination reperfusion therapy has not improved survival in patients with acute myocardial infarction (MI). Further characterization of the timing of reperfusion may elucidate the paradoxical impact of combination therapy on surrogate biomarkers of reperfusion and clinical outcomes.
Methods: The INTEGRITI trial was a dose-ranging, phase II trial evaluating reduced-dose tenecteplase and eptifibatide in patients with acute ST-elevation MI. Patients from North American sites were included in a continuous ST-segment monitoring substudy for 24 hours using digital 12-lead Holter sampling of the electrocardiogram every 60 seconds (Rozinn 152). Patients who received combination therapy with 50% of the standard tenecteplase dose (0.5 μg/kg) and eptifibatide (180 μg/kg double-bolus with a 2.0 μg/kg/min continuous infusion) were compared to patients who recieved full-dose tenecteplase monotherapy. ST recovery parameters were based upon the timing of stable ST resolution (>= 50%) and the presence of any ST re-elevation in the lead with peak ST elevation.
Results: ST-recovery parameters are listed in the table. Continuously updated ST recovery analyses demonstrated greater ST-resolution in the combination therapy group at 30 minutes (57.7% vs. 43.8%), 60 minutes (82.7% vs. 65.6%), and 90 minutes (90.4% vs. 78.1%).

Variable	Full-Dose TNK (n = 45)	50% TNK + Eptifibatide (n = 73)	p-value
Time to Stable ST Resolution (mins)	98 (0,148)	55 (0,95)	0.058
Stable ST Resolution by 2 hrs (%)	67.7	89.4	0.016
ST Recovery Curve Area (uV/min)	4858 (598,13721)	1710 (0,4156)	0.020
Recurrent Ischemia (%) *	57.1%	34.0%	0.050

*Includes cyclic flow and late ST-segment re-elevation after initial ST resolution. TNK, tenecteplase.

Conclusions: Combination therapy with reduced-dose tenecteplase and eptifibatide accelerates early reperfusion and reduces the risk of recurrent ischemia in patients with acute MI. These results suggest that combination therapy may improve myocardial salvage, but further studies are needed to delineate the impact of this benefit on clinical outcomes.

3361 Influence of enoxaparin and early revascularisation on death or myocardial infarction after thrombolysis in myocardial infarction

L. Wallentin[1], B. Lindahl[2], P. Armstrong[3], C. Granger[4]. [1]*Uppsala University Hospital, Uppsala, Sweden;* [2]*University Hospital, Dept. of Cardiology, Uppsala, Sweden;* [3]*Dept of Cardiology, Alberta, Canada;* [4]*Duke University, Director, Cardiac Care Unit, Durham NC, United States of America*

The ASSENT-3 trial showed that enoxaparin (Enox; n=2040) or abciximab + heparin (n=2017) in comparison to the standard treatment with unfractionated heparin (UFH; n=2038) reduced in-hospital rates of death or myocardial infarction (MI) - 6.8, 7.3% versus 9.1% (p=0.016). We evaluated the two heparin arms concerning the risk of occurrence of these events after discharge as enoxaparin treatment was terminated either at in-hospital revascularisation (revasc.) or at discharge (disch.)
Methods: The ASSENT-3 trial randomised ST-elevation MI patients in 25 countries to fibrinolytic treatment with TNK-tPA and either 48 hours infusion of UFH (APTT 50-70 sec) or s.c. Enox b.i.d. (1 mg/kg b.w.) until revascularisation or hospital disch - maximum 7 days. The primary end-point was a composite of 30-days mortality and in-hospital myocardial infarction or severe ischemia. Myocardial infarction from disch. until 30-days follow-up was collected as readmissions caused by reinfarction. In-hospital revasc. was at the discretion of the physician and varied from 2 - 72% between the countries.
Results:

Results death + MI	n/n	UFH	Enox	p
All: In-hospital	2038/2040	9.1%	6.8%	0.006
All: Entry - 30d	2038/2040	10.5%	9.1%	0.14
Revasc: Disch-30d	673/623	1.0%	1.3%	0.68
No revasc:Disch-30d	1210/1282	1.9%	3.3%	0.031

In multivariate analyses in hospital revasc. was significantly associated with a lowered (p=0.005) risk of death or MI after hospital discharge after adjusting for age, diabetes, infarct size and medication.
Conclusion: Revascularisation early after thrombolysis of acute ST-elevation MI seems associated with a reduced occurrence of death or myocardial infarction and to contribute to maintain the long-term benefits of adjuvant treatment with enoxaparin.

GLYCOPROTEIN IIB/IIIA – NEW ASPECTS

3362 Troponin release in patients with unstable angina – Relation to platelet aggregability and PLA2 polymorphism

C. Heeschen[1], C.W. Hamm[2]. [1]*Molecular Cardiology, Frankfurt, Germany;* [2]*Kerckhoff Heart Clinic, Div. of Cardiology, Bad Nauheim, Germany*

The glycoprotein IIb/IIIa receptor (GP IIb/IIIa) plays a pivotal role in platelet aggregation. Recent data suggest that the PlA2 polymorphism (GP IIIa subunit) is associated with an adverse outcome. However, it is unknown for patients with unstable angina whether there is an association between PlA2 polymorphism, platelet reactivity, and Troponin T (TnT) release. **Methods and Results:** We prospectively studied the TnT status, the GP IIIa genotype (PCR-based restriction fragment length polymorphism analysis), and the platelet reactivity (P-selectin expression, circulating monocyte-platelet aggregates) in 125 patients with unstable angina. TnT elevation > 0.1 ug/L was observed in 37% of the patients. At least one PlA2 allele was present in 24.5% of the patients whereas for TnT-positive patients at least one PlA2 allele was present in 53.7% of the patients. The PLA2 polymorphism was associated with increased platelet aggregability as indicated by increased P-selectin expression (74.9% versus 52.4%; PLA2 vs. PLA1; $P<0.01$) and increased number of circulating monocyte-platelet aggregates (32.9% versus 19.8%; $P<0.01$). TnT elevation was also highly predictive of increased platelet reactivity as indicated by P-selectin expression (72.5% vs. 48.1%; TnT pos. vs. TnT neg.; $P<0.01$) and circulating monocyte-platelet aggregates (38.2% vs. 16.9%; $P<0.01$). Consequently, a high correlation was observed between genotype and TnT elevation ($r=0.63$; $P<0.001$). However, in a multivariate analysis, TnT elevation, but not PLA2 polymorphism, was an independent predictor of platelet activation ($P<0.001$).
Conclusions: Our findings indicate that molecular variants of the gene encoding GP IIIa play a role in platelet reactivity. In patients with unstable angina, TnT appears to be a powerful surrogate marker for platelet hyperreactivity. Our observations are compatible with and provide an explanation for the reported predominant benefit of GP IIb/IIIa receptor antagonists in patients with elevated TnT levels.

3363 Influence of glycoprotein IIb/IIIa antagonist abciximab on platelet induced monocyte tissue factor expression

S. Steiner, D. Seidinger, E. Minar, K. Huber, C.W. Kopp. *AKH Wien, Internal Medicine II, Vienna, Austria*

Background: Tissue Factor (TF), the major physiological initiator of the coagulation cascade is normally not expressed by cells within the circulation. However, activated platelets induce monocyte TF expression. We studied the effect of abciximab, a glycoprotein IIb/IIIa antagonist used in percutaneous coronary interventions (PCI), on platelet-monocyte cross talk and monocyte TF expression in vitro. **Methods:** Expression of TF as well as total (CD42) and activated (CD62P, CD40 Ligand) platelet load was determined on CD14 positive monocytes by a four colour whole blood cytometric technique after stimulation with thrombin receptor agonist (TRA; 12.5μM) in the absence or presence of abciximab (50μg/ml). Whole cell procoagulant activity was assessed in a chromogenic assay. **Results:** Percentage of activated platelets (CD62P) on monocytes correlated positively with total monocyte platelet load (CD42; $r=0.97$, $p<0.001$) and CD40 Ligand after stimulation ($r=0.90$, $p<0.001$). TF mean fluorescence intensity (MFI) was positively correlated with platelet activation measured by CD62 MFI in timecourse ($r=0.75$, $p<0.001$) TRA stimulation resulted in a significant increase in monocyte TF expression ($p<0.001$), whereas preincubation with abciximab abolished this effect ($p=0.3$) and significantly reduced TF after 1, 5, 10 and 30 minutes (see table). Abciximab preincubation significantly lowered percentage of CD62 expression on platelet-monocyte aggregates after TRA stimulation ($p<0.05$). Similarly, whole cell procoagulant activity was decreased with abciximab pretreatment ($p<0.05$).

	0 min	1min	5min	10min	30min	60min
TRA	12.9 ± 3.3	33.0 ± 9.2	25.2 ± 12.1	28.9 ± 11.9	37.2 ± 8.7	37.4 ± 13.8
TRA+abcixmab	12.9 ± 3.3	13.6 ± 7.1	12.6± 5.8	15.4 ± 8.9	15.4 ± 10.5	20.2 ± 14.3
p-value	1.0	0.001	0.04	0.018	0.002	0.069

Percentage of TF positve monocytes (mean±std) in timecourse after TRA stimulation w/o abciximab (n=6)

Conclusion: We demonstrate reduced TF expression and procoagulant activity due to altered total and activated platelet load on monocytes by abciximab. Next to inhibition of platelet aggregation this my further contribute to the efficacy of abciximab in preventing thrombotic complications in PCI.

3364 Eptifibatide blocks the increase in C-reactive protein levels induced by coronary angioplasty

A. Merino[1], M. Artaiz[1], I. Alins[1], I. Segura[1], V. Iñigo[1], B. Vidal[1], A. Rodriguez[1], E. Alegria[2]. [1]*Palma de Mallorca, Spain;* [2]*Clinica Universitaria, Pamplona, Spain*

Background: The increase in C-reactive protein levels usually observed after coronary angioplasty has been thought to be produced by an increased inflammatory response to lesion dilatation. However, this inflammatory response could be initiated by the high intraarterial thrombogenic activity induced by balloon-produced plaque fracture.
Methods: We measured C-reactive protein levels by nephelometry in patients with coronary angioplasty after blocking thrombosis by means of a selective platelet GP IIb-IIIa receptor antagonist. Ninety patients who underwent a coronary angioplasty procedure at our cardiac catheterization laboratory were included. We excluded patients with recent myocardial infarction, recent surgery or inflammatory, metabolic or neoplastic diseases. C-reactive protein was determined pre angioplasty, 24 and 48 hours after the procedure. In 48 patients Eptifibatide perfusion was initiated immediately after the procedure, and continued for only 24 hours.
Results are shown in the table.

C-reactive protein after PTCA

	n	Pre-PTCA	24 h	48 h
Eptifibade	48	0.41(0.48)	0.41(0.65)	0.95(0.89)**
Control	42	0.52(0.44)	1.16(0.98)*	1.62(1.45)**
p		ns	p<0.001	p<0.01

PTCA: Percutaneous coronary angioplasty. Numbers are: mean(SD);* p<0.05 to Pre-PTCA; ** p<0.05 to 24 h.

Conclusions: Eptifibatide, a synthetic peptide, which is a selective blocker of the platelet GP IIb-IIIa receptor with no known anti-inflammatory effects, significantly blocked C-reactive protein concentration elevation after angioplasty. C-reactive protein increased again after Eptifibatide perfusion was interrupted. These results suggest that arterial thrombosis may trigger the incresase in C-reactive protein elevation after coronary angioplasty.

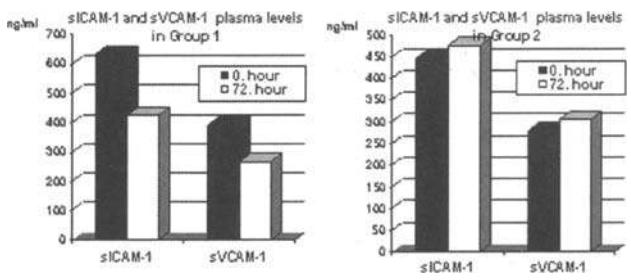
3365 Glycoprotein IIb/IIIa antagonists and inflammation: a new effect mechanism in patients with unstable angina pectoris

E. Ercan[1], H. Bozdemir[1], C. Ceyhan[2], T. Tekten[2], A. Onbasi[2], I. Altugoglu[3], G. Bozdemir[1], A. Akilli[1]. [1]*Cardiology,* [2]*Adnan Menderes Univ., Cardyology, Aydýn;* [3]*Microbiology, Ege Univ. Medical School, Izmir, Turkey*

Aim: Inflammation has an important role in the pathogenesis of unstable angina pectoris (UAP). The anti-inflammatory effect of Tirofiban, glycoprotein IIb/IIIa antagonist, was evaluated in patients with UAP.
Methods: This study compares changes in level of intercellular adhesion molecule-1 (sICAM-1) and vascular cell adhesion molecule-1 (sVCAM-1) between patients receiving tirofiban (Group 1: n=15) or placebo (Group 2: n=20) in addition to heparin and aspirin for treatment of an UAP. Blood samples were drawn at 0 hour and 72 hour. 10 patients with stable coronary artery disease (Group 3) and 10 patients with normal coronary angiography (Group 4) were selected as control groups.
Results: Circulating venous plasma sICAM-1 and sVCAM-1 (p<0.0001) levels were higher in the UAP patient group (Group 1,2) than the control groups. In Group 1, sICAM-1 and sVCAM-1 (p<0.0001) levels decreased significantly as compared with the baseline (table).

Group		Mean	Std. Dev.	p
1	Pair 1 sICAM-1(0h)-sICAM-1(72h)	209.6	139.2	0.000
1	Pair 2 sVCAM-1(0h)-sVCAM-1(72h)	121.6	50.9	0.000
2	Pair 1 sICAM-1(0h)-sICAM-1(72h)	-29.8	109.9	0.24
2	Pair 2 sVCAM-1(0h)-sVCAM-1(72h)	-25.7	51.2	0.037

In Group 2, sICAM-1 (p:0. 24) and sVCAM-1 (p<0.037)levels were remained unchanged or increased (figure).



Conclusion: After the Tirofiban infusion, inflammatory response decreased significantly in patients with UAP.

3366 Effects of roxifiban on platelet aggregation and major receptor expression in patients with coronary artery disease

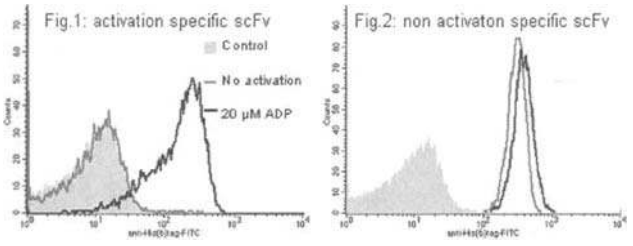
V.L. Serebruany[1], A. Malinin[1], C.M. O'Connor[2], P.A. Gurbel[1]. [1]*Johns Hopkins University, Sinai Hospital, Baltimore, United States of America;* [2]*Duke University, Durham, United States of America*

Background: It has been expected that therapy with oral GPIIb/IIIa blockers including roxifiban will reduce mortality and vascular complications in a long-term. However, platelet-related properties of roxifiban in the clinical setting are not well known. We measured platelet characteristics during chronic treatment in patients with coronary artery disease enrolled in the Roxifiban Oral Compound Kinetics Evaluation Trial (ROCKET-I).
Methods: ROCKET-1 was designed as a randomized, double blind, multicenter, dose-ranging study of roxifiban, administered either as monotherapy or concomitantly with aspirin compared to aspirin alone. Thirty-one patients were assigned for 24 weeks of therapy with aspirin (n=7), roxifiban (n=9), roxifiban+aspirin (n=15). Platelets were assessed five times in each patient at baseline, and at week 2, 4, 12, 18, 24 thereafter by aggregometry, and flow cytometry.
Results: Baseline platelet characteristics were similar between all three groups. There was a consistent significant decrease of ADP- (p=0.0001), and collagen-induced (p=0.002) platelet aggregation in the roxifiban-treated patients when compared with those treated with aspirin alone. Flow cytometry revealed paradoxical late activation of GP IIb/IIIa expression (p=0.007) when roxifiban was used without aspirin which was significant compared to aspirin, and aspirin-roxifiban groups. There were no differences among groups in GP Ib expression, although it's rise was more profound in the roxifiban-treated patients. There were substantial differences in the P-selectin expression. While aspirin time-dependently decreased per cent of P-selectin positive platelets (p=0.02), treatment with roxifiban resulted in the phasic changes with the early inhibition (p=0.01), and then two-fold activation (p=0.0001) starting at week 12 of the therapy. There was an early transient activation of PECAM-1 expression (p=0.008) at week 2, followed by the later inhibition of this receptor (p=0.003) in patients treated with roxifiban.
Conclusion: Despite achieving sustained inhibition of platelet aggregation, therapy with roxifiban has been associated with over expression or phasic changes of major platelet receptors. These data may explain clinical concerns with the use of oral GPIIb/IIIa inhibitors linking higher mortality rates and incidence of thrombotic episodes with paradoxical switching to alternative passways of platelet activation.

3367 Selection of human single chain antibodies against the activated conformation of GPIIb/IIIa from a natural and a synthetic phage library

M. Schwarz[1], P. Roettgen[2], S. Knackmuss[2], N. Basler[3], C. Büttner[2], C. Bode[3], M. Little[2], K.H. Peter[3]. [1]*University of Freiburg, Department of Cardiology and Angiology, Freiburg i. Br., Germany;* [2]*Affimed Therapeutics, Heidelberg, Germany;* [3]*University Freiburg, Cardiology, Freiburg, Germany*

All GPIIb/IIIa-blockers, which are currently in clinical use are binding to the receptor irrespectively to its conformational state. However an activation- specific blocker might provide several advantages, such as decreased bleeding complications and less induction of ligand-induced binding sites.
Therefore we used phage display to obtain activation-specific single chain antibody fragments(scFv) from two different libraries: A natural library was constructed using cDNA from human lymphocyte donors encoding heavy and light chains of antibodies. These sequences were assembled in the phagemid vector pEXHAM1. A synthetic library was constructed by introduction of a randomised nucleotide-sequences in the CDR3 region of a constant framework scFv-sequence. As target for the selection we used activated GPIIb/IIIa on ADP-stimulated platelets and GPIIb/IIIa on transfected CHO-cells bearing a GFFKR-Deletion. The various resulting clones were expressed in the periplasmic space of E.coli and screened in flow cytometry, using an FITC-labelled anti-His(6)-tag antibody. In addition to some non-activation-specific antibodies (see fig. 2), more than 8 activation-specific were obtained from both libraries. These activation-specific antibodies demonstrate nearly no binding to non-activated platelets,which is 3 to 8 fold increased on ADP-stimulated platelets (see figure).



Distinct activation specifities of scFv.

In analogy to the GPIIb/IIIa-binding-sequence on fibrinogen the CDR3-regions of nearly all activation specific scFv's demonstrated RXD-sequences.The obtained scFv-sequences might help to improve the understanding of the function of GP IIb/IIIa and its interaction with ligands and blockers. Moreover, these newly generated human scFv-antibodies may represent a new class pharmaca for an advanced GPIIb/IIIa-blockade.

PERCUTANEOUS CORONARY INTERVENTION IN 2002: ACHIEVEMENTS, HOWEVER, SOME DARKNESS REMAINS!

3368 Coronary artery perforations: incidence, predictors and clinical outcome

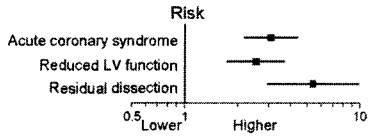
G.S. Stankovic, M.F. Massimo Ferraro, K.T. Kostas Toutouzas, A.C. Alaide Chieffo, N.C. Nicola Corvaja, R.A. Remo Albiero, C.D.M. Carlo Di Mario, A.C. Antonio Colombo. *EMO Centro Cuore Columbus, Milan, Italy*

Background: Coronary perforation is an uncommon but potentially life-threatening complication of percutaneous coronary intervention (PCI). The aim of the present study was to determine the incidence, associated factors, in-hospital and late outcome of patients sustaining a coronary perforation.
Methods and Results: Between 4/1993 and 11/2001 5728 patients with 10000 lesions were treated in our institution with different PCI modalities (2838 angioplasty - POBA, 6836 coronary stenting, 444 directional coronary atherectomy - DCA, 518 rotational atherectomy - ROTA, 48 laser angioplasty and 637 cutting balloon, 25 other new devices, including overlap). Clinical, procedural and angiographic characteristics were compared between patients with ruptured vessels and overall population.
Coronary perforations occurred in 84 patients (1.47%) and were graded according to Ellis classification (56 class 2 and 28 class 3). Perforation occurred during: POBA 45 (53.6%), DCA 8 (9.5%), ROTA 3 (3.6%), cutting balloon 2 (2.4%), guidewire manipulation 23 (27.4%) and other devices 3 (3.6%). Treatment: CABG 11,prolonged inflation 36, stenting 20 (PTFE covered stent 10), only protamin administration 17 perforations. None of clinical variables correlated with perforation occurrence, although trend was observed for women (2.13% vs. 1.36%, p=0.09). Perforations were more commonly observed following atheroablative procedures (2.4% of 639 procedures vs. 1.3% of 5005 non-atheroablative procedures, OR=1.8, 95%CI 1.1-3.2, p=0.027) and there was a trend for use of platelet GP IIb/IIIa inhibitors (2.6% vs. 1.4%, p=0.06). Perforations occurred more frequently when complex lesions were treated (1.9% vs. 0.5%, OR=3.6, 95%CI 1.8-7.2, p=0.001) and higher balloon-to-artery ratio used (1.29±0.25 vs. 1.19±0.31 mm, OR=7.6, 95%CI 2.8-20.7, p=0.001).
In-hospital outcome: 27 patients had major adverse cardiac events (32.1%). 15 patients (17.8%) had myocardial infarction (MI) (8 non-Q-wave MI and 7 Q-wave MI), 11 patients (13.1%) underwent emergency CABG and 7 patients died (8.3%). All patients who underwent emergency CABG or died had class 3 perforation.
Late outcome: Clinical follow-up was performed for all 77 eligible patients after 33±28 months. Six patients (7.8%) died, 8 patients (10.4%) underwent CABG and two patients (2.6%) had Q-wave MI.
Conclusions: Coronary perforations occurred more frequently in patients with complex lesions, higher balloon-to-artery ratio and following atheroablative procedures. Class 3 coronary perforation carries a high incidence of adverse outcome, including death.

3369 Predictors for thrombotic events within the first month after stent placement in small coronary arteries

J. Hausleiter, A. Kastrati, J. Mehilli, H. Schühlen, J. Pache, J. Dirschinger, A. Schömig. *Deutsches Herzzentrum München, München, Germany*

Thrombotic stent occlusion leading to myocardial infarction or death is a severe complication within the first month after stent placement. Stent placement in small coronary arteries (<3.0mm) represents an increasing proportion of the stent placement procedures each year. The purpose of this study was to investigate the predictors of thrombotic events occurring within 30 days after the procedure including also the role of stent design.
Methods: Successful stent placement in small coronary arteries was performed in a consecutive series of 3112 patients. All patients received the combined antiplatelet therapy with aspirin and ticlopidine/clopidogrel for 4 weeks. Thrombotic events were defined as death, myocardial infarction or stent occlusion documented by angiography.
Results: The cumulative thrombotic event rate was 4.2%. The figure demonstrates the three strongest predictors for thrombotic events. Stent design which is an important predictor for long-term outcome in small coronary arteries, was not identified as significant risk factor for early thrombotic events (P=0.38).



Risk for thrombotic events.

Conclusions: Early thrombotic complications occurred in a low percentage of patients in this large, unselected population. The predictors for thrombotic complications are predominantly clinical factors, indicating the need of a pre-interventional risk stratification with an intensified antithrombotic regimen for high risk patients. Although the stent design has a major impact on the angiographic and clinical long-term outcome, this analysis demonstrates that early thrombotic events are not influenced by differences in stent design.

3370 Ventricular fibrillation during coronary angiography/angioplasty: an incidental event or a prognostic marker?

V. Zeldets, A. Katz, A. Abuful, H. Gilutz, J.M. Weinstein, M. Merkin, R. Ilia, C. Cafri. *Soroka University Medical Center, Cardiology, Beer-Sheva, Israel*

Background: Ventricular Fibrillation (VF) during coronary angiography/angioplasty (CA) is a known phenomenon, attributed to various etiologies and perceived as an innocent event. There are no data of the impact of this event on prognosis.
Aim: To analyze the prognostic implications of VF during CA.
Methods: Analysis of 5328 CA procedures performed at our institute revealed 25 cases of VF. The clinical characteristics, indications, co- morbidity factors, type of procedure, time to mortality of the VF patients (pts) were analyzed and compared to 201 matched controlled CA pts. without VF. Non-ionic/low osmolarity contrast media was routinely used in all the acute/unstable pts.
Results: Analysis of multiple demographic, clinical and technical procedure parameters did not reveal any significant differences between the VF and non-VF pts.
DM, COPD and use of IIb IIIa inhibitors was higher among VF pts ($p<0.05$). The mortality of VF vs. non-VF pts was 40% vs. 14%, respectively (p=0.001), during follow-up of 10.4+17.8 m. Mortality 24 hours post CA was 24% in the VF pts vs. 5.8% in the non-VF pts (p=0.001). The in hospital mortality among the VF pts that underwent CA during acute MI or cardiogenic shock was 50% (6/12). The mortality of the elective pts with VF during CA was 31% (4/13).
Conclusions: VF during CA seems to be a prognostic marker for mortality. It implications should be viewed beyond incidental occurrence related to mechanical events or contrast material osmolarity. Therefore those pts should be evaluated and treated as high-risk pts.

3371 Prevention of renal function worsening by haemofiltration in patients with chronic renal failure undergoing percutaneous coronary interventions

G. Marenzi[1], G. Lauri[1], E. Assanelli[1], M. Grazi[1], J. Campodonico[1], D. Trabattoni[2], A. Bartorelli[2]. [1]*Centro Cardiologico Monzino, Unità Cure Intensive Coronariche, Milan, Italy;* [2]*Institute of Cardiology, Centro Cardiologico Monzino, Milan, Italy*

Radiocontrast exposure and hemodynamic instability during percutaneous coronary interventions (PCI) are significant causes of renal dysfunction that can require hemodialysis (HD), particularly in patients with pre-existent renal insufficiency. Treatment with HD is associated with poor outcomes, including a 40% in-hospital mortality rate. Therefore, a preventive strategy targeted for beneficial outcomes is an important challenge; however, no effective measures have been found. We investigated the role of continuous veno-venous hemofiltration (CVVH), as compared with isotonic hydration, in preventing radiocontrast nephropathy in high-risk patients. Indeed, CVVH allows: 1) high-volume, controlled hydration before and after exposure to contrast agent, 2) removal of dye from the circulation resulting in reduced kidney exposure, 3) intravascular volume stability. Seventy-five consecutive patients with chronic renal insufficiency (serum creatinine > 2 mg/dl) undergoing PCI, were submitted to either percutaneous (Y-shaped double lumen catheter inserted in a femoral vein)CVVH (n=41; 37% diabetes; baseline creatinine = 3.1±1 mg/dl) or to conventional treatment (n=34; 35% diabetes, baseline creatinine = 3.0±1 mg/dl) with isotonic saline at a rate of 1 ml/kg/hour. CVVH (fluid replacement rate of 1000 ml/hr without weight loss) was started 9±10 hours before and continued 24 hours after PCI. Saline hydration was started one day before and continued 24 hours after PCI. The mean radiocontrast volume was 270±140 ml in CVVH patients and 238±152 ml in controls (p=NS). After PCI, serum creatinine increased (>0.5 mg/dl) in 0% patients of CVVH-treated group and in 74% of saline group (p<0.0001) and, at discharge, in 5% and in 88%, respectively (p<0.0001). Temporary HD was required in 29% of cases of the saline group and in no case of the CVVH group. In 2 cases (saline group), permanent HD was required. In-hospital mortality was 2.4% in CVVH group and 14.7% in saline group (p<0.001).

Conclusions: In patients with chronic renal insufficiency undergoing PCI, periprocedural CVVH is an effective treatment to prevent renal function deterioration due to contrast nephrotoxicity and to improve in-hospital prognosis.

3372 Randomized comparison of tirofiban, eptifibatide, and abciximab in minimizing myocardial damage during high-risk percutaneous coronary intervention: TEAM pilot trial

S.K. Sharma, A. Kini, N. Perez, J. Suleman, E.A. Fisher, J.D. Marmur, M. Richard. *The Mount Sinai Medical Center, Cardiology Dept., New York NY, United States of America*

Background: The diverse results of various randomized PCI trials of GP IIb/IIIa inhibitors (GPI) may be due to different levels of platelet inhibiton (PI) achieved by a particular GPI agent. TEAM pilot trial is a double blind, randomized study of the three GPI during high-risk clinical (rest angina, post MI) or lesion (type C, ostial, calcified, thrombotic, multivessel intervention) PCI settings. TEAM study hypothesis was that with similar levels of PI (>90%), all three agents will have an equal class effect in reducing myocardial damage and 30-day major adverse cardiac events (MACE).

Methods: We analyzed 180 PCI patients randomized to one of the three arms: tirofiban (RESTORE dose), eptifibatide (PURSUIT dose), and abciximab (EPILOG dose), with similar baseline clinical, angiographic, and procedural characteristics. Patients with <90% PI (by RPFA with Ultegra device) after 10 min of GPI infusion, received additional half bolus of the blinded agent prior to PCI.

Results: In 232 lesions treated, angiographic success was 97.3% and procedural success 98.9%, 0.6/2.2% major/minor TIMI bleeding complications, 2.2/1.1% mild/severe thrombocytopenia in the entire group and were similar between the three agents. Mean peak activated clotting time was 255 sec and was similar between the three groups.

Results of the TEAM trial

Variable	Tirofiban (n=56)	Eptifibatide (n=61)	Abciximab (n=63)	p
Need for additional bolus (%)	58.9	31.1	53.9	0.004
Final PI prior to PCI (%)	93±4	93±3	93±4	NS
Any CKMB elevation (%)	16.1	14.7	14.3	NS
Troponin-I >2 ng/ml (%)	28.6	26.2	25.4	NS
30-day MACE (%)	5.4	3.3	4.8	NS

Conclusion: PCI patients with high-risk clinical/lesions require increased GPI dose compared to the recommended dose for an optimal PI. With this strategy, all three GPI had similar effect on myocardial salvage and 30-day MACE, and was not associated with increase in bleeding. Therefore, routine PI measurement may further improve the results of PCI in high-risk patients.

3373 Reduction in peri-procedural myocardial infarction by pre-procedural statin medication

J. Herrmann[1], A. Lerman[1], D. Baumgart[2], L. Volbracht[3], C. von Birgelen[2], M. Haude[2], G. Heusch[4], R. Erbel[2]. [1]*Mayo Clinic Rochester, Division of Cardiovascular Diseases, Rochester, United States of America;* [2]*University of Essen, Department of Cardiology, Essen, Germany;* [3]*University of Essen, Department of Clinical Chemistry, Essen, Germany;* [4]*University of Essen, Department of Pathophysiology, Essen, Germany*

Background: Stenting-related myocardial injury has been recognized as a frequent and prognostically important event, depending in its extent at least in part upon microcirculatory impairment in association with platelet aggregation, inflammation, and increase in oxidative stress. Recent studies underscored the non-lipid-lowering effects of HMG-CoA reductase inhibitors (statins) with antithrombotic, anti-inflammatory, and anti-oxidative aspects. Thus, we tested the hypothesis that pre-procedural statin treatment is associated with a reduction in the extent of stenting-related myocardial injury without the need of lower serum lipid concentrations.

Methods: Series of 296 consecutive patients (pts.) undergoing stenting of a de-novo coronary or graft stenosis, stratified according to the pre-procedural status of statin therapy (229 statin-pos. pts.; 67 statin-neg. pts.). Incidence of peri-procedural myocardial injury was assessed by analysis of creatine kinase (CK; upper limit of normal (ULN) 70 IU/l for women, 80 IU/l for men), and cardiac troponin T (cTnT; rapid bedside test; threshold 0.1 ng/mL) before and 6, 12, and 24 hours after the intervention.

Results: Total cholesterol and LDL serum concentrations were not different between statin-pos. and statin-neg. pts. (209 ± 45 vs. 203 ± 43 and 137 ± 42 vs. 136 ± 41 mg/dL, p=NS). Compared with statin-neg. pts., the incidence of CK elevation >3x ULN was significantly lower in statin-pos. pts. (see table). Pre-procedural statin treatment was associated with a lower risk of post-procedural CK elevation >3x ULN in both univariate (RR 0.07, 95% CI 0.01-0.63; p=0.018) and multivariate analysis (OR 0.08, 95% CI 0.01-0.75; p=0.027).

Post-procedural cardiac marker outcome

	Statin-neg. (n=67)	Statin-pos. (n=229)	p value
pos. cTnT [%]	22.4	17.9	NS
CK 1-3x ULN [%]	14.9	14.4	NS
CK >3x ULN [%]	6.0	0.4	0.01

Conclusions: Pre-procedural statin treatment is associated with a reduction in the incidence of larger-sized, stenting-related myocardial infarctions. Prospective, randomized trials are warranted to further assess this cardioprotective effect of statins in coronary intervention.

EXPLOITING THE POTENTIALS OF CORONARY FLOW RESERVE

3374 Influence of adjunctive GP IIb-IIIa inhibitors or thrombus extraction devices on CFR in patients with acute coronary syndromes treated with stent

M. Pan[1], J. Suárez de Lezo[1], M. Romero[1], A. Medina[2], J. Segura[1], D.J. Pavlovic[1], M. Rodríguez[1], J. Muñoz[1]. [1]*Reina Sofía Hospital, Cardiology Dept., Cordoba;* [2]*Dr. Negrin Hospital, Cardiology Dept., Las Palmas, Spain*

Coronary distal embolization is a potential complication of patients with thrombus containing lesions treated by stents. Platelet aggregates or larger fragments of thrombus may produce transient alterations in coronary blood flow that could be minimized by mechanical or pharmacological methods. We studied the protective effect of thrombus aspiration devices (X-sizer® or Rescue®) versus glycoprotein IIb-IIIa inhibitors on the immediate and 24-hour coronary blood flow patterns after successful stent implantation. We included 45 patients with acute coronary syndrom due to thrombus containing lesions, 40 (88%), with a recent myocardial infarction. In 10 patients (group I) a mechanical aspiration of the thrombus was carried out before stent implantation, 24 patients (group II) received ReoPro® bolus and post-stent 12 hour infusion and the remaining 11 (group III) constituted the control group, with no adjunctive measures. After stent implantation, distal Doppler coronary flow velocity (APV) was measured in all patients at baseline conditions and post-adenosine intracoronary bolus. The same study was repeated 24 hours later. There were no differences among groups in terms of age, gender, clinical condition or lesion location. Immediate normalization of coronary flow reserve (CFR>2) took place in 1 patient from group I (10%), 1 from group II (4%) and 3 from group III(27%); p:ns. Serial changes of average peak velocities (cm/s) are shown in the table. Patients from group I had the highest CFR at 24 hours (p<0.05).

	Baseline APV	Hyperaemic APV	Post stent CFR	24 h baseline APV	24 h hyperaemic APV	24 h CFR
Group I	17.4 ± 9.4	28.1 ± 16.2	1.6 ± 0.3	18.5 ± 8.4	37.9 ± 11.3	2.2 ± 0.5
Group II	13.2 ± 8.5	18.2 ± 11.4	1.3 ± 0.3	15.8 ± 5.2	28.2 ± 9.9	1.8 ± 0.4
Group III	14.5 ± 5.7	23.1 ± 9	1.7 ± 0.3	17.7 ± 7	28.4 ± 10	1.7 ± 0.3

Conclusions: In patients with acute coronary syndromes successfully treated with stents, the immediate CFR is impaired despite the use of mechanical or pharmacological methods. An early (24 hours) recovery of mycrovascular function is observed in patients with adjunctive measures, specially in those with previous thrombus removal.

3375 Relationship between TIMI frame count and intracoronary Doppler measurements in patients treated with abciximab

P. Coste[1], V. Bernard[2], J.M. Perron[3], R. Roudaut[3], J. Bonnet[2]. [1]*Intensive Care Unit, Bordeaux-Pessac;* [2]*Hopital Cardiologique, University of Bordeaux, Pessac;* [3]*Cardiologique, Intensive Care Unit, Bordeaux-Pessac, France*

Background: The Thrombolysis in Myocardial Infarction frame count (TFC) is a reproducible, objective and quantitative index of coronary blood flow. Close linear correlation was observed between coronary velocities and TFC, but this relation was weaker after coronary angioplasty. Consequently, we sought to investigate whether abciximab may modify this correlation by inhibiting platelet activation in patients treated with elective coronary stenting.
Methods: The study cohort consisted of 12 patients (pts) who underwent elective stenting (PCI) of the left anterior descending coronary artery with abciximab (0.25 mg/kg IV bolus followed by 0.125 μg/kg/min infusion). Pts with myocardial infarction or general conditions known to impair distal microcirculation such as diabetes or left ventricular hypertrophy were excluded. Non ionic contrast injection was performed using an automatic injector (10 ml at 6 ml/sec) and cineangiography was recorded at 25 frames/sec. TFC analysis was done by two independent observers. Coronary velocities measurement were simultaneously obtained with a Doppler-tipped angioplasty wire positioned distally to the stenosis. Average peak velocity (APV) at baseline and following hyperaemia after 30 μg intra coronary adenosine were recorded three times, before angioplasty, after balloon and stenting, respectively. Aortic pressure, and heart rate were continuously recorded during the procedure.
Results: Minimal lumen diameter increased significantly from 1.20 ± 0.2 mm at baseline, to 1.80 ± 0.5 after balloon angioplasty and to 2.95 ± 0.4 mm after stenting. As anticipated, baseline APV were not significantly influenced by stent implantation, however APV during hyperaemia increased from 21 ± 10 to 43 ± 17 cm/sec after PCI (p < 0.001). Therefore coronary velocity reserve normalised in all of the cases (from 1.5 ± 0.4 to 2.5 ± 0.1 after PCI, respectively). Similarly, TFC was unchanged at baseline, and increased after stent implantation during hyperaemia (from 18 ± 4 to 8 ± 3 frames after PCI, p< 0.001). A significant linear correlation was found between APV and TFC measurements (r = 0.61, SEE = 15, p < 0.01) but with a notable scatter of the data. Neither mean aortic pressure nor heart rate were modified throughout the procedure.
Conclusion: During PCI with abciximab, TFC and Doppler flow measurements are grossly correlated. This study does not favour the hypothesis of a platelet dependent mechanism to explain these discrepancies and suggests that TFC cannot be used as a surrogate endpoint to assess coronary physiology.

3376 The ideal drug for no-reflow: comparison of adenosine, verapamil, nicardipine and nitroprusside

B. Noel, G. Rossignol, L. Atton, G.R. Barbeau. *Ste-Foy, Canada*

Background: No-reflow phenomenon is a well described complication of emergency and elective percutaneous coronary angioplasty. Treatment of no-reflow with vasodilator drugs has been suggested. In search of the ideal drug, adenosine, verapamil, nicardipine and nitroprusside were compared relatively to their efficacy, lenght of action and potential side effects in normal pigs.
Methods: Intracoronary adenosine (10, 25, 50, 100, 150 and 300 mcg), verapamil (50, 100, 200 and 500 mcg), nicardipine (15, 50, 100 and 200 mcg) and nitroprusside (25, 50, 100, 250 and 500 mcg) were serially administered in a randomized, double-blinded fashion in the left circumflex coronary artery in 7 pigs. Coronary flow reserve was assessed using a continuous Doppler Flowire. Parameters including EKG, heart rate, pressure measurements (central venous, left ventricule, aortic and femoral), and LV dP/dT analysis were recorded.
Results: Optimal dosages for each drug in regard to the increase in CFR were respectively adenosine 300 mcg (2,93 ± 0,45), verapamil 200 mcg (2,16 ± 0,45), nicardipine 50 mcg (3,04 ± 0,43) and nitroprusside 250 mcg (2,97 ± 0,55). No significant difference was shown in CFR increase among adenosine, nicardipine and nitroprusside at optimal established dosage.However,verapamil was shown to be significantly less potent than these three drugs in terms of CFR increase (p = 0,01). Duration of effect was statistically different between all the drugs, with nicardipine presenting the most prolonged effect (1041 ± 157 sec, p < 0,01) compared with verapamil (328 ± 46 sec, p < 0,01), nitroprusside (87 ± 11 sec, p < 0,01) and adenosine (38 ± 12 sec, p < 0,01). Effect on systolic blood pressure was minimal with adenosine (-1,7 ± 0,9 mmHg), intermediate with verapamil (-6,0 ± 5,9 mmHg) and nicardipine (- 8,6 ± 7,2 mmHg), and pronounced with nitroprusside (-19,0 ± 5,7 mmHg). None of the drugs significantly affected heart rate at the optimal established dosage.
Conclusions: We conclude that there is equivalent CFR increase using adenosine, nicardipine or nitroprusside. These drugs are also clearly superior to verapamil to increase CFR. Nicardipine, when compared to adenosine and nitroprusside, offers equivalent potency and a much more prolonged vasodilator effect. Nitroprusside showed a clear tendancy to decrease systemic blood pressure but this side-effect was of short duration and auto-resolutive. Finally adenosine can safely be used at dosages higher than those accepted in actual clinical practice without significant side effects.

3377 Evaluation of microvascular reperfusion by ST segment resolution and coronary flow reserve after recanalized acute anterior myocardial infarction

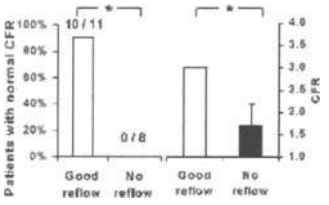
L.J. Chen[1], P. Colonna[1], A.H. Selem[1], R. Montisci[2], C. Caiati[1], M. Ruscazio[2], L. Meloni[2], S. Iliceto[1]. [1]*University of Padua, Division of Cardiology, Padua, Italy;* [2]*University of Cagliari, Division of Cardiology, Cagliari, Italy*

Background: Persistent ST segment elevation shortly after recanalization reflects sustained electrical transmural injury and correlates well with impaired myocardial reperfusion at the tissue level. Measurement of coronary flow reserve (CFR) is the physiological approach to assess the severity of coronary stenosis and microvascular dysfunction. We hypothesized that patients with a rapid ST segment return to baseline have a better microvascular function, as expressed by preserved CFR.
Methods: We studied 15 patients with a first anterior acute myocardial infarction, 12 treated with primary PTCA and 3 with intravenous thrombolysis. A surface ECG was obtained on admission and after recanalization (90 minutes after admission ECG). The sum of ST segment elevation was measured in V1 to V6 and I, aVL leads and the percentage of recovery of the summation at 90 minutes ECG was computed. Coronary blood flow velocity in the left anterior descending coronary artery was detected noninvasively 3±1 days after revascularization by transthoracic Doppler echocardiography. CFR was calculated by the ratio of the averaged peak systolic-diastolic flow velocity (APV) during adenosine infusion to baseline APV. A CFR >2.0 was regarded as normal.
Results: Eight out of the 15 patients (53%) had ST segment resolution (ST elevation <50% of initial value), while 7 did not, with the ST recovery percentage of 30±11% versus 74±19%, p< 0.001. CFR was 2.4±0.6 in patients with ST resolution, compared with 1.6±0.5 (p<0.01) in patients with persistent ST elevation. A normal CFR was present in 7 of the 8 (88%) patients with ST resolution, whereas only in 1 of the 7 (14%) with persistent ST elevation (p<0.05).
Conclusion: Assessment of microvascular reperfusion by ST segment resolution agrees with CFR measurement. ST segment resolution after revascularization indicates a better microvascular function, as demonstrated by preserved CFR.

3378 Influence of microvascular integrity on coronary flow reserve evaluated shortly after acute myocardial infarction

P. Colonna[1], R. Montisci[1], L. Chen[1], C. Cadeddu[1], A.H Selem[1], M. Ruscazio[1], L. Meloni[1], S. Iliceto[2]. [1]*University of Cagliari, Cardiovascular and Neurological Dept, Cagliari, Italy;* [2]*University of Padua, Division of Cardiology, Padua, Italy*

Background: Following acute myocardial infarction (AMI), the microcirculation can be damaged, with a reduction of coronary flow reserve (CFR) in the infarct related artery. We hypothesized that, in patients with AMI and no-reflow at myocardial contrast echocardiography (MCE), the CFR in the infarct related artery is reduced.
Methods: In 19 patients with anterior AMI submitted to primary PTCA and without residual stenosis we studied: 1) perfusion with MCE and harmonic power Doppler with intravenous Levovist and 2) coronary flow velocity in the left descending coronary artery with contrast-enhanced transthoracic echo Doppler at baseline and after adenosine injection. Patients had no-reflow if the ratio between the number of segments with perfusion defect and the total number of segments in the dyssynergic area was >0.5.
Results: Among the 19 patients with AMI, 11 showed a good reflow, while 8 showed the no-reflow phenomenon. The CFR was 3±0.6 in the 11 patients with a good reflow, and 1.7±0.5 ($p<0.0001$) in the 8 no-reflow patients. Ten of 11 (91%) patients with a good reflow at MCE, and none of the 8 (0%) patients with no-reflow (* $p<0.001$) showed a normal (>2.5) CFR. There was a significant negative correlation between the percentage extent of perfusion defect and the CFR ($p<0.0001$; $r=0.75$).



CFR after AMI.

Conclusion: In patients with AMI, CFR is more impaired in the presence of no-reflow at MCE. Contrast echocardiography allows a comprehensive noninvasive evaluation of both microvascular integrity and vasodilatory flow reserve after AMI.

3379 Can intracoronary Doppler flow wire predict viability detected by sestamibi SPECT after successful primary PTCA in patients with acute myocardial infarction?

H.U. Stempfle[1], R. Schmid[2], A. Tausig[2], V. Auer[1], T. Limmert[1], K. Theisen[1], V. Klauss[1]. [1]*Med. Klinik Innenstadt, Cardiology, Munich, Germany;* [2]*Med. Klinik Innenstadt, Nuclear Medicine Dept., Munich, Germany*

Background: The extent of myocardial salvage after primary percutaneous transluminal coronary angioplasty (PTCA) in acute myocardial infarction (AMI) is variable and can not be predicted on the basis of vessel patency. The aim of this study was to evaluate the tissue salvage and the microvascular integrity after successful intervention in AMI by coronary blood flow velocity and sestamibi perfusion imaging. Methods: Twenty-two patients (17m, 5 f; mean age 57±14 yrs.) undergoing primary PTCA and stent implantation for AMI were studied. 99mTC Sestamibi was injected intravenously before intervention and single photon emission computed tomography (SPECT) was performed immediately after successful reperfusion to determine the area at risk before PTCA due to the minimal 99mTC Sestamibi redistribution. Sestamibi SPECT was repeated 3 days and 6 months after AMI. Area at risk (%) was determined automatically by myocardial perfusion tomography (PERFIT) with the use of a multistage, 3D iterative inter-subject registration of patient images to normal templates (2SD) and myocardial salvage was calculated. Coronary flow velocity was measured using a Doppler-tipped guidewire in the infarct related artery after successful completion of primary PTCA and in an angiographically normal reference vessel. Absolute coronary flow reserve (CFR) and relative CFR (rCFR) were calculated using hyperemic to basal average peak velocity. Results: Despite successful reperfusion of the target vessel (TIMI grade III flow) CFR and rCFR remained impaired (1.8±0.9 and 0.77±0.21). Area at risk decreased significatly from 21±9% to 9±10% ($p<0.05$) corresponding to 11±8% myocardial salvage. Acute CFR and rCFR showed no correlation with the area at risk after primary PTCA. The increase of CFR within 6 months correlated with the myocardial salvage ($p<0.01$). Conclusions: Despite successful primary PTCA in AMI, CFR and rCFR remain often impaired because of a significant loss of microvascular integrity. The long-term success of primary PTCA can be assessed by myocardial salvage and the change of CFR which might be a useful parameter for additional reperfusion strategies such as glycoprotein IIb/IIIA receptor inhibition.

ELECTROCARDIOGRAM AND PROGNOSIS IN HEART FAILURE

3380 Reading electrocardiogram changes when an echo, a right heart catheterization, and a cardiopulmonary exercise test is available: are we wasting our time?

F. Grigioni, L. Potena, G. Boriani, G. Magnani, A. Musuraca, C. Magelli, F. Coccolo, A. Branzi. *University of Bologna, Institute of Cardiology, Bologna, Italy*

Background: Previous studies demonstrated that intraventricular conduction delays predict poor prognosis in congestive heart failure (CHF). However, little is known about the prognostic implications of QRS widening in such patients. Methods: We analyzed 105 CHF patients referred for heart transplantation (age 53±10 years; 88% male; 40% ischemic cardiomyopathy; LVEF 24±6%, 56% in NYHA class III-IV) undergoing a concomitant complete clinical and instrumental (i.e. electrocardiogram (ECG), echocardiogram, right heart catheterization, cardiopulmonary exercise test) assessment (index evaluation). Inclusion criteria was the availability of a previous ECG performed > 6 months before index evaluation. Results. At two years from index evaluation, incidence of cardiac death or need for heart transplantation (CD/HT) was overall 61±6%. At multivariate analysis, QRS widening occurred before index evaluation turned out to be a predictor of CD/HT (adjusted RR per msec of increase [95% CI] 1.02[1.01-1.04], P=0.003) independently from age, NYHA class, EF, systolic blood pressure, mean pulmonary artery pressure, and peak oxygen consumption. Incidence of CD/HT in patients with QRS widening >=0.5 msec/month (a cut-off corresponding to the mean value of QRS widening) at two years was higher as compared to those with QRS widening <0.5 msec/month (76±7 vs. 49±8%, $P<0.001$). Conclusions. Accelerated QRS widening detected by surface ECG is independently and unfavorably associated with an adverse outcome in CHF. Prospective studies are needed to investigate the usefulness of this parameter for selecting candidates to HT and for evaluating the effects of biventricular pacing.

3381 Clinical characteristics and survival of patients with chronic heart failure and prolonged QRS duration

P.R. kalra, R. Sharma, W. Shamim, W. Doehner, A.P. Bolger, P. Poole-Wilson, A.J.S. Coats, S.D. Anker. *National Heart Lung Institute, Cardiac Medicine, London, United Kingdom*

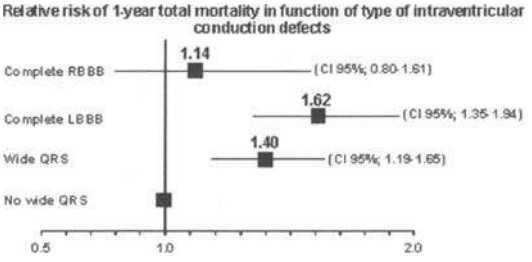
Background: Prolongation of QRS duration (>120 ms) is a common finding in patients with chronic heart failure (CHF), being associated with an impaired prognosis. Whilst resynchronisation of ventricular contraction may be of benefit in patients with severe QRS prolongation (>150 ms), this has yet to be determined for patients with moderate QRS prolongation (120-150 ms).
Methods: We evaluated 155 patients with CHF of varying severity (New York Heart Association, NYHA class 2.6±0.8, mean±SD) secondary to left ventricular systolic impairment. Maximal exercise testing was performed in 149 patients from which peak oxygen consumption (VO2) was determined. The mean follow-up of the 155 patients was 838±748 days (range 4 to 2531), of which 62 died or underwent heart transplantation after 4 to 2160 days (mean 482±514). Patients were sub-grouped into 3 categories according to QRS duration: <120 ms (normal QRS, n=82), 120 to 150 ms (moderate prolongation, n=44) and >150 ms (severe prolongation, n=29).
Results: When compared to patients with a normal QRS duration, those with moderate prolongation had a significantly worse NYHA class (2.4 vs 3.0), peak VO2 (17.7 vs 14.9 mL/kg/min) and left ventricular ejection fraction (26 vs 22%, respectively, all $p<0.05$). In contrast, patients with moderate QRS prolongation had similar impairment of NYHA class and peak VO2 as compared to those with severe QRS prolongation (all $p>0.05$). The optimal QRS duration for predicting 2 year event free survival in the CHF patients was 120 ms (receiver operating characteristic analysis: area under curve 0.73; 95% CI 0.64 to 0.81). Patients with a QRS duration >120ms had a worse prognosis at 2 years (cumulative event free survival 47%; 95% CI 35 to 59) as compared to those with a normal QRS duration (84%; 95% CI 75 to 93; $p<0.0001$).
Conclusions: CHF patients with moderate QRS prolongation share similar impairment of exercise capacity and functional class to those with severe prolongation. A QRS duration of 120 ms is the best medium-term predictor of event free survival. Whether biventricular pacing would benefit patients with moderate QRS prolongation is not known and requires further evaluation in prospective clinical trials.

3382 Left but not right bundle branch block is an independent predictor of prognosis in patients with heart failure: report from the IN-CHF Registry

S. Baldasseroni, G.M. Boffa, A. Camerini, L. Gonzini, A. Murrone, S. Provasoli, A. Terranova, A.P. Maggioni on behalf of IN-CHF Investigators. *ANMCO Research Center, Florence, Italy*

Introduction: Many clinical factors influence the prognosis of heart failure (HF). While left bundle branch block (LBBB) has been already identified as a negative prognostic factor, the independent effect of right bundle-branch block (RBBB) is still unknown. The aim of the study was to compare the effects of these two different intraventricular conduction defects on prognosis of HF.

Methods and Results: These data were derived from the database of the Italian Network on Congestive Heart Failure (IN-CHF). Entry in the Registry required that patients had a diagnosis of HF based on the ESC guidelines. We analyzed 1- year follow-up data of 5517 unselected outpatients with HF of different etiologies. Wide QRS was defined when QRS duration was >120msec in a 12-lead ECG. Wide QRS was present in 2066 patients (37.4%), 25.2% with complete LBBB, 6.1% with complete RBBB, 6.2% with other intraventricular defects. When we considered 1-year mortality at univariate analysis patients with complete LBBB had a significant higher mortality than those without LBBB (16.10% vs 11.95%, p=0.0001) but this was not true for complete RBBB (11.90% vs 11.95%, p= NS). At univariate analysis, using the patients with no wide QRS as reference group, the relative risk of death of patients with wide QRS and complete LBBB was statistically higher (Figure). When we adjusted for clinical and hemodynamic parameters only complete LBBB still remained an independent predictor of death in patients with HF (RR 1.36 CI 95% 1.15-1.61).



Conclusions: LBBB but not RBBB is an independent predictor of prognosis in outpatients with HF.

3383 Univariate analysis of frequency domain HRV indices as predictors of mortality in chronic heart failure; 5-year results of the UK heart study

R. Moore, D. Groves, M.T. Kearney, D.L. Eckberg, T.S. Callahan, W.E. Shell, K.A.A. Fox, J. Nolan. *UK Heart Study, United Kingdom*

Background: CHF is associated with progressive autonomic dysfunction. This alteration is believed to have a direct role in the process of deteriorating cardiac function and by implication may be related to the timing of cardiac death. Markers of cardiac autonomic activity have therefore been investigated for their potential use as prognostic indicators providing the possibility for identifying high-risk individuals, who may benefit from more intensive therapy.

Methods: The baseline heart rate variability (HRV) of 529 CHF patients, aged 18-80 years, NYHA grade I-III was studied using 24 hour ambulatory ECG recordings. Time domain HRV indices (standard deviation of normal RR intervals(SDNN), number of increases in successive RR intervals >50ms(sNN50), root of the mean of square of successive RR intervals (rMSSD) and frequency domain HRV indices (total power (TP), very low power (VLF), low power (LF), and high power (HF)) were evaluated and related to total mortality, sudden cardiac death, and progressive cardiac death at five year follow up using univariate analysis and Cox proportional hazard model. Baseline assessment of cardiac function, biochemistry and cardiac rhythm were obtained in all patients.

Results:

	All Cause mortality	Progressive Cardiac	Sudden Cardiac
	OR, P Value	OR, P Value	OR, P Value
SDNN	0.886, 0.0001	0.863, 0.0002	0.947, 0.146
sNN50	0.994, 0.217	0.982, 0.056	1.003, 0.651
RMSSD	0.957, 0.641	0.963, 0.779	1.062, 0.636
TP	0.942, 0.006	0.881, 0.001	1.006, 0.807
HF	0.853, 0.020	0.698, 0.01	0.985, 0.850
LF	0.780, 0.006	0.671, 0.01	0.965, 0.743
VLF	0.934, 0.016	0.846, 0.002	1.016, 0.635
**NLF	1.448, 0.001	1.531, 0.002	1.202, 0.211
**NHF	0.738, 0.005	0.688, 0.008	0.856, 0.313

OR: Odds Ratio, ** Normalised Values

Conclusions: A lower SDNN index was significantly associated with higher all cause mortality and progressive cardiac death. All the frequency domain indices whether quoted in absolute or normalised values were significantly associated with all cause and progressive cardiac death.

3384 QT dispersion in hypertensive diabetic and non-diabetic patients with congestive heart failure

A. Radman[1], J. Murin[1], J. Bulas[1], A. Reptova[1], T. Ravingerova[2], K. Kozlikova[3], J. Jaber[1], W. Ghanem[1]. *[1]University hospital, 1st internal clinic, Bratislava, Slovakia; [2]SAS, Institute of Heart Research, Bratislava, Slovakia; [3]Medical Faculty CU, Inst. Med. Physics & Biophysics, Bratislava, Slovakia*

Background: Blood pressure (BP) and QT dispersion (QTd) are important prognostic risk factors in congestive heart failure (CHF) patients (pts).

Aim: QTd in hypertensive diabetic (D) and non-diabetic (ND) pts with CHF and its relation to ambulatory BP measurement values in D pts was analysed.

Patients and methods: Group D: 70 pts (m/f: 40/30, mean age 64.7±9.0 y), group ND: 52 pts (m/f: 28/24, 62.5±10.9 y). Diagnosis of CHF was proved clinically (ECG, ECHO: EF<40%). D was defined clinically or by positive oGTT. Hypertension (HT; mmHg) was mild - moderate (150.9/87.4 - D, 146.6/89.8 - ND) and of 5.5 y (D) and 6.2 y (ND) duration. Mean BMI was 27.7±3.1 kg/m^2 (D), 28.2±5.8 kg/m^2 (ND). Serum lipids were normal or borderline (HDL-C, TG). Smokers (23% D, 25% ND). NYHA class: I (4.3% D, 9.6% ND), II (51.4% D, 57.7% ND), III (41.4% D, 30.8% ND, p<0.05), IV (2.9% D, 1.9% ND). Treatments: ACEI (92.0% D, 95.0% ND), diuretics (86.0% D, 83.0% ND), digoxin (67.0% D, 54.0% ND, p<0.05), beta-blockers (41.0% D, 44.2% ND). QTd and rate corrected QTd (Bazett, QTdc) were defined as the difference between the max and min QT and QTc intervals, resp. Statistical analysis: Chi-square test, Student's t-test. Significant differences for p<0.05.

Results: Both groups matched (sex, age, duration & intensity of HT & obesity, serum lipids, smoking, NYHA class, treatment). The QT and QTc intervals, QTd and QTdc in D and ND pts are in table. D pts with QTdc>65 ms in comparison to QTdc<65 ms had significantly higher BP (133±14/80±11 vs. 112±14/65±6 mmHg, resp.) and significantly higher BP night/day ratio (0.94±0.05/0.89±0.07 vs. 0.86±0.06/0.80±0.05, resp.).

QT interval characteristics

Parameters [ms]	Group ND (n=52)	Group D (n=70)	p
QT interval max	401.7 ± 18.6	409.2 ± 20.3	= 0.074
QT interval min	341.2 ± 19.0	344.8 ± 17.9	> 0.35
QTc interval max	421.1 ± 15.8	429.7 ± 14.3	= 0.008
QTc interval min	372.0 ± 19.4	387.5 ± 21.0	< 0.001
QTd	47.1 ± 17.8	61.2 ± 19.6	< 0.001
QTdc	51.0 ± 13.3	65.0 ± 21.8	< 0.001

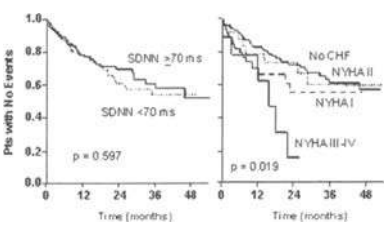
Conclusion: HT D pts with CHF have higher QTd than HT ND pts. D pts have higher BP values during the night in the group with higher QTd (> 65ms) in comparison with D pts with lower QTd.

3385 Age, cardiac revascularization procedures and heart rate variability: influence on short- and long-term prognosis after cardiac rehabilitation

S. Fumagalli[1], C. Franceschini[1], G.M. Fallani[1], A. Europei[2], L. Garuglieri[2], L. Boncinelli[1], N. Marchionni[1]. *[1]Coronary Care Unit, Dept. of Gerontology - University, Firenze, Italy; [2]ESAOTE SpA, Firenze, Italy*

Heart rate variability (HRV) is a useful tool to assess prognosis in patients (pts) with acute myocardial infarction (AMI) or congestive heart failure (CHF). With this study we wanted to evaluate the relationship among age, cardiac revascularization procedures and HRV, comparing CABG (n=123, 69+9 yrs) and PTCA (n=96, 63+12 yrs) pts consecutively enrolled in a programme of cardiac rehabilitation with Controls (n=90, 57+15 yrs). Time domain analysis of HRV was obtained through 24-hours ECG Holter recordings. CABG and PTCA pts had significantly lower values of HRV when compared to Controls (SDNN – CABG: 70 ± 24 vs PTCA: 92 ±35 vs Controls: 141±23 ms, p=0.001; RMSSD – CABG: 22±10 vs PTCA: 27±10 vs Controls: 35±13 ms, p=0.001). Age was also inversely related to HRV parameters. These relationships were maintained after adjustments for history of angina, CHF, diabetes, hypertension and MI. During the follow-up, mortality and new admissions to hospital were associated only with the presence and the degree of CHF, while no relationship was identified between HRV and prognosis, as usually observed in pts with myocardial infarction or left ventricular failure not undergoing CABG or PTCA (Kaplan-Meier and Cox Models).

In conclusion, age and cardiac revascularization procedures exert a deep influence on HRV, independently increasing the loss of homeostatic capacities, and creating important substrates allowing the development of frequent arrhythmias such as atrial fibrillation.



NEW MARKERS OF HEART FAILURE

3386 Dynamics of the left ventricular mass in heart failure patients with and without cachexia: a prospective cardiovascular magnetic resonance study

V.G. Florea[1], J. Moon[2], D.J. Pennell[2], W. Doehner[3], A.J.S. Coats[3], S.D. Anker[3]. [1]*Medical University of Moldova, Chisinau, Moldova, Republic of;* [2]*Royal Brompton and Harefield NHS Trust, Cardiovascular Magnetic Resonance Unit, London, United Kingdom;* [3]*National Heart and Lung Institute, Cardiac Medicine Dept., London, United Kingdom*

Background: Although the "cachectic heart" has been described as a pathologic decrease in the size and mass of the heart, no studies have followed in-vivo changes in cardiac dimensions or left ventricular (LV) mass over time in chronic heart failure (CHF) patients with cardiac cachexia. This study sought to assess the direction and magnitude of changes in LV mass and cavity size over time in patients with CHF body wasting, *i.e.* cardiac cachexia.
Methods: Repeated cardiac magnetic resonance (CMR) studies were performed in 9 CHF patients with cardiac cachexia compared to 28 matched CHF patients without cachexia (age 69±12 versus 65±9 years, p=0.20; body mass index 23±1 versus 29±5 kg/m^2, p=0.0005). LV mass and volumes were analyzed blind to patient classification twice, at baseline and after a mean follow-up of 15 (range 7-22 months). According to our previous findings, CMR requires 9 patients with heart failure to detect a 10 g change in LV mass over time with a statistical power of 90% and an alpha-error of 0.05.
Results: At baseline, LV end-diastolic volume (197±78 versus 203±65 ml) and end-systolic volume (131±75 versus 126±63 ml), LV mass (213±44 versus 222±62 g), and LV ejection fraction (38±19% versus 40±16%) did not differ between patients with and without cachexia (all p>0.10). During follow-up, there was a significant decrease in LV mass in patients with cachexia (-16 g, p<0.05) and a trend to increase in LV mass in patients without cachexia (+7 g, p=0.12, comparison between groups: p=0.010).
Conclusions: The direction of changes over time in LV mass differs in CHF patients with cachexia as compared to those without cachexia. A significant decrease in LV mass occurs in patients with cardiac cachexia. This study documents in vivo the occurrence of wasting of the left ventricle in patients with chronic heart failure who demonstrate general body wasting.

3387 Low T3 syndrome: a strong predictor of death in patients with heart disease

A. Pingitore, G. Iervasi, M. Raciti, P. Landi, M. Scarlattini, A. L'Abbate, L. Donato. *Clinical Physiology Institute, CNR, Pisa, Italy*

Background: Low-T3 syndrome has been documented in patients with several heart disease and commonly interpreted as an 'euthyroid sick syndrome', i.e. an adaptive compensatory response to conserve energy. However, some clinical and experimental data have suggested a potential negative impact of low T3 state on the prognosis of cardiac patients. Aim of the study. To assess the role of thyroid hormones in the prognosis of a large population of patients with heart disease.
Methods: 573 consecutive patients with known heart disease (78% with documented ischemic heart disease or primary left ventricular dysfunction) underwent prospectively thyroid function profile evaluation. Patients were divided in two subgroups as follows: Group I, 173 (30%) patients with low T3, i.e. with fT3 below the lower limit of the reference interval (fT3< 2.0 pg/ml); Group II, 400 patients with normal fT3 (* 2.0 pg/ml). Events considered were cumulative deaths and cardia death. Results. During the 1-year follow-up, there were 25 cumulative deaths in group I and 12 in group II (14.4% vs 3%, p<.0001) of which 13 cardiac deaths in group I and 6 in group II (7.5% vs 1.5%, p<.0006) respectively. Using the Cox proportional hazards model, fT3 was the most important predictor of cumulative death (hazard ratio 3.582, p<.0001), followed by age (hazard ratio 1.051, p<.004), ejection fraction (hazard ratio 1.037, p<.006) and dyslipidemia (hazard ratio 2.955, p<.002). With interactive procedure, fT3 added higher significant prediction of death after considering all the other traditional variables (c2 18.10, p<.001). Conclusion. Low-T3 state is a strong predictor of death in cardiac patients. In these patients with low-T3 levels the administration of substitutive doses of synthetic T3 can be hypothesized in the attempt to improve prognosis.

3388 Vascular oxidative stress and endothelial dysfunction in patients with chronic heart failure: role of xanthine oxidase and superoxide dismutase

U. Landmesser[1], S. Spiekermann[1], S. Dikalov[2], R. Wilke[1], H. Tatge[1], D. Harrison[2], B. Hornig[1], H. Drexler[1]. [1]*Medizinische Hochschule Hannover, Kardiologie und Angiologie, Hannover, Germany;* [2]*Emory University, Division of Cardiology, Atlanta, United States of America*

Background: Endothelial vasomotor dysfunction contributes to increased peripheral vascular resistance and reduced myocardial perfusion in chronic heart failure (CHF). Impairment of endothelium-dependent vasodilation in patients with CHF is, at least in part, due to accelerated degradation of nitric oxide by oxygen radicals. We therefore determined activities of endothelium-bound extracellular superoxide dismutase (ecSOD), a major vascular antioxidant enzyme system, and endothelium-bound xanthine oxidase (XO), a radical forming enzyme within the arterial wall, and their relation to flow-dependent, endothelium-mediated vasodilation (FDD) in patients with CHF.
Methods and Results: ecSOD and XO activities, released from the endothelium into plasma by heparin bolus injection (5000 IE), were studied in fourteen patients with CHF (NYHA III; dilated cardiomyopathy) and ten age-matched control subjects. ecSOD activity was analyzed using a spectrophotometric assay, whereas xanthine oxidase activity was determined by electron spin resonance spectroscopy (ESR) using the spin label C-PH. FDD of the radial artery was measured using high-resolution ultrasound and was assessed before and after intra-arterial infusion of the antioxidant vitamin C (25 mg/min.) to determine the portion of FDD inhibited by radicals.
In patients with CHF endothelium-bound ecSOD activity was substantially reduced (5.0 ± 0.7 vs. 14.4 ± 2.6 U x ml-1 x min-1; P < 0.01) and closely related to FDD (r=0.61). Endothelium-bound XO activity was increased by more than 200% (38 ± 10 vs. 12 ± 4 nmol O2.- x μl-1; P < 0.05) and inversely related to FDD (r=-0.35) in patients with CHF. In patients with low ecSOD and high XO activity a substantially greater benefit from the antioxidant vitamin C on FDD was observed, i.e. the portion of FDD inhibited by oxygen radicals correlated negatively with ecSOD (r=-0.71), but positively with XO (r=0.75) activity.
Conclusion: These results suggest that both, reduced ecSOD and increased XO activity contribute to increased vascular oxidant stress in patients with CHF. This loss of "vascular oxidative balance" within the arterial wall likely represents a novel mechanism contributing to endothelial dysfunction in patients with CHF.

3389 Reduced levels of the GLUT4 transport protein in skeletal muscle relate to impaired insulin sensitivity in chronic heart failure

W. Doehner[1], D.V. Gathercole[2], M. Cicoira[1], R. Wensel[1], A. Krack[1], A.J.S. Coats[1], P.G. Camici[2], S.D. Anker[3]. [1]*National Heart and Lung Institute, Clinical Cardiology Dept., London, United Kingdom;* [2]*Imperial College, MRC Clinical Science Centre, London, United Kingdom;* [3]*Charité, Campus Virchow, Cardiology, London, Germany*

Background: Chronic heart failure (CHF) is an insulin resistance state, independently of an ischaemic aetiology. The underlying patho-mechanism is not known.
We aimed to investigate, a) whether the expression of GLUT4, the main insulin dependent glucose transport protein is reduced in skeletal muscle in CHF compared to healthy controls, and b) whether expression of GLUT4 is correlated with insulin resistance in CHF patients.
Methods: In 29 patients with CHF (age 66±2y, NYHA I/II/III/IV: 2/16/10/1, peak VO2 20.0±1.5 ml/kg/min) and in 7 healthy control subjects (age 58±5y) a skeletal muscle biopsy was obtained from the gastrocnemius muscle or quadriceps muscle (fine needle technique). Total amount of GLUT4 protein was assessed by western blotting (results normalised to the myosin heavy chain band of a coomassie blue stained gel). In 20 patients and 3 controls insulin sensitivity was assessed (by intravenous glucose tolerance testing using a minimal modelling approach). Body composition was analysed by dual energy x-ray absorptiometry (DEXA) scanning.
Results: Patients and controls were similar for BMI (25.5±0.8 vs 25.8±1.5 kg/m^2) and total and regional fat mass (all p>0.2). GLUT4 was lower in CHF patients than in controls (0.75±0.07 vs 1.24±0.19 arbitrary units, p<0.01). Reduced GLUT4 occurred in parallel to severity of CHF, being lowest in NYHA III/IV (0.596±0.08 p<0.01 vs controls) compared to NYHA I/II (0.84±0.09, p<0.05 vs controls). GLUT4 was lowest in patients with ischaemic aetiology (0.69±0.06, p<0.01 vs to controls) compared to those with dilated cardiomyopathy (1.01±0.2). Insulin sensitivity was 1.71±0.3 min-1.μU.ml-1.104 in CHF patients compared to 3.57±0.6 min-1.μU.ml-1.104 in controls (p<0.05). In patients and controls, the amount of GLUT4 correlated directly with insulin sensitivity (r=0.55) and inversely with fasting insulin levels (r=-0.52, both p<0.01).
Conclusion: In CHF, total amount of GLUT4 transport protein in skeletal muscle tissue is reduced compared to healthy controls. This may contribute to the insulin resistance seen in CHF patients.

3390 Elevated plasma amylase levels are corellated with circulating interleukin-6 activation in advanced chronic heart failure

J.T. Parissis[1], S. Adamopoulos[2], K. Venetsanou[3], D. Mentzikof[1], A. Moraiti[1], V. Nikolaou[1], S. Karas[1], D. Kremastinos[1]. [1]"Amalia Fleming" Hospital, 1st Dept. of Cardiology, Athens; [2]Onassis Cardiac Surgery Ctr., Dept. of Cardiac Medicine, Athens; [3]St Anargiri Hospital, Research Dept., Athens, Greece

Background: It has been reported that proinflammatory cytokine activation is associated with mesenteric venous congestion in advanced chronic heart failure (CHF) This study investigates whether plasma amylase is elevated in severe CHF and whether this elevation is correlated with proinflammatory cytokine activity in the plasma of CHF patients.
Methods: Plasma levels of amylase, tumor necrosis factor-a (TNF-a) and interleukin-6 (IL-6) were measured (ELISA,Cytoscreen US-Biosource International) in 37 patients with severe CHF (NYHA III: 18, NYHA IV: 19; Ischemic: 25, Dilated: 12; LVEF: 28±4%) and 20 healthy control subjects.
Results: Plasma levels of amylase (392±29 vs 170±13 mg/dl, $p<0.005$), TNF-a (6.5±1.9 vs 2.7±0.7 pg/ml, $p<0.001$) and IL-6 (7.3±1.7 vs 3.2±0.5 pg/ml, $p<0.001$) were significantly elevated in CHF patients as compared with those of healthy control sublects. NYHA IV patients exhibited significantly higher levels of plasma amylase, TNF-a and IL-6 than those of NYHA III patients (all $p<0.05$).There were no significant differences in plasma amylase and proinflammatory cytokines between patients with ischemic CHF and those with dilated cardiomyopathy. In CHF patients plasma amylase levels were significantly correlated with plasma IL-6 activity ($r=0.48$, $p<0.05$) and right atrial pressure ($r=0.57$, $p<0.01$). Finally, plasma IL-6 was correlated with right atrial pressure ($r=0.55$, $p<0.03$).
Conclusions: I) Plasma amylase levels are elevated in CHF patients according to the severity of the disease. II) Plasma amylase levels are correlated with IL-6 activation, possibly as a result of mesenteric venous congestion in severe CHF.

3391 Endotoxin sensitivity and immune competence in chronic heart failure

S. Krüger[1], J. Graf[1], U. Janssens[1], D. Kunz[2], T. Stickel[1], P. Hanrath[1]. [1]University Clinic, Medical Clinic I, Aachen, Germany; [2]Clinical Chemistry, University Clinic, Aachen, Germany

Background: Raised concentrations of endotoxin (lipopolysaccharide/LPS) are found in patients with chronic heart failure (CHF). Tolerance of monocytes to LPS can be induced by LPS itself resulting in a downregulation of cytokine response to LPS challenge. This phenomenon of LPS desensitization has also been suggested for CHF. We investigated whether CHF patients really show a desensitization to LPS stimuli at rest or after physical exercise, which was used as a model of limited inflammatory reaction.
Methods and Results: We prospectively studied 35 patients with CHF (60 ± 10 years, 9 women) and 20 healthy control subjects with cardiopulmonary exercise testing. At rest and directly after exercise blood samples were taken for the quantitative determination of HLA-DR expression of monocytes as a measure for immune competence and for the measurement of TNFa generation after ex vivo stimulation by LPS. Left ventricular ejection fraction (26 ± 6% vs. 60 ± 3%, $p < 0.001$) and peak oxygen uptake (15.0 ± 3.6 vs. 19.8 ± 4.1 ml/min/kg, $p < 0.001$) were significantly lower in CHF patients compared to controls. HLA-DR expression was comparable in CHF patients and controls at rest (24103 ± 8323 vs. 25784 ± 7734 ABS/cell, n.s.) as well as after exercise (27154 ± 9820 vs. 29452 ± 8677 ABS/cell, n.s.). TNFa production by LPS stimulated monocytes ex vivo was higher in CHF patients compared to controls at rest (445 ± 293 vs. 315 ± 141 pg/ml, $p < 0.05$) and after exercise (523 ± 396 vs. 395 ± 183 pg/ml, n.s.).
Conclusions: TNFa generation capacity is higher at rest and equal after physical exercise in CHF patients compared to controls. Thus patients with CHF seem to show a marked susceptibility to low inflammatory stimuli and no desensitization to LPS. This phenomenon could explain higher concentrations of inflammatory cytokines, susceptibility to infections, cytokine induced catabolic metabolism, and increased mortality in CHF.

NEUROHORMONAL MECHANISMS IN HEART FAILURE: CURRENT PERSPECTIVES

3392 Parathyroid hormone-related protein is produced in the myocardium and increased in patients with congestive heart failure

K. Ogino[1], K. Ogura[1], Y. Kinugasa[1], M. Shimoyama[1], I. Hisatome[1], J.P. Bilezikian[2], C. Shigemasa[1]. [1]Tottori University, Div of Cardiology, Dept of Medicine, Yonago, Japan; [2]Columbia University, Department of Medicine, New York, United States of America

Background and Objectives: Parathyroid hormone-related protein (PTHrP) is produced in a wide variety of different cells including cardiomyocytes. Its production is augmented by mechanical and neurohumoral stimulation, and PTHrP has positive chronotropic and vasodilatory effects. Thus, in the heart, PTHrP has the potential to serve as a new mechano-sensitive regulatory molecule. In this study, we evaluated peripheral and central levels of PTHrP in patients with congestive heart failure (CHF), and test the hypothesis that PTHrP is released from the heart in patients with CHF.
Methods: Intact full-length PTHrP (i-PTHrP) and C-terminal PTHrP (c-PTHrP) levels were measured in the plasma of 64 patients with CHF and 12 controls. Plasma PTHrP concentrations in the coronary sinus and aortic root were also measured in 18 CHF patients and 10 controls.
Results: Both plasma i-PTHrP and c-PTHrP levels were significantly higher in patients with CHF (0.31 ± 0.03 pmol/L and 37.5 ± 1.3 pmol/L, respectively) than in normal control subjects (0.24 ± 0.04 pmol/L and 29.7 ± 1.5 pmol/L, respectively). Both PTHrP measurements increased according to NYHA class ($p<0.05$), with those in NYHA III showing levels of i-PTHrP and c-PTHrP that were 77.5% and 50.5% higher than controls. There were significant correlations between c-PTHrP levels and plasma norepinephrine, BNP, angiotensin II, endothelin-1 levels ($R = 0.32, 0.21, 0.21$ and 0.33, respectively, $p<0.05$). Plasma i-PTHrP was significantly correlated with left ventricular ejection fraction (LVEF), end-diastolic and end-systolic dimensions ($p<0.05$). Plasma i-PTHrP levels were significantly higher in the coronary sinus than in the aortic root in CHF patients, but among controls concentrations of i-PTHrP were indistinguishable at these two sites. There were no significant relationships between plasma c-PTHrP level of the coronary sinus and pulmonary capillary wedge pressure (PCWP), cardiac index (CI), stroke volume index (SVI), left ventricular end-diastolic pressure (LVEDP), left ventricular end-diastolic volume (LVEDV) or LVEF. On the other hand, plasma i-PTHrP level of the coronary sinus was significantly correlated with LVEDV ($R = 0.61$, $p<0.05$) but it was not correlated with PCWP, CI, SVI, LVEDP or LVEF.
Conclusions: This is the first report demonstrating that PTHrP is produced in the myocardium and increased in CHF; and suggests that PTHrPs measurements might be useful in clinical assessment of these patients.

3393 Blunted baroreflex control of renal sympathetic activity in patients with heart failure

M. Petersson[1], P. Friberg[2], G. Lambert[3], B. Rundqvist[1]. [1]Sahlgrenska Univerity Hospital, Cardiology, Göteborg, Sweden; [2]Sahlgrenska University Hospital, Clinical Physiology, Göteborg, Sweden; [3]Baker Institute, Melbourne, Australia

Heart failure is associated with a blunted heart rate and vascular baroreflex response. Hitherto, studies on renal sympathetic function in terms of renal baroreflex mechanisms are sparse in patients with heart failure (CHF).
The aim of this study was to examine whether selective unloading of cardiopulmonary and sinoaortic baroreceptors failed to reflexely increase renal sympathetic activity in patients with CHF compared with healthy subjects.
Methods: Patients, n=11, age 51±3 y(mean±SE), with CHF, LVEF 19±2%, NYHA II-III and healthy subjects (HS), n=5, age 55±2 y, underwent a right heart and renal vein catheterization. Hemodynamics, renal and total body noradrenaline (NA) spillover rates and plasma renin renal gradient (PRA-gradient) were measured at baseline and during a continuous infusion of glyceryl trinitrate (GTN). NA-spillover was assessed by radioisotope dilution technique and renal blood flow was measured by infusionsclearance of PAH. After baseline measurements, all subjects received GTN until cardiac filling pressures were reduced without affecting arterial pressures (non-hypotensive level). GTN infusion rate was then increased until a stable reduction of mean arterial pressure by 10 mmHg was achieved (hypotensive level).
Results: In HS, no differences in NA spillover rates were found at the non-hypotensive level, whereas the PRA-gradient increased ($P<0.05$). During hypotension in renal NA spillover tended to increase, without any statistically significant changes in total body NA spillover (renal NA spillover: baseline 527±173, non-hypotensive 686±173, hypotensive 824±129 pmol/min, P=NS.; PRA-gradient: baseline 0.097±0.07, non-hypotensive 0.30±0.08*, hypotensive 0.30±0.05* Ang I x mL-1 x h-1, *$p<0.05$ vs. baseline). In CHF, the non-hypotensive level resulted in a small increase in renal NA spillover. At the hypotensive level, renal NA spillover was reduced (baseline 1377±159, non-hypotensive 1511±173, hypotensive 982±208*# pmol/min, $P<0.05$ vs. baseline* and vs. non-hypotensive#), whereas the PRA-gradient increased (baseline 2.9±0.97, non-hypotensive 4.0±1.3, hypotensive 15.4±6.4* Ang I x mL-1 x h-1, *$P<0.05$ vs. baseline). Total body NA spillover rates remained unchanged (baseline 5065±1005, non-hypotensive 4852±948, hypotensive 4753±737 pmol/min, P=NS.).
Conclusions: These results indicate a defective baroreflex control of sympathetic outflow to the kidney in human CHF with a paradoxical decrease of the latter when sinoaortic baroreceptors are unloaded. PRA increased in both groups, suggesting a dominating influence of intrarenal factors on renin release.

3394 Modulation of the positive inotropic effect of angiotensin II by the endocardial endothelium and endothelin-1

P. Castro-Chaves, R. Roncon-Albuquerque Jr, A.F. Leite-Moreira. *Faculty of Medicine, Physiology Dept., Porto, Portugal*

Introduction: Recent studies have suggested that the vascular effects of angiotensin II (angt II) are partially dependent on the production and release of endothelin-1. These neurohumoral agents also have important myocardial actions, but their acute interaction at this level has not yet been explored. The main goal of our study was to investigate the modulation of angt II positive inotropic effect by the endocardial endothelium (EE) and by endothelin-1 (ET-1). **Methods:** The effects of the addition of increasing concentrations of angt II (10^{-9}, 10^{-8}, 10^{-7}, 10^{-6}, 10^{-5}) were evaluated in rabbit right papillary muscles (modified Krebs; 0.6 Hz; 1.8mM Ca^{2+}; 35°C) in the following conditions: (i) intact EE (Protocol A; n=11); (ii) after the selective removal of EE with Triton X-100 (0,5%; 1s; Protocol B; n=8) (iii) intact endothelium in the presence of PD-145065 (Protocol C; n=9; 1 mM), a nonselective antagonist of ET-1 receptors. Calculated parameters: active tension (AT; mN/mm^2), peak rates of tension rise and decline (dT/dtmax and dT/dtmin, respectively; $mN/mm^2/s$), time to half relaxation (tHR, ms), peak shortening (PS; mm) and peak rate of shortening (dL/dtmax; mm/s). Results are presented as mean±SEM in % of baseline ($p<0.05$). **Results:** In Protocol A, angt II had a dose-dependent positive inotropic effect, maximal for 10-6 M. At this concentration, angt II increased 122±13% AT, 117±16% dT/dtmax, 86±9% dT/dtmin, 12±2% tHR, 121±18% PS and 101±17% dL/dtmax. In Protocols B and C the maximal effect was significantly decreased. In Protocol B, angt II 10-6 M increased 72±16% AT, 32±7% dT/dtmax, 59±11% dT/dtmin, 95±24% PS and 41±22% dL/dtmax, without altering tHR. In Protocol C, the same concentration of angt II increased 48±11% AT, 54±14% dT/dtmax, 39±8% dT/dtmin and 40±10% EM, without altering tHR and dL/dtmax. The positive inotropic effect of angt II was not statistically different between Protocols B and C. **Conclusions:** The positive inotropic effect of angt II was significantly attenuated by the selective removal of EE and by the nonselective endothelin receptor antagonist, confirming the initial hypothesis of a potential interaction between these agents in myocardial function. These results have particular importance for the pathophysiology of heart failure, where both neurohumoral agents are activated and the endothelium is dysfunctional.

3395 Increased serum levels of metalloproteinases and their tissue inhibitors in patients with heart failure and cardiac cachexia

G. Filippatos, S. Xydonas, N. Prosmiti, D. Manolatos, D. Kardara, B. Krokos, G. Drougas, F. Kardaras. *Evangelismos Hospital, 2nd Dept. of Cardiology, Athens, Greece*

Introduction: Extracellular matrix (ECM) plays an important role in left ventricular remodeling. The structure of ECM is maintained by the dynamic equilibrium of metalloproteinases (MMP), which degrade ECM, and of their tissue inhibitors (TIMP). Neurohormones and cytokines regulate MMP and TIMP actions. Their role in CHF has not been studied. The purpose of this study was to examine the role of MMP and TIMP in patients with CHF, with and without cardiac cachexia, a condition that is associated with neurohormonal activation and increased mortality.
Methods: We studied 30 men with CHF, NYHA II-IV, of whom 20 had cachexia, aged 66±9 (mean±SD), and Left Ventricular ejection fraction (EF) 28±8%. We measured serum levels of metalloproteinase-1 (MMP-1), metalloproteinase-3 (MMP-3) and tissue inhibitor of metalloproteinases-1 (TIMP-1). Cachexia was defined as the loss of >7.5% of body weight, in a 6-month period, which was not caused by diet or edema absorption.
Results: MMP-1 and MMP-3 were significantly increased in patients with cardiac cachexia compared to those without cachexia (30±40 vs 11±8 and 231±170 vs 130±100 ng/ml, $p<0.05$ respectively). Levels of TIMP-1 were relatively increased in patients with CHF and cardiac cachexia (360±170 vs 251±150 ng/ml, $p<0.08$).
Conclusion: In this study it is shown that in patients with CHF and cardiac cachexia there is intense activation of MMP-1 and MMP-3 and to a lesser degree activation of TIMP-1. The disturbance of MMP/TIMP equilibrium is a possible mechanism of Left Ventricular remodeling and may serve as marker of adverse prognosis in patients with cardiac cachexia.

3396 Temporal changes of plasma soluble apoptosis mediators are associated with heart failure neurohormonal overactivation and clinical deterioration

J.T. Parissis[1], S. Adamopoulos[2], K. Venetsanou[3], A. Moraiti[1], D. Mentzikof[1], S. Karas[1], D. Kremastinos[2]. [1]*"Amalia Fleming" Hospital, 1st Dept. of Cardiology, Athens;* [2]*Onassis Cardiac Surgery Ctr., Dept. of Cardiac Medicine, Athens;* [3]*St Anargiri Hospital, Research Dept., Athens, Greece*

Background: Recent investigations indicate that an abnormal immune response and apoptotic process contribute to adverse left ventricular (LV) myocardial remodeling in chronic heart failure (CHF). This study investigates whether alterations in soluble apoptosis mediators (sTNFRI: soluble Tumor Necrosis Factor Receptor I, sFas: soluble Fas, sFasL: soluble Fas Ligand) occur in relation to plasma neurohormonal activation and progress of the syndrome in patients with CHF.
Methods: Plasma levels of sTNFRI, sFas and sFasL were serially examined in 25 CHF patients (age: 65±5 yrs; ischemic: 16, dilated: 9) at baseline and up to 6 months using commercially available ELISA tests (Biosurce International; Diaclone). Plasma norepinephrine (PN) and plasma renin activity (PRA) were quantified by HPLC and RIA, respectively. Finally, LV end-diastolic diameter (LVEDD), LV end-systolic diameter (LVESD) and diastolic transmitral flow [early (E) and atrial (A) filling velocities, E/A ratio, deceleration time (DT) of E] were echocardiographically determined.
Results: When compared to age- and sex-matched healthy controls (n=15), sTNFRI (4.2±0.9 vs 1.8±0.1 ng/ml, $p<0.01$), sFas (4.8±1.1 vs 2.5±0.7 ng/ml $p<0.05$) and sFasL (41.3±7.7 vs 16.5±3.1 pg/ml, $p<0.001$) plasma levels at baseline were significantly elevated in CHF patients. During follow up, an absolute increase in plasma sTNFRI from baseline (+1.2±0.3 ng/ml, $p<0.01$) was accompanied by increase in PN ($p<0.05$) and PRA ($p<0.05$), worsening functional class ($p=0.057$) and sorter DT of E ($p<0.05$) in CHF patients. An absolute increase in plasma sFas during follow up (+1.5±0.5 ng/ml, $p<0.05$), was also associated with an elevation in PN ($p=0.060$), worsening functional status ($p<0.05$) and increased LVEDD ($p<0.01$). Finally, an increase in plasma sFasL from baseline (+16.1±3.9 pg/ml, $p<0.01$) was associated with worsening functional status ($p=0.051$). There were no significant differences in temporal changes of plasma soluble apoptosis mediators and neurohormones between CHF patients with ischemic and those with dilated cardiomyopathy.
Conclusions: I) Soluble apoptosis mediators are elevated in CHF patients. II) Temporal changes in neurohormonal system activation may influence the expression of soluble apoptosis mediators despite the etiology of CHF. III) These changes in apoptotic process and neurohormonal activation may be associated with the progression of LV remodeling and subsequent clinical deterioration in CHF.

3397 Interdependence of atrial and ventricular neuronal function

M. Waldmann[1], G.W. Thompson[2], G.C. Kember[3], J.L. Ardell[4], J.A. Armour[2]. [1]*Universitätsklinikum, RWTH-Aachen, Medizinische Klinik 1, Aachen, Germany;* [2]*Dalhousie University, Department of Physiology and Biophysic, Halifax, Canada;* [3]*Dalhousie University, Department of Physics, Halifax, Canada;* [4]*University of East Tennessee, Department of Pharmacology, Johnson City, United States of America*

To characterize the interdependency of function displayed among atrial (RAGP) and ventricular (VIGP) neurons, their response characteristics to alterations in the ventricular mechanical or chemical milieu and the coordination of atrial and ventricular neuronal activities were evaluated in 10 anesthetized dogs. This was done during basal states, during enhanced ventricular sensory inputs, during altered cardiodynamics and during focal ventricular ischemia. Atrial and ventricular neuronal activity displayed periodic coupled behavior (cross correlation coefficients of activities that reached 0.88±0.03; range 0.71-1) for 15-30 seconds periods of time during basal states. Periods of coupled activity occurred every 30-50 seconds. Atrial and ventricular neurons were activated when their ventricular sensory inputs were exposed to angiotensin II (VIGP: 16.6±4.5 basal vs. 30.1±7.4, $P<0,01$) (RAGP: 17.7±4.0 basal vs 53.0±16.1, p=n.s), the alpha-2-adrenoceptor agonist clonidine or the nitric oxide donor SNAP (VIGP: 16.0±2.3 basal vs. 21.4±4.1, $P<0,01$) (RAGP: 7.4±1.7 basal vs 20.3±2.5, p=n.s). Most atrial neurons were activated by ventricular mechanosensory inputs (VIGP: 20.2±4.9 basal vs. 15.6±4.8, $P<0,01$) (RAGP: 11.7±3.6 basal vs 22.0±5.5, p=n.s), while most ventricular ones responded to atrial mechanosensory stimuli (VIGP: 9.5±3.0 basal vs. 21.8±5.4, $P<0,01$)(RAGP 14.9±3.1 basal vs. 15.5±4.3, p=n.s.). Fewer neurons responding to epicardial application of adenosine, bradykinin, an alpha-1- or beta-1-adrenoceptor agonist or veratridine. Both populations of neurons were excited when right atrial neurons were exposed to nicotine (VIGP: 14.4±3.0 basal vs. 28.2±9.0, $P<0,01$) (RAGP: 8.6±1.5 basal vs 18.3±6.4, p=n.s). Transient ventricular ischemia activated atrial and ventricular neurons both before, but not after their decentralization (VIGP: 16.5±4.2 before vs. 11.2±2.7 after decentralisation, $P<0,01$) (RAGP: 17.7±3.1 before vs 9.4±4.0 after decentralisation, p=n.s). These data indicate that atrial and ventricular neurons receive multimodal ventricular sensory inputs, particularly with respect to angiotensin II, alpha-adrenoceptor agonists and nitric oxide donors. Furthermore, both populations of neurons frequently respond to perturbations in the mechanical or chemical milieu of the heart similarly. It is concluded that interdependence of function is displayed by atrial and ventricular neurons, forming the basis for coordinate control over regional cardiac function in physiological and ischemic states.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND A2 BLOCKERS: ROLES IN HEART FAILURE THERAPY

3398 Valsartan reduces morbidity in heart failure patients receiving background angiotensin-converting enzyme inhibitors but not receiving beta-blockers: results from Val-HeFT

H. Krum[1], A. Maggioni[2], C. Farsang[3]. [1]*Alfred Hospital, Clinical Pharmacology, Prahran, Australia;* [2]*ANMCO Research Center, GISSI Group, Florence and Milan, Italy;* [3]*St. Imre Teaching Hospital, First Department of Internal Medicine, Budapest, Hungary*

Background: The Valsartan Heart Failure Trial (Val-HeFT) demonstrated that the angiotensin II receptor blocker valsartan reduced overall morbidity in heart failure (HF) patients when added to standard background therapies e.g. ACE inhibitors (ACEi) and/or beta blockers. However, many HF patients are unable to tolerate, have contraindications to, or are not prescribed beta blockers. Accordingly, we sought to examine the effect of valsartan on morbidity and mortality amongst Val-HeFT patients receiving an ACEi in the absence of beta blockers.
Methods: Val-HeFT was a placebo-controlled study of valsartan 160 mg bid in 5010 NYHA class II-IV HF patients. The study's co-primary endpoints were time to death & time to first morbid event (death, sudden death with resuscitation, intravenous inotropic or vasodilator therapy for >= 4 hours or hospitalisation for HF). The present analysis examined the effect of valsartan on these endpoints in the 3034 Val-HeFT patients who were receiving an ACEi, but not a beta blocker, at randomisation.
Results: The baseline characteristics of this subgroup did not differ from the overall Val-HeFT population. At study end (mean duration 23.0 months), mortality did not differ significantly between placebo (22.5%) and valsartan (21.8%). In contrast, the incidence of morbid events was significantly lower with valsartan (31.0%) than placebo (36.3%), hazard ratio 0.817, p= 0.002. This was due mainly to a 34% reduction in risk of first hospitalisations for HF (224 in valsartan, 316 in placebo; p<0.00001). Significant improvements in left ventricular ejection fraction, quality of life and neurohormonal parameters were also observed with valsartan versus placebo (all P=<0.001).
Conclusion: Valsartan significantly reduces morbidity in HF patients when added to ACEi therapy in the absence of beta blockers. These benefits most likely arise as a result of more complete blockade of the renin-angiotensin system.

3399 Comparative and combined antiremodelling effects of angiotensin-converting enzyme inhibitors and beta-adrenoceptor blockers in congestive heart failure

L.R. Tumasyan[1], A.B. Nargizyan[2], H.S.H. Kamalyan[1], N.N. Khudabashyan[1]. [1]*Institute of Cardiology, Heart Failure, Yerevan, Armenia;* [2]*Institute of Cardiology, Heart Failure, Yerevan, Armenia*

Background: Because left ventricular (LV) remodeling determines prognosis in congestive heart failure (CHF) the attenuation of this process is an important therapeutic goal.
The aim of our study was to assess the relative long-term effects of angiotensin converting enzyme inhibition or beta-blocker (BB) therapy and their combination on LV remodeling process in patients (pts) with CHF.
Methods: 106 consecutive pts (mean age 58.8±0.8, male 84) with NYHA III functional class CHF caused by ischemic or idiopathic dilated cardiomyopathy were randomly assigned to receive: Perindopril (P) (up to 4 mg/day, n=23), Carvedilol (C) (up to 25 mg twice a day, n=20), Bisoprolol (B) (up to 10 mg/day, n=19) alone and combined therapy of P+C (n=24) and P+B (n=20) at same doses in addition to diuretics and digoxin. Echocardiography was performed to assess LV end-diastolic (EDV), end-systolic (ESV) volumes, LV mass, sphericity index (SI), relative wall thickness (RWT) and pulmonary capillary wedge pressure (PCWP) at baseline and 12 months in all pts.
Results: BB monotherapy produced significant reduction in ESV (at 7%, p<0.05 in C and 9.7%, p<0.05 in B), leading to a greater median increase in EF compared with P (5.84% vs. 1.95%, p<0.05 and 5.9% vs. 1.95%, p<0.05). Monotherapy and combined treatment of each drug caused similar significant reduction in PCWP (p<0.05) and EDD (p<0.05). Adjunctive treatment produced a trend toward a greater increase in EF from baseline (at 5.1%, p=NS in P; 5.8%, p<0.05 in C; 6.0%, p<0.05 in B; 9.6%, p<0.05 in P+C and 10.1%, p<0.05 in P+B) and significantly greater favorable changes from baseline levels in LV mass (at 7.5%, p<0.05 in P; 8.1%, p<0.05 in C; 7.2%, p<0.05 in B; 15.1%, p<0.01 in P+C and 14.3%, p<0.01 in P+B), SI (at 7.9%, p<0.05 in P; 8.1%, p<0.05 in C; 7.7%, p<0.05 in B; 15.4%, p<0.01 in P+C and 15.5%, p<0.01 in P+B) and RWT (at 7.7%, p<0.05 in P; 8.2%, p<0.05 in C; 7.4%, p<0.05 in B; 15.3%, p<0.01 in P+C and 14.9%, p<0.01 in P+B).
Conclusions: Although long-term P therapy did not alter LV ESV, and either C or B associated with reduction in chamber volume, each drug produced favorable changes in LV mass, SI and RWT. The combined treatment resulted in further improvement in the attenuation of LV remodeling process.

3400 Pulse pressure responses in patients treated with valsartan and hydrochlorothiazide combination therapy

R. Carretta[1], P. Trenkwalder[2], F. Martinez[3], A. Tykarski[4], I. Teitelbaum[5], T. Fagan[6], O. Saccucci[7], J-M. Mallion[8]. [1]*Università di Trieste, Dipartimento di Medicina Clinica, Trieste, Italy;* [2]*Kreiskrankenhaus Starnberg GmbH, Medizinische Klinik, Starnberg, Germany;* [3]*Fundacion Rusculleda, Corboda, Argentina;* [4]*Klinika Nadcisnienia Tetniczego AM, Posnan, Poland;* [5]*Yorkview Medical Centre, Ontario, Canada;* [6]*University of Arizona, Tucson, United States of America;* [7]*Novartis Pharma AG, Basel, Switzerland;* [8]*CHU Grenoble, Medecine interne et cardiologie, Grenoble, France*

Background: Pulse pressure (PP), which is defined as the systolic blood pressure (BP) minus the diastolic BP, is believed to be a powerful indicator of cardiovascular risk. However, there is little information from clinical trials concerning drug-induced changes in PP. This parameter was examined in a comparative study of the angiotensin receptor blocker (ARB) valsartan and hydrochlorothiazide (HCTZ) as a combination therapy for hypertension in patients not controlled on valsartan monotherapy.
Aims: The effect of valsartan monotherapy (Val-mono) and two doses of valsartan plus HCTZ were compared in patients with mild to moderate HT whose BP was not adequately controlled with Val-mono.
Methods: This multicentre double-blind, parallel-group study employed a 4-week single-blind run-in period on Val 160mg o.d. to select patients whose BP was inadequately controlled with monotherapy. At the end of this period (baseline) 2002 patients were randomised to either same treatment Val-mono (663 patients) or one of 2 combination therapies, Val 160mg plus HCTZ 12.5mg o.d. (Val/HCTZ12.5) or Val 160mg plus HCTZ 25mg o.d. (Val/HCTZ25) – (663 and 657 patients respectively). Patients were treated for 8 weeks and evaluations performed every 4 weeks. The primary variable was a change from baseline in the Mean Sitting Diastolic BP (MSDBP) and a change in the Mean Sitting Systolic BP (MSSBP).
Results: The mean sitting PP before the Val-mono run-in was 58.9 mmHg (SD 11.8) in patients, who were later randomized to Val-mono, 59.1 mmHg (SD 11.8) in those randomized to Val/HCTZ12.5 and 58.9 mmHg (SD 11.6) in those randomized to Val/HCTZ25. After the Val-mono run-in period, PP had decreased in all groups to 54.1 mmHg (SD 12.2), 54.7 mmHg (SD 12.1) and 54.1 mmHg (SD 12.03), respectively. A mean decrease of 4.66mm overall. After the 8 week double-blind period, additional reductions in PP were observed with combination therapies to 52.4 (SD 12.4) mmHg for Val/HCTZ12.5 and 51.2 (SD 12.1) mmHg for Val/HCTZ25. Giving overall reductions of 6.7mm and 7.7mm, respectively.
Conclusions: In this trial with selected hypertensive patients whose BP was not adequately controlled with valsartan monotherapy there was an initial improvement in PP with Val-mono. Uptitration to Val/HCTZ produced further PP reductions suggesting that this therapeutic combination is highly effective in reducing PP.

3401 Suppression of renal aquaporin-2 overexpression by valsartan and fosinopril as a new treatment target of congestive heart failure

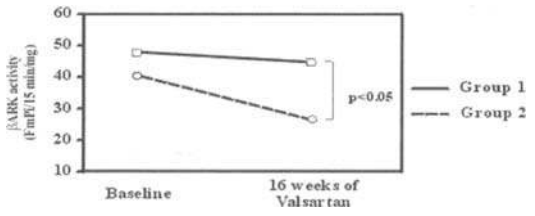
C.M. Yu, P.S. Li, K.W.H. Lai, K.L.Y. Lam, J. Leung, K.N. Lai. *Queen Mary Hospital, Department of Medicine, Hong Kong, Hong Kong*

Background: In patients with congestive heart failure (CHF), fluid overload is the main clinical manifestation though their mechanism is not fully understood. Recently, a family of proteins, the aquaporins, has been shown to regulate water reabsorption in different regions of the kidney which is likely to play a role in water retention in CHF. Treatment with angiotensin converting enzyme inhibitor or angiotesin II type-1 receptor blocker have been shown beneficial in patients with CHF. However, their effect on water balance and aquaporins expression remains unclear. This study investigated the role of these drugs on renal aquaporins expression in a rat model of CHF secondary to myocardial infarction.
Method: CHF was induced by left anterior descending coronary artery ligation in 8-week old Sprague Dawley rats. They were randomized to receive fosinopril (Fos), valsartan (Val) or combination of both drugs (Co) for 4 weeks. The mRNA expression of aquaporin-1 and -2 in kidneys was quantified by multiplex reverse transcription-polymerase chain reaction using TATA Box protein gene as a control. The protein expression of aquaporin was estimated by Western blot hybridisation and immunohistochemistry. Blood pressure was measured by non-invasive tail-cuff technique.
Results: The blood pressure was significantly reduced in all the treatment arms, without change in heart rate. Aquaporin-2 mRNA expression was increased significantly after AMI in both cortical (Sham: 18±4 vs CHF: 35±6 vs Fos: 25±11 vs Val: 23±6 vs Co: 26±9%; $p<0.01$ for Sham vs CHF, $p<0.05$ for CHF vs any treatment group) and medullary tubules (Sham: 23±2 vs 51±8 vs 20±5 vs 23±5 vs 24±8%; $p<0.005$ for Sham vs CHF, $p<=0.001$ for CHF vs any treatment group), and was normalized after any of the 3 medical regimens. Aquaporin-2 protein expression was significantly increased in CHF, and was attenuated by drug treatment (Sham: 0.86±0.25, CHF: 1.54±0.37, Fos: 1.16±0.32, Val: 1.16±0.19, Co: 1.37±0.10, ANOVA $p<0.05$). Immunohistochemistry showed that the sites of expression of aquaporin-2 are the renal tubules, especially from the medullary collecting ducts. On the other hand, aquaporin-1 mRNA and protein expressions were unchanged in CHF or after medical treatment.
Conclusion: Treatment with either Fos, Val or Co could modify the increased renal expression of aquaporin-2 in CHF secondary to AMI. As aquaporin-2 has a role in enhancing water reabsorption, suppression of this regulatory protein may contribute to the alleviation of fluid overload and CHF rehospitalisation in the clinical setting.

3402 Effect of valsartan on beta-adrenergic receptor kinase (betaARK1) activity in heart failure

E. De Tommasi[1], G. Iaccarino[2], M. Iacoviello[1], C. Ceconi[3], C. Forleo[1], B. Rizzon[1], P. Rizzon[1], M.V. Pitzalis[1]. *[1]University of Bari, Institute of Cardiology, Bari, Italy; [2]Dipartimento di Medicina Clinica, Federico II University of Naples, Naples, Italy; [3]Cardiovascular Research Centre, Fondazione Salvatore Maugeri, Brescia, Italy*

In chronic heart failure the increased beta-adrenergic receptor kinase (betaARK1) activity causes downregulation of beta-adrenergic receptors, thus favouring heart failure progression. Little is known about the interaction between renin-angiotensin system and betaARK1 activity. To better understand this relationship we evaluated the effect of an AT1 receptor antagonist (ARB) on betaARK1 activity.
We studied 24 patients (mean age 59 ± 9, 18 males) with NYHA functional class II or III (mean value: 2.3±0.5), left ventricular ejection fraction <40% (mean value: 29.7±6.5), who were not taking ACE-inhibitors, ARBs and beta-blockers from at least 1 month before the study. Patients were in stable clinical conditions and received the maximum tolerated dose of Valsartan (V) once daily (up to 160 mg). At baseline and after 16 weeks of V administration, angiotensin II (ATII) plasma levels and betaARK1 activity were evaluated.
V was not not able to significantly increase ATII plasma levels (from 12.6±6.8 pg/ml to 17.1±16.8 pg/ml) and reduce betaARK1 activity (from 44.8±28.4 FmPi/15 min/mg to 37.9±22.2 FmPi/15 min/mg). However, patients showing an increase of ATII plasma levels (group 1) after V had significantly lower values of betaARK1 activity than those found in patients in whom ATII did not increase (group 2) (ANCOVA analysis) (figure). V dosage was not different between the two groups (153±24 mg vs 154±22 mg).



In conclusion, in chronic heart failure, Valsartan is able to reduce betaARK1 activity only when ATII is increased. This favourable effect may be due to the ATII interaction with AT2 receptors when the AT1 receptors are blocked.

3403 Comparative influence of angiotensin-converting enzyme inhibitors, beta-blockers and nitrates on left ventricular diastolic filling in congestive heart failure

L.R. Tumasyan[1], A.B. Nargizyan[2], H.S.H. Kamalyan[1], N.N. Khudabashyan[1]. *[1]Institute of Cardiology, Heart Failure, Yerevan, Armenia; [2]Institute of Cardiology, Heart Failure, Yerevan, Armenia*

Background: Recent studies have shown, that left ventricular (LV) diastolic filling is a strong predictor of survival in chronic heart failure (CHF). A direct comparison of the diastolic effects of angiotensin converting enzyme inhibitors, b-blockers and long-acting nitrates has rarely been performed.
The aim of our study was to assess the relative long-term effects of Fozinopril (F), Carvedilol (C) and Isosorbide Dinitrate (ID) on Doppler-derived parameters of diastolic filling in CHF.
Methods: 80 consecutive patients (pts) (mean age 58.9±0.2 years, male 66) with NYHA III-IV functional class CHF of ischemic origin were randomly assigned to treatment with F (up to 20 mg/day) for 6 months, followed by 6 months of combined treatment F+C (up to 25 mg twice daily, n=42) and F+ID (up to 60 mg/day, n=38) in addition to diuretics and digoxin. Peak early (E) and late (A) transmitral filling velocities, E/A ratio, acceleration (AT) and deceleration times (DT) of E-wave, LV isovolumic relaxation (IVRT), overall LV filling time (OFT) were obtained using pulsed-wave Doppler echocardiography at baseline, 6 and 12 months. All pts were in sinus rhythm and had the restrictive filling pattern (E/A>2, DT<130 msec).
Results: F treatment has significantly prolonged AT (from 75±1.8 to 81±2.4 msec, $p<0.05$) and DT (114±8.1 to 138±8.6 msec, $p<0.05$), decreased E (87.3±2.1 to 80.4±2.8 cm/sec, $p<0.05$) and E/A (2.31±0.14 to 1.9±0.15, $p<0.05$) and had trend toward increasing of IVRT (42±4.2 to 50.4±6.1 msec, p=NS), OFT (352±11 to 380±14 msec, p=NS) and A (37.8±3.6 to 42.3±1.1 cm/sec, p=NS). Adding C has resulted to further prolongation of AT (to 88±2.6, $p<0.05$) and DT (to 170±12.6, $p<0.05$), increasing of E (to 70.2±4.0, $p<0.05$) and E/A (to 1.4±0.2, $p<0.05$) and has significantly prolonged IVRT ((to 70.2±7.6, $p<0.05$) and OFT (to 410±5.1, $p<0.05$), leading to improved late diastolic filling, depicted by increased A (to 50.1±0.8, $p<0.05$). Treatment with ID has significantly prolonged IVRT (to 72.2±5.4, $p<0.001$) and OFT (to 411±12, $p<0.02$), increased A (to 52.2±2.2, $p<0.05$), decreased E (to 67.9±5.6, $p<0.05$) and E/A (to 1.3±0.25, $p<0.05$) and had tendency to further prolongation of AT (to 85±3.7, p=NS) and DT (to 155.4±7.7, p=NS).
Conclusions: All tested drugs have significantly improved LV diastolic filling, but affected different parameters and thus apparently acted through different mechanisms. Therefore the combined therapy may result in additive favorable changes in LV diastolic function.

CONDUCTION DISTURBANCE AND VENTRICULAR FUNCTION

3416 Is QRS duration a good index of right to left ventricular systolic asynchrony? Comparison with conventional and tissue Doppler imaging criteria

F. Anselme[1], G. Habib[2], A. Savouré[1], R. Lakhdar[1], S. Ouali[1], I. Schuster[1], A. Cribier[1], G. Derumeaux[1]. [1]*C.H.U. Charles Nicolle, Service de Cardiologie, Rouen, France;* [2]*La Timone Hospital, Marseille, France*

Background: Biventricular pacing is a new promising technique aimed to achieving cardiac resynchronisation through inter- and intraventricular delay correction in heart failure. Therefore, accurate diagnosis of desynchronisation of right (RV) and left (LV) ventricular activation is of crucial importance. The usual accepted selection criteria for biventricular pacing include NYHA III-IV, LV dilatation, LV EF < 35% and QRS duration > 150 ms.
Aim: To assess right to left ventricular asynchrony by comparing QRS duration, right- (RV) and left ventricular (LV) pre-ejection delay measured by conventional Doppler and tissue Doppler imaging (TDI).
Methods: 50 patients (Pts) with primary dilated cardiomyopathy (NYHA III, LVEF<40%, LVEDD>60mm) were divided into 3 groups according to QRS duration (ms): Gr 1 (n=28, QRS<110), Gr 2 (n=13, 110<QRS<150) and Gr 3 (n=19, QRS>150). Echo parameters of RV to LV asynchrony were blindly measured by: 1) the difference between the onset of QRS and the onset of aortic and pulmonary flow, respectively (QAo-QPulm,ms); 2)the difference between the onset of QRS and the peak of systolic velocities recorded at the lateral corner of tricuspid and mitral annulus,respectively (QM-QT, ms).
Results: RV to LV asynchrony assessed by QAo-QPulm>40 was present in: 9/28Pts (32%) in Gr1; 3/13 (23%) in Gr2 and 14/19 (74%) in Gr3. In Pts with QAo-QPulm>40, QM-QT was significantly higher in all groups than in Pts with QAo-QPulm<40: Gr 1: 90±35 vs 34±18 ms; Gr2: 96±44 vs 44±22 ms and Gr 3: 107±35 vs 27±21 ms, $p<0.05$. QM-QT<80ms identified 31/34 Pts with QAo-QPulm<40 while QM-QT>80 identified 15/26 Pts with QAo-QPulm>40. No significant correlation was found between QRS duration and QAo-QPulm and QM-QT values, respectively. At the opposite, QM-QT values were significantly correlated with QAo-QPulm ($r=0.78$, $p<0.01$).
Conclusion: Accurate diagnosis of RV to LV asynchrony should not be only based on QRS duration but should combine mechanical indices derived from conventional and tissue Doppler imaging in order to better identify the potential patients to benefit from resynchronisation therapy.

3417 Timing of regional myocardial motion and deformation in cardiomyopathies with LBBB: a Doppler myocardial and strain rate imaging study

L. Herbots, O.A. Breithardt, P. Claus, M. Kowalski, W. Droogne, M.C. Herregods, B. Bijnens, G.S. Sutherland. *University Hospital Gasthuisberg, Cardiology Dept., Leuven, Belgium*

Cardiac resynchronisation therapy (CRT) aims to improve regional myocardial asynchrony and haemodynamic function in pts with heart failure and left bundle-branch block (LBBB). Exact timing of regional function might be important for selecting patients and optimal pacing site. Doppler Myocardial Imaging(DMI) quantifies regional myocardial velocities and has been proposed for guiding CRT. However besides myocardial deformation, velocities are reflecting overall cardiac motion. Regional deformation rate(Strain Rate) and deformation(Strain, S)(calculated from regional velocity gradients)are less influenced by cardiac motion. This study investigated the timing of regional mechanical activation in ischemic(ICM) and idiopathic dilated cardiomyopathies(DCM) with LBBB and normals(nls) measured by DMI and Strain Rate Imaging (SRI).
Methods: Colour DMI data was obtained at >150 frames/s from the left ventricular(LV) sept, lat, inf, ant and post walls (apical window, longitudinal function) in 10 pts with DCM and LBBB(age 52±14y, QRS 169±29ms, EF 22±8%), 10 pts with ICM and LBBB(age 64±11y, QRS 155±26ms, EF 30±8%) and 10 nls(age 51±15y, QRS 79±12ms, EF 69±11%). Data was post processed to determine time from onset of QRS to maximal systolic or post systolic myocardial velocity(Vm) and deformation(Sm). LV walls with earliest and latest maximal motion/deformation were selected in each patient. Analysis was performed with custom made software enabling exact timing of global cardiac events.
Results: Earliest and latest Vm and Sm were variable within each patient or normal. Earliest Vm occurred in the sept wall in 50% of nls(150±21ms), in 20% of DCM (216±49ms) and in 40% of ICM (176±36ms) while 60% of nls (239±50ms), 50% of DCM (347±63ms) and 40% of ICM (292±40ms) had latest maximal motion in the post wall. Earliest Vm was found in the ant wall in 40% of DCM and in 30% of ICM. Earliest Sm occurred in the sept wall in 40% of nls (356±36ms), in 70% of DCM (385±67ms) and in 60% of ICM (372±55ms) while 60% of nls (488±56ms), 50% of DCM (593±58ms) and 50% of ICM (560±68ms) had latest maximal deformation in the post wall. Of all investigated subjects, 10% had earliest and latest Vm and Sm in the same walls.
Conclusions: Location of earliest and latest mechanical activation in DCM and ICM with LBBB and nls was highly variable throughout the LV walls. Earliest/latest maximal velocity compared with earliest/latest deformation within one patient occurred most often in different cardiac walls. Selecting patients and guiding CRT only on base of maximal velocities might have its limitations.

3418 Quantitative tissue Doppler can measure and localize improvement of ventricular dyssynchrony in dilated cardiomyopathy after biventricular pacing

D. Mele[1], S. Aggio[2], G. Pasanisi[1], H. Kuwornu[1], F. Zanon[2], I. D'Aiello[1], P. Zonzin[2], R. Ferrari[1]. [1]*Arcispedale S.Anna, U. O. di Cardiologia, Ferrara, Italy;* [2]*Ospedale SM della Misericordia, U.O. di Cardiologia, Rovigo, Italy*

Background: Dilated cardiomyopathy (DCM) is characterized by abnormal left ventricular (LV) activation and contraction, that can be coordinated by biventricular (BIV) pacing, resulting in improved LV ejection fraction (EF). The aim of this study was to provide new indexes of LV contractile synchronicity obtained by quantitative Tissue Doppler Echocardiography (TDE) and to use them to evaluate the effect of BIV pacing on contractile dyssynchrony in patients with DCM.
Methods: Thirteen patients with DCM, NYHA class III-IV and QRS duration > 120 msec underwent a TDE study before and within 24h after BIV pacemaker implantation using a GE Vivid-Five echo scanner. Color high frame rate TDE cineloops were analyzed in the 4-chamber view extracting velocity profiles at a segmental level. The time intervals between the beginning of systolic shortening at basal septum and lateral wall (septum-lateral wall synchronicity index, SL-SI, msec), at basal and apical septum (intra-septal synchronicity index, IS-SI, msec), and at basal and apical lateral wall (intra-lateral synchronicity index, IL-SI, msec) were measured. The LV-EF was measured by the monoplane Simpson's rule.
Results: After BIV pacemaker implantation, SL-SI decreased from 122.0±48.0 to 53.1±47.1 msec ($p=0.0007$), IS-SI decreased from 74.8±47.1 to 37.1±31.6 msec ($p=0.0278$), and IL-SI decreased from 45.1±34.5 to 25.7±25.4 msec ($p=0.0229$). EF increased from 22.8±5.4 to 30.9±4.9% ($p=0.0001$) and QRS duration decreased from 196.0±27.0 to 157.0±19.0 msec ($p=0.0007$). SL-SI, IS-SI and IL-SI correlated inversely and significantly with EF ($r=-0.56$, $p=0.0029$; $r=-0.50$, $p=0.01$; $r=-0.47$, $p=0.0156$, respectively).
Conclusions: TDE allows direct measurement of intraventricular synchronicity, providing new indexes that also localize the level of dyssynchrony. In patients with DCM, this technique shows that the improvement in intraventricular synchronicity after BIV pacing occurs both within and between the LV walls and correlates with acute improvement in LV-EF. TDE, therefore, can potentially be helpful to guide ventricular resynchronization therapy in heart failure.

3419 Tissue Doppler imaging assessment of asynchrony predicts positive left ventricular remodelling after biventricular pacing in heart failure

M. Penicka[1], P. Geelen[1], B. De Bruyne[2], E. Barbato[1], M. Goethals[1], P. Goemaere[1], M. De Zutter[1], J. Bartunek[1]. [1]O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium; [2]O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium

Resynchronization by biventricular pacing (BP) has been shown to reverse left ventricular (LV) remodeling in patients with heart failure (HF). Nevertheless, the prediction of benefit remains controversial. Tissue Doppler imaging (TDI) allows precise assessment of regional electromechanical coupling time (EMCT).
Aim: To determine a value of conventional- and TDI-derived echocardiographic parameters to predict benefit of the BP on LV remodeling.
Methods: Twenty-one consecutive patients with HF (NYHA 3.2±0.8) and wide QRS complex (179±28 ms) undergoing BP were studied prospectively by echocardiography. LV morphology and conventional Doppler derived indices of LV filling and ejection were assessed prior to BP. In addition, differences between regional EMCT in basal segments of the LV (LV asynchrony, LVasyn) and in basal left and right ventricular free wall (interventricular asynchrony, LV-RVasyn), respectively, were assessed by TDI. At 3 months follow-up, responders (R) were defined by an absolute increase in LV ejection fraction (LVEF) > 5% (n=15).
Results: LVEF increased significantly in R (22±5 vs 33±7%, p<0.01) but not in nonresponders (NR) (21±4 vs. 22±4%, NS). Baseline heart rate, QRS duration and PQ interval, LV dimensions and EF were similar in both groups (not shown). LV filling time (LVFT) was shorter (38±15 vs. 48±17% of cardiac cycle, p<0.05) and isovolumic contraction (IVCT) longer (20±7 vs. 14±11% of cardiac cycle, p<0.05) in R vs. NR. LVasyn (73±18 vs. 47±11 ms, p<0.05) and LV-RVasyn (82±24 vs. 48±13 ms, p<0.05) were greater in R vs NR, respectively. The accuracy of TDI-derived indices to predict an increase in LVEF was superior to conventional echo-Doppler indices (table).

	Sensitivity	Specificity	PPV	NPV	Accuracy
LVFT < 45%	67	67	83	44	67
IVCT > 15%	73	67	85	50	71
LVasyn > 65 ms	80	83	92	63	81
LV-RVasyn > 55 ms	80	83	92	63	81
LVasyn > 65 or LV-RVasyn > 55 ms	93	83	93	83	90

Conclusions: The TDI-derived parameters of asynchrony appears to be accurate predictors of the positive effects of BP on the LV remodeling. The use of such-derived indices may help to avoid unnecessary implantations.

3420 Ischaemic and not ischaemic myocardial post-systolic motion in patients with left bundle branch block: analysis of pulsed tissue Doppler

R. Citro[1], M. Galderisi[2], D. Mattioli[3], S. Cicala[4], P. Guarini[5], D. Aquino[1], O. de Divitiis[2], G. Gregorio[1]. [1]San Luca Hospital, Department of Cardiology, Vallo della Lucania, Italy; [2]Federico II University, Division of Emergency Medicine, Naples, Italy; [3]Centro Studi Cuore, Rome, Italy; [4]Second University, Cardiology, Naples, Italy; [5]Clinica "Villa dei Fiori", Acerra (NA), Italy

Aim of the study: Pulsed Tissue Doppler (PW-TD) assessment of posterior interventricular septum (IVS) asynchrony in patients (pts) with left bundle branch block (LBBB) and with and without left anterior descending coronary artery (LAD) stenosis.
Population and methods: 42 consecutive pts (males: 21; mean age = 59±11 years) with chronic, complete LBBB underwent coronary angiography, standard Doppler-echo and PW-TD, placing the sample volume at the level of posterior septum and of the mitral annulus, in apical 4-chamber view. Myocardial systolic indexes (systolic peak velocity = Sm, pre-contraction time = PCTm and contraction time = CTm), diastolic measurements (early diastolic and atrial velocities - Em and Am, Em/Am ratio, relaxation time = RTm) and post systolic motion (PSM) peak velocity were obtained. Pts were divided into 2 groups according to the absence (group A, 27 pts) or presence (group B, 15 pts) of LAD stenosis >50%.
Results: see table. In the overall population PSM was related to age (r = -0.38, p<0,01), septal wall thickness (r = -0.38, p<0.01) and ejection fraction (EF) (r =0.32, p<0.05). By multivariate analysis EF (B=0.32) and significant LAD stenosis (B=0.43; both p<0.05) were independent predictors of PSM (cumulative R square = 0.24, p<0.05) while sex, age and diastolic blood pressure did not enter the model.

	Group A	Group B	P
Sm (cm/s)	6.17 (1.8)	5.19 (0.8)	<0.05
PCTm (ms)	133.1 (35.5)	143.5 (33.5)	<0.05
CTm (ms)	242 (58.1)	240.6 (55.3)	NS
Em (cm/s)	6.7 (1.6)	7.0 (1.9)	NS
Am (cm/s)	7.7 (3.8)	9.9 (3.7)	<0.05
Em/Am	0.83 (0.5)	0.76 (0.2)	NS
RTm (ms)	133.8 (37.2)	159.3 (27.5)	<0.02
PSM (cm/s)	5.3 (1.8)	8.0 (4.0)	<0.005

Conclusions: PW-TD allows to distinguish different patterns of septal myocardial asynchrony in LBBB with and without coronary artery disease. Pts with ischemic LBBB are characterized by a greater amplitude of PSM and longer length of PTCm and, above all, of RTm. LAD stenosis and EF are to be the main determinants of PSM magnitude.

3421 Doppler tissue imaging and congenital long QT syndrome

C. Savoye-Klug[1], D. Klug[2], P.V. Ennezat[2], I. Denjoy[3], T. Le Tourneau[2], G. Deklunder[2], S. Kacet[2]. [1]Hopital Cardiologique CHRU, EFCV, Lille, France; [2]Hopital Cardiologique, Lille, France; [3]hopital Lariboisière, Paris, France

Our objective was to evaluate the value of Doppler Tissue Imaging (DTI) in patients with long QT syndrome (LQTS) as a new phenotypic marker.
Methods: Ten patients with congenital LQTS (mean age; 34 ± 9 years) and 14 control subjects were studied. Standard echocardiography and DTI analysis were performed. Using an offline computer, myocardial velocities were measured in basal and mid segments of the septal, lateral, posterior and anterior walls, in apical view. Peak velocities and time intervals were measured in each segment.
Results: Conventionnal echocardiography was normal for both groups. DTI analysis demonstrated increased systolic and diastolic peak velocities for all segments in LQTS patients. In LQTS patients, increase was significant in almost segments, by example in basal septal (Peak S: 7.2 vs 4.6 cm/s; Peak E: -10 vs -6.9 cm/s; p < 0.05) and mid septal walls(Peak S: 4.7 vs 3.2 cm/s; Peak E: -9.3 vs -5.5 cm/s; p < 0.05). Regional isovolumic relaxation time and systolic velocity half time (VHT) were significantly longer in LQTS group with a prolonged late systolic phase, resulting in a plateau morphology.
These preliminary results show an increase in systolic and diastolic peak velocities, with an increase in the regional isovolumic relaxation time in patients with LQTS. DTI seems to be an interesting new phenotypic marker for LQTS.

INNOVATING APPLICATIONS OF TRANSOESOPHAGEAL ECHOCARDIOGRAPHY

3422 Eustachian valve is a confounder of contrast echocardiography but not of color Doppler in detecting a right-to-left-shunt across a PFO

H. schuchlenz[1], G. saurer[1], W. weihs[1], P. rehak[2]. [1]LKH-GRAZ, 2.Med., Graz, Austria; [2]Dep. Surgery, LKH-Univ.-Graz, Dep.Med.Engen.and Computing, Graz, Austria

Patent foramen ovale (PFO) is an accepted risk factor for paradoxical embolisation. Transesophageal contrast echocardiography (cTEE) is accepted as the method of choice for the diagnosis of PFO, but its diagnostic accuracy compared with color Doppler and with an associated Eustachian valve (EV) has not been established. The eustachian valve is a remnant of the embryonic right valve of the sinus venosus, which directs the blood from the inferior vena cava to the interatrial septum and across the PFO (if present). It is seen in the majority of newborn infants but much less frequently in adults, studied by transthoracic echocardiography
The aim of this study was to determine the influence of a large Eustachian valve on the accuracy of contrast and color Doppler echocardiography in detecting a right-to-left-shunt across a PFO.
Methods: In 292 consecutive patients (age 42±12 years) with cryptogenic stroke we asertained the precence of PFO and EV using TEE. None of these patients had a right or left heart pathology. A PFO was diagnosed based on the observation of right-to-left passage of contrast bubbles or by using color Doppler with a low Nyquist limit (20-45 cm/sec) if turbulent right-to-left flow through the valve-like structure could be documented. In case of conflicting results contrast agent was administered via a femoral vein cTEE-IVC. A large EV was defined with a size >1.5 cm measured in the bicaval view.
Results: A total of 192 pts (66%)showed evidence of a PFO with either echo technique. A PFO could be detected in 166 of 204 pts (56.8%) by cTEE [specifity 100%], versus 184 of 204 pts (64%) by color Doppler [specifity 97%]. A large EV was measured in 31 pts with PFO vs in 6 pts without PFO (p<0.001). The presence of a large EV decreased the sensitivity of cTEE from 81% (without EV) to 61% (p<0.001), whereas color Doppler sensitivity was unchanged 90%
Conclusion: The presence of a large EV decreases the accuracy of cTEEin detecting PFO, whereas color Doppler is not confounded by EV. EV confounds the clinical value of cTEE but not of color Doppler TEE in detecting PFO.

3423 Do left-sided echo contrast agents improve diagnostic accuracy of transoesophageal echocardiography in patients with suspected aortic dissection?

M.R. Schulze, Y. Franke, S.A. Lange, S. Schoen, A. Schmeisser, R.H. Strasser. *Medical Clinic II, Technical University, Dresden, Germany*

Transesophageal echocardiography (TEE) has a high sensitivity and specificity to diagnose a suspected aortic dissection (AD) by interpretating 2D, M-Mode, and colour doppler information. Contrast echocardiography (CE) is widely used for assessment of left ventricular wall motion in patients (pat.) with poor image qualities. At present it is not known if CE gives further information in pat. with suspected AD.

Methods: TEE with CE was performed in 43 consecutive pat. (31 m; 12 f; mean age 65+14 y) with unexplained thoracic pain and suspected AD (clinical, CT, TEE). 12 pat. had a prior cardiovascular operation (aortic valve replacement (AVR), coronary bypass, ascending aortic conduit) and 6 of these pat. had a second cardiovascular operation (3 due to Typ A AD after AVR). During TEE examination one or more boli of echocardiographic contrast media (CM; Optison®) able to cross the pulmonary vascular bed were given intravenously.

Results: An AD and/or partial or partially covered perforation could be detected in 13 pat. (n=6 Typ A; n=5 Typ B; n=1 Typ B and perforation; n=2 perforation of the aorta) and in 3 preoperated pat. with aortic conduits perforation sites could be diagnosed. After intravenous administration of CM there was an initial shadowing of the ascending aorta by CM in the left atrium and the pulmonary artery. This effect disappeared after a few seconds and the lumen and wall of the ascending and descending aorta could be visualized with a clear delineation of the aortic wall especially in preoperated pat. and pat. with large aortic aneurysms. Only with CM a dissecting membrane could be diagnosed or better visualized in 4 pat., and in all pat. more entrys/reentrys could be detected. In preoperated pat. there was a better visualizaton of perforation sites between native aorta and aortic conduit with CM. In 1 pat. with a large aortic aneurysm only with CM thrombotic material was detected inside the aorta.

Conclusion: CM greatly improves diagnostic accuracy of TEE in pat. with suspected aortic dissection by better identification of dissecting membranes and detection of entries/reentries, perforation sites, and thrombotic material.

3424 Assessment of the pulmonary veins by transoesophageal echocardiography: determination of standard values of pulmonary venous flow and diameter

C. Schneider, E. Bahlmann, C.H. Heuser, S. Ernst, M. Antz, K.H. Kuck. *St.Georg Hospital, Cardiology, Hamburg, Germany*

Background: Pulmonary vein (PV) stenosis has been described as a rare complication after radiofrequency catheter ablation. Using transesophageal echocardiography (TEE) PV stenosis can be identified by increasing blood flow and decreasing vessel diameter.

Aim: For further evaluation and quantification standard values are necessary which should be determined in this study.

Methods: In 206 patients (137 men, mean age 62y) without cardiac diseases TEE was performed assessing mean (PVVm) and peak (PVVp) pulmonary venous flow velocity, velocity time integrals (VTI) and pulmonary vein diameter. All PV (left upper and lower PV, right upper and lower PV) were analysed.

Results: In 204 of 206 patients all PV could be visualized by color doppler imaging. In two patients the left and right lower PV could not be assessed. The table describes the results of all measurements.

	Left upper PV	Left lower PV	Right upper PV	Right lower PV
PVVm (cm/sec) Standard Error	32 ± 13,5	27 ± 12,1	34 ± 15,1	29 ± 8,8
PVVp (cm/sec) Standard Error	53 ± 18,8	32 ± 13,6	64 ± 28,2	53 ± 17,6
VTI (cm) Standard Error	24 ± 10,8	22 ± 10,9	26 ± 13,7	22 ± 8,7
Diameter (mm) Standard Error	13,4 ± 2,8	12,4 ± 2,6	13,6 ± 2,6	12,7 ± 2,5

Measurements of pulmonary venous flow velocities and vessel diameters by transesophageal echocardiography

Conclusion: For better evaluation and quantification of pathological pulmonary venous flow we determined standard values of mean and peak flow velocities, velocity time integrals and vessel diameters by transesophageal echocardiography.

3425 Transoesophageal echocardiography: a screening method for pulmonary venous stenosis/occlusion after catheter ablation of atrial fibrillation

C. Schneider, E. Bahlmann, C.H. Heuser, S. Ernst, M. Antz, K.H. Kuck. *St.Georg Hospital, Cardiology, Hamburg, Germany*

Background: Pulmonary vein (PV) stenosis has been described as a rare complication of radiofrequency treatment.

Methods: We report on 5 patients of a total of 280 who complained about dyspnea and hemoptysis during follow up after catheter ablation of atrial fibrillation. Subsequently transseptal pulmonary venous angiograms were performed followed by recanalization of 3 totally occluded PV and ballon dilatation of 2 high-degree PV stenosis. In one patient mild PV stenosis was found. Severe stenosis was angiographically defined as narrowing of more than 70%, mild stenosis of less than 50%. Transesophageal echocardiography (TEE) was performed in all 5 patients, assessing mean (PVVm) and peak (PVVp) pulmonary venous flow velocity, velocity time integrals (VTI) and pulmonary vein diameter. A control group of 206 patients was investigated by TEE to determine standard values of these parameters. Data of angiography and TEE were correlated.

Results: In totally occluded PV no flow was detectable. In all patients with severe stenosis averaged PVVm (1.74m/sec), PVVp (2.35m/sec) and VTI (133.6cm) were observed to be increased in comparison to the control group (averaged PVVm 0.28m/sec, PVVp 0.48m/sec, VTI 21cm). Averaged pulmonary vein diameter was less than 7mm (12mm in the control group). In the patient with mild stenosis averaged PVVm (0.9m/sec), PVVp (1.6m/sec) and VTI (60cm) were measured slightly increased. TEE showed reestablished pulmonary venous flow in all recanalized vessels. In only one case of 280 investigations a angiographically normal PV could not be visualized by TEE.

Conclusion: TEE with assessment of pulmonary venous flow parameters and vessel diameter can be used to detect pulmonary venous stenosis and occlusion after catheter ablation and is also able to serve as follow-up tool after recanalization.

3426 Evaluation of the morphological changes of the aorta and its branches by TEE in patients with Takayasu arteritis

R. Jabara[1], Y. Shapira[2], Y. Molad[3], E. Krausze[3], A. Koren[3], A. Sagie[2]. [1]*Hadassah University Hospital, Heart Institute, Jerusalem, Israel;* [2]*Rabin Medical Center, Department of Cardiology, Petach Tikva, Israel;* [3]*Rabin Medical Center, Petach Tikva, Israel*

Background: Takayasu arteritis is a chronic inflammatory disease of unknown etiology affecting mainly the aorta and its major branches, exhibiting intimal hyperplasia, medial degeneration and adventitial fibrosis. CT and MRI were reported to be useful methods for the evaluation of the morphological changes in the aorta and its branches in Takayasu arteritis. There are no reports regarding the role of transesophageal echocardiography (TEE) in the assessment of intimal thickening of the aortic wall in these patients.

Purpose: The aim of the present study was to test the value of TEE in the evaluation of morphological properties in the aortic wall in Takayasu arteritis.

Methods: The thoracic aorta was studied in 10 female patients (mean age 34 ± 3 y) with Takayasu arteritis by TEE. Intimal thickening was defined pathologically when it reached above 3 mm.

Results: TEE revealed thickening of the intima of the thoracic aortic wall in all patients (mean maximal intimal thickening 3.9 ± 0.7mm, range 3.2-4.5 mm). Maximal intimal thickening was noted in the aortic arch in 6 patients (60%), and in the aortic arch and ascending aorta in 2 patients. In the remaining 2 patients all thoracic aortic segments were diffusely involved (4.5 mm). In these last 2 patients, intimal thickening and narrowing of the proximal portion of the cranial vessels were also demonstrated. TEE detected mild aortic regurgitation in 4 patients (40%).

Conclusions: This study demonstrates for the first time that TEE can detect intimal thickening of the thoracic aortic wall, and therefore may be a useful adjunctive tool for the diagnosis of Takayasu arteritis.

3427 Usefulness of the transoesophageal echocardiography in the monitoring of the endoluminal graft for the treatment of the thoracic aorta diseases

G. Dialetto[1], A. Bortone[2], F.E. Covino[1], G. Scognamiglio[1], L. de Luca Tupputi Schinosa[2], M. Cotrufo[1]. [1]*A.O. Monaldi, CardioThoracic and Respiratory Science, Naples, Italy;* [2]*University of Bari, Division of Cardiovascular Surgery, Bari, Italy*

Background: The implantation of transcatheter aortic endoprosthesis is an innovative and minimally invasive tecnique for the treatment of the thoracic aorta diseases. Its growing use, justified by the high rate of mortality with surgical approach, requires a careful monitoring both during its implantation to guide a correct placement and in the follow-up period to evaluate its efficacy and safety.
Aim of the study: To evaluate the usefulness of the transesophageal echocardiography (TEE) in the intra- and post-procedural monitoring of the graft implantation.
Methods: Thirty-five consecutive patients (4 F, 31 M), with prior diagnosis of aortic dissection type B of Stanford (14 pts), aneurysm of thoracic aorta (11 pts), and post-traumatic rupture of thoracic descending aorta (10 pts) have been studied. All the patients underwent deployment of endovascular stent-grafts in the descending thoracic aorta, and the procedure was entirely monitored with angiography, fluoroscopy and TEE exam. The safety of this approach has been evaluated during the follow-up period with angio-TC and TEE at six months and at 1 year after the implantation.
Results: In all the patients the intra-procedural TEE allowed an optimal visualization of the graft and its relationship with the aortic wall, playing a key-role for the correct placement of the graft in the 31.4% of cases (11 pts). Intra-procedural TEE was also determinant for the discovery of 1 case of intimal rupture in a patient with dissection and, with the help of Color-Doppler, for the diagnosis of 2 cases of leak. During the follow-up TEE showed the appearance of peri-prosthetic leaks, confirmed at angio-TC exam, in 2 patients with prior aortic aneurysm.
Conclusions: TEE has demonstrated to be an important diagnostic tool in the monitoring of aortic endoprosthesis. This simply and reliable tecnique, giving the cardiologist important anatomical and functional informations both during the procedure and later, during the follow-up, contributes to improve the safety of this new therapeutical option for diseases of the descending thoracic aorta and to promptly identify eventual related complications.

NEW MARKERS FOR STRESS-INDUCED ISCHAEMIA

3432 Vasodilator stress echocardiography: regional wall motion and/or coronary flow reserve for the diagnosis of coronary artery disease?

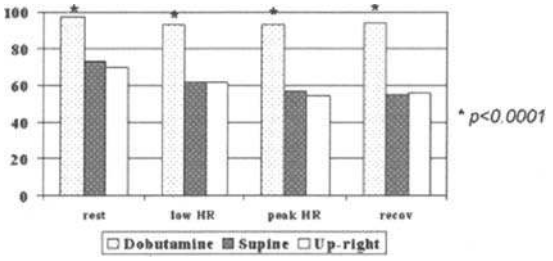
F. Rigo[1], M. Richieri[1], W. Curtaia[1], C. Zanella[1], P. Della Valentina[1], E. Pasanisi[2], A. Raviele[1], E. Picano[2]. [1]*Mestre Hospital, Cardiology Division, Mestre, Italy;* [2]*Institute of Clinical Physiology, PISA, Italy*

Background: Vasodilator stress echocardiography allows semi-simultaneous imaging of left anterior descending (LAD) coronary flow and regional wall function.
Aim: to assess the relative (and additive?) value of regional flow and function for noninvasive identification of angiographically assessed LAD disease in patients with chest pain syndrome. Methods: 191 consecutive in-hospital patients (111 males, age=64±18 years) with chest pain syndrome and normal regional and global left ventricular function were enrolled. All underwent dipyridamole (up to 0.84 mg/kg over 10') stress echo, including wall motion analysis by 2-D echo (2DE) and coronary flow reserve (CFR) evaluation of LAD by TTE-Doppler, with or without contrast injection. A new regional wall motion abnormality in at least 2 contiguous segments was required for 2DE positivity. CFR was evaluated as the ratio of dipyridamole to rest peak diastolic coronary blood flow velocity. A CFR <2 was required for CFR positivity. All patients had coronary angiography within 15 days and a diameter reduction >50% of LAD was considered significant.
Results: Of the 191 patients, 61 had CAD, and 130 no CAD. A regional wall motion abnormality in LAD territory was present in 44, a reduced LAD CFR in 54 patients. Sensitivity for detecting LAD disease was 73% for 2DE and 87% for CFR (p=ns); specificity 91% for 2DE and 78% for CFR (p<.01); accuracy was 85% for 2DE and 81% for CFR (p=ns). The positive predictive value of 2D- echo was 80% and the negative predictive value of a normal CFR was 93%. Conclusion: CFR can be obtained during vasodilator stress echo. Its diagnostic accuracy for detecting LAD disease is lower than regional wall motion abnormalities - due to limited specificity.However, the two informations of flow and function can be additive in terms of prediction of underlying angiographic anatomy, since a positive 2D echo is more efficient to include CAD disease, and a negative CFR is more efficient to exclude it.

3433 Could we apply regional strain and strain rate measurement during all forms of stress echocardiography?

G. Davidavicius[1], M. Kowalski[2], J. D'hooge[2], R. Ian Williams[3], G. Pierre-Justin[4], L. A. Pierard[4], M.C. Herregods[2], G. Sutherland[2]. [1]*Department of Cardiology, Leuven, Belgium;* [2]*University Hospital Gasthuisberg, Department of Cardiology, Leuven, Belgium;* [3]*University Hospital of Wales, Wales Heart Research Institute, Cardiff, United Kingdom;* [4]*University Hospital Sart Tilman, Department of Cardiology, Liege, Belgium*

Regional strain (S) and strain rate (SR) reflect differing aspects of myocardial function. S is related to stroke volume while SR correlates better with local dp/dt. Together, they offer a new approach to understanding and quantifying normal and abnormal responses during stress echo. However, SR/S are signal noise dependent and artifacts induced by respiration during excercise stress could preclude their use.
Study Aims: To compare the feasibility of regional peak systolic (p) Velocity and SR/S data collection/analysis during up-right bicycle (Group 1, n=10), supine bicycle Group 2, n=10) and dobutamine (DSE) (Group 3, n=10) stress echo.
Methods: pVel/pSR/pS data were acquired at each stress stage for 14 segments per patient/stage.
Results: The number of analysable segments (pSR/pS) per stage was significantly higher for DSE (p<0.0001)(Fig.1). A detailed comparison of data yield for each stress modality showed that for DSE: pVel/pSR/pS traces were interpretable in 94.6% segments. (The highest number of rejected segments were in the basal and apical segments). Signal noise meant that pSR/pS responses were not interpretable in 40% of Group 1 segments (12% basal-LW, 10% apical segment-AW). In Group 2, 40% segmental responses were also un-interpretable (apical segment AW 20%; apical IW 16%). In comparison, pVel could be measured in a higher number of segments: 74%-Group 1 (highest % exclusions - apical segments of Sep and AW (22%)) and 70% Group 2 (exclusions - apical segments IW 16% - apical AW 20%).



Percentage of analysable segments.

Conclusion: The application of SR/S imaging to the quantitation of stress echo may be currently be limited to DSE as signal noise precluded adequate data acquisition during excercise. For excercise this was also true for measurement of segmental pVel response.

3434 Quantifying radial deformation: the response in regional strain rate and strain during differing types of stress exercise

G. Davidavicius[1], M. Kowalski[2], J. D'hooge[2], R. Ian Williams[3], G. Pierre-Justin[4], L.A. Pierard[4], M.C. Herregods[2], G. Sutherland[2]. *[1]Department of Cardiology, Leuven, Belgium; [2]University Hospital Gasthuisberg, Department of Cardiology, Leuven, Belgium; [3]University Hospital of Wales, Wales Heart Research Institute, Cardiff, United Kingdom; [4]University Hospital Sart Tilman, Department of Cardiology, Liege, Belgium*

Background: It has been shown experimentally that strain rate (SR) and strain (S) parameters can quantify changes in regional radial systolic function over a wide range of heart rates and differing contractile states. For normal myocardium, SR correlates better with local dp/dt while changes in strain (S) are related to changes in stroke volume/EF. Thus peak systolic(p)SR/S measurement may offer a new approach to understanding and quantifying normal and abnormal responses during stress echo.
Study Aims: To investigate the ability of pSR/pS to quantify changes in regional myocardial function and to compare their normal responses to see if they differ during up-right bicycle (Group 1, n=10), supine bicycle exercise (Group 2, n=10) and dobutamine (DSE) (Group 3, n=10) stress.
Methods: Peak systolic (p) SR and S were acquired at each exercise stage: baseline (B), low HR=100-120 b/m (L) and peak HR=140-160 b/m (P), recovery (R). Data was acquired from parasternal long (pLax) and short axis (pSax) views from the posterior wall basal segment(BSPW).
Results: Data was obtained from 80 segments (n=10). Mean systolic values from BSPW are shown in the table (pLax; pSax).

	Group 1			Group 2			Group 3		
	Vel cm/s	SR 1/s	S %	Vel cm/s	SR 1/s	S %	Vel cm/s	SR 1/s	S %
pLax

(* p<0.005 vs baseline)

Conclusions: Independent of stress type (exercise vs pharmacologic), both pSR and pVel values increased linearly and reached a maximum at peak stress (HR=140±7). In contrast, segmental pS response was biphasic, with pS increasing during low HR stages (100±12 b/m). pS values then fell at HR>140. This biphasic S response (vs.linear SR)is due to fall in stroke volume at peak exercise.

3435 Index of postsystolic motion as a marker of the severity of stress induced myocardial ischaemia

M. Deljanin Ilic[2], S. Ilic[1], D. Petrovic[1], B. Ilic[1], D. Djordjevic[2]. *[1]Institute of Cardiology, Clinical Cardiology, Niska Banja, Yugoslavia; [2]Institute of Cardiology, Echo Lab, Niska Banja, Yugoslavia*

The aim of the study was a quantitative assessment of the impact of stress induced myocardial ischemia on systolic (S) myocardial velocities (m.v.) and index of post-systolic motion (PSM) changes during dobutamine echocardiography (DE) using pulsed wave Doppler myocardial imaging (PW-DMI).
Methods: We studied 42 patients (pts) with known or suspected coronary artery disease. In all pts DE (from 5 up to 40 mcg/kg/min, plus atropine up to 1 mg if needed) was performed. DE identified ischemia by the occurrence of wall motion abnormalities (WMA) with stress. A 11-segments left ventricular (LV) model was utilized. At baseline and after DE in each adequately visualized dyssynergic LV segment, we analyzed the presence of PSM and from apical approach, we measured peak myocardial velocity (m.v.) of systolic (S) and PSM wave using PW DMI. Index of PSM was assessed as followed: (peak S velocity at peak stress - peak velocity of PSM)/peak S velocity at peak stress.
Results: During DE 112 ischemic myocardial segments in 31 pts were detected, while in 11 pts WMA were not appeared. Out of 112 LV segments 61 (54.5%) were hypokinetic, 42 (37.5%) were akinetic and 9 (8.0%) were dyskinetic. After DE in ischemic LV segments S decreased from 8.6 ± 3.1 to 6.2 ± 3.7 cm/s, P<0.001. Value of index of post-systolic motion was significantly lower in hypokinetic than in akinetic segments (0.21 ± 0.06 vs 0.39 ± 0.11, P<0.001), in hypokinetic than in dyskinetic sements (0.21 ± 0.06 vs 0.67 ± 0.09, P<0.001) and in akinetic than dyskinetic segments (P<0.001). After DE, in segments without stress induced WMA S m.v. significantly increased (P<0.001).
Conclusion: Our data show that PSM develops actually in segments with stress provoked myocardial ischemia and that index of post-systolic motion can be used as a marker of the severity of myocardial ischemia.

3436 Quantitative dobutamine stress echocardiography based on a new automatic analysis algorithm for tissue Doppler data

J. Schröder, R. Hoffmann, A. Franke, H. Kühl, P. Hanrath. *University Aachen, Medical Clinic I, Aachen, Germany*

The main limitation of dobutamine stress echocardiography (DSE) is its subjective interpretation. Tissue Doppler imaging (TDI) has been used with promising results for quantitative analysis of DSE. However, it required extensive time consuming analysis.
We evaluated a new analysis algorithm which allows acquisition of TDI data in the background of the 2D image during DSE and subsequent instantaneous automatic analysis of TDI information.
Methods: In 30 consecutive patients undergoing coronary angiography DSE was performed with color TDI data being acquired in the background. An analysis algorithm was used which allows automatic comparison of obtained peak systolic tissue velocities with expected "normal" peak systolic tissue velocities and subsequent color coding of areas reaching the normal value. Quality of 2D image with simultaneous acquisition of TDI data was assessed on a three grade score (1: worst to 3: best) and compared with image quality of mere 2D image acquisition. Results of DSE based on quantitative TDI analysis were compared to DSE results based on visual 2D assessment.
Results: Image quality of 2D images with simultaneous acquisition of TDI data was almost similar compared to mere 2D image acquisition (2.68±0.37 vs 2.74±0.36, respectively, p=n.s.). There was agreement between DSE test results based on visual evaluation of 2D images and DSE test results based on color coded automatic analysis of quantitative TDI data in 87% of patients (kappa= 0.58). Accuracy of DSE for detection of coronary artery disease defined by coronary angiography with analysis of TDI in addition to 2D images was 83% vs. 78% for analysis of 2D images alone (p=n.s.).
Conclusion: Simultaneous acquisition of TDI and 2D data is highly feasible as it allows rapid acquisition of TDI data without a substantial loss in 2D image quality. Automatic analysis of TDI data allows rapid quantitative analysis of regional myocardial function at peak stress. It increases the security on the accurate interpretation of DSE test results.

3437 Pulsed Doppler myocardial imaging can help to distinguish symptomatic from asymptomatic myocardial ischaemia during stress echocardiography

S. Ilic, M. Deljanin Ilic, Lj. Nikolic, V. Stoickov, D. Marinkovic. *Institute of Cardiology, Clinical Cardiology, Niska Banja, Yugoslavia*

Objective: to compare regional systolic and diastolic myocardial velocities (m.v.) changes induced by symptomatic or asymptomatic myocardial ischemia (m.i.) during stress echocardiography using pulsed wave Doppler myocardial imaging (PW DMI).
Methods: In the study group of 95 pts with known or suspected CAD exercise stress echocardiography (ExE) was performed. ExE identified ischemia by the occurrence of wall motion abnormalities (WMA) with stress. Apical views were used to assess m.v. (Acuson-Sequoia, PW DMI) on baseline and at the peak stress. The sample volume was placed in each of 11 segments in which the left ventricle was divided, and we calculated peak m.v. of systolic (S), early (E) and late (A) diastolic waves and their ratio E/A.
Results: During ExE 182 ischemic myocardial segments in 65 pts were detected (118 segments in 36 pts with symptomatic and 64 segments in 29 pts with asymptomatic m.i.), while in 30 pts WMA were not appeared. After ExE value of wall motion score and number of ischemic segments per patient were significantly bigger in pts with symptomatic than in pts with asymptomatic m.i. (P<0.02 and P<0.01). In segments with ExE provoked symptomatic and asymptomatic WMA, DMI variables showed similar dynamics: E decreased by 25% and 18.1%, A increased by 7.7% and 6.1%, ratio E/A decreased by 28.3% and 23.5% and S decreased by 11.1% and 8.2% compared with baseline values. After ExE the rate of E and E/A ratio reduction in ischemic segments was significantly higher in pts with symptomatic than in pts with asymptomatic m.i. (P<0.005 and P<0.02).
Conclusion: Our data showed that both types of m.i. have similar effects on DMI variables, but changes are more pronounced in symptomatic m.i. Reduction of E wave and E/A ratio in ischemic segments are significantly higher in symptomatic than in asymptomatic m.i.

POSTER DISPLAY VI

MODERATED POSTER SESSION VI

P3438 A third family with aortic dissection/aneurysm and patent ductus arteriosus association. Is there a new syndrome?

P. Khau Van Kien[1], A. Lalande[2], C. Bonnet[3], A. Dellinger[4], M. David[5], F. Brunotte[6], X. Jeunemaitre[7], J.E. Wolf[3]. *[1]CHU le Bocage, Centre de Génétique, Dijon Cedex, France; [2]Université de Bourgogne, LPPCE, Dijon, France; [3]CHU le Bocage, Centre de Cardiologie, Dijon, France; [4]Centre hospitalier, Service de cardiologie, Chalon sur saône, France; [5]CHU le Bocage, Chirurgie Cardio-Vasculaire, Dijon, France; [6]CHU le Bocage, Centre d'IRM, Dijon, France; [7]Hôpital Européen Georges Pompidou, Génétique moléculaire, Paris, France*

We report a large family presenting an unusual association of familial thoracic aortic dissection/aneurysm (TAD/TAA) and patent ductus arteriosus (PDA).
Subjects and methods: this family composed of 179 members was ascertained from a single asymptomatic probant because of his familial history. Forty first-degree relative subjects from three different generations have been enrolled in a clinical investigation protocol composed of two parts:
– A medical questionnaire concerning available medical records, state of health and allowing to investigate the familial history. A standardized clinical examination focused on classical signs of Marfan and Ehlers-Danlos syndromes.
– An annual long-term follow-up based on: standardized cardiovascular examination, transthoracic echocardiography and a thoracic MRI, completed by transesophageal ultrasonography when necessary, allowing the accurate measurement of the aorta, great vessels and heart. At the time of the inclusion, blood measurements of total and LDL-HDL cholesterol, triglycerides and glucose were performed
Results: 9 cases of TAD and TAA among this family 4 TAD (2 males and 2 females) and 5 TAA (4 males and 1 female). The 5 cases of TAA were discovered by systematic screening in asymptomatic individuals. 8 cases of PDA (newborn until 27 years-old) without any particular neonatal context were noted in this family 2 of them were discovered by the study at age 3 and 5. Among the 5 cases of stroke, two of them had a documented intracranian carotid aneurysm. The distribution of TAA/TAD, PDA and vascular events within the family was compatible with an autosomal dominant with incomplete penetrance pattern of inheritance as it is in both families previously described in the literature. For each affected individuals, there was no argument for Marfan, Ehlers-Danlos or CHAR syndromes. There was no particular familial context of arterial hypertension or atherosclerosis.
Conclusion: According to the literature, familial aortic dissection/aneurysm with patent ductus arteriosus may be a new entity due to a common genetic defect that has to be discovered.

P3439 Evidence for increased circulating apoptotic endothelial cells in patients with coronary artery disease

L. Rössig, U. Kämper, S. Fichtlscherer, A. Stritzke, M. Vasa, B. Assmus, A.M. Zeiher, S. Dimmeler. *University of Frankfurt, Molecular Cardiology, Frankfurt am Main, Germany*

Endothelial dysfunction in coronary artery disease (CAD) correlates with enhanced oxidative stress and increased cytokine levels, which both induce apoptosis of endothelial cells in vitro. However, evidence for the occurrence of increased endothelial cell apoptosis in CAD was documented previously only in animal models or by post mortem analysis of vessel tissue. Therefore, we developed a method for the assessment of the level of apoptotic circulating mature endothelial cells in patients with CAD in vivo by 4-channel flow cytometry.
To distinguish mature from progenitor endothelial cells, we incubated venous blood samples following red cell lysis with a perCP-linked antibody against CD45. Among CD45-negative cells, we defined cells being double-positive for the endothelial cell-specific epitopes vWF (stained with a PE-linked anti-vWF antibody) and CD146 (FITC channel) as mature endothelial cells. Levels of circulating mature endothelial cells were profoundly increased in patients with CAD (mean±SEM=110±22/μl, n=43) compared with healthy control subjects (15±6/μl, n=15, $p<0.001$). Using the fourth fluorescence channel, we measured endothelial cell apoptosis by APC-labelled annexin V staining. Levels of apoptotic endothelial cells were ~50-fold increased in CAD patients (26±9% vs. 0.5±0.2%, control, $p<0.001$). The number of apoptotic circulating endothelial cells significantly increased with age ($r=0.33$, $p<0.02$). In a subset of patients, we determined the number of endothelial progenitor cells (EPC), which we defined as cells positive for both, the progenitor marker Ac133 and the endothelial cell marker KDR. In contrast to mature endothelial cells, endothelial progenitor cells (EPC) were decreased in CAD (3.3±1.3%, n=16 vs. 34±11% in control, n=6, $p<0.001$) and decreased with age ($r=-0.60$, $p<0.005$).
In conclusion, we established a novel flow cytometry-based method to analyze circulating endothelial cells from venous blood samples. The allover number of mature endothelial cells is increased in the circulation of patients with CAD, whereas these patients have markedly decreased levels of endothelial progenitor cells. By assessing annexin V binding of endothelial cells, these data also provide clinical evidence for the occurrence of endothelial cell apoptosis in patients with CAD.

P3440 100 consecutive cardiac myxomas: a surgical pathology experience

C. Basso[1], I. Rigato[1], D. Casarotto[2], M. Valente[1], G. Thiene[1]. *[1]University of Padua, Pathology, Padova, Italy; [2]Cardiac Surgery, Padova, Italy*

Background: The role of pathologist in the field of primary cardiac tumors has been evolving and it is primarily carried out in the in vivo diagnosis of surgically resected specimens to establish tumor histotype, to identify malignancy and to make differential diagnosis with other masses. Design and Results. In the period 1970-2000, 140 surgically resected primary cardiac tumors have been studied by histology and immunohistochemistry. Twelve (8.5%) turned out to be malignant and 128 (91.5%) benign. Among the malignant tumors, 3 were endocavitary and clinically misdiagnosed as myxoma. 100 (69%) of all benign cardiac tumors were eventually diagnosed as myxomas, coming from 99 pts, 34 male and 65 female, mean age 52±15 (range 6-85). Myxoma was located in the left atrium in 78 cases, right atrium in 19, right ventricle in 2 and left ventricle in 1. Myxoma was an incidental finding at echo in 26% of pts; in the remaining pts constitutional and obstructive symptoms were present in 81% and 40%, respectively; embolism occurred in 23%. The surface was smooth or gently lobulated in 65% and villous in 35%; superficial thrombus was present in 11% and haemorrhage in 18%. Eight myxomas (mean age 60±9 yrs, $p<0.01$ vs remaining pts) showed heavy partial or diffuse calcification at x-Ray ("lithomyxoma"). At histology, myxoma showed pseudovascular aspect in 70%, both pseudovascular and secretive aspects in 20% and isolated stellate cells embedded within a myxoid background in 10%. At immunohistochemistry, myxoma cells showed positivity for vimentin (100%), alfa smooth muscle actin (50%), neurofilaments and S100 (50%). Conclusions. Myxoma represents the most common primary cardiac tumor removed at surgery (70%) and mostly occurred in middle-ages women. One fourth are incidental discoveries at 2-D echo. Thorough histological examination is mandatory to differentiate myxomas from endocavitary malignancies.

P3441 Pregnancy outcome in women with valve prostheses. A comparative study

W.S. Avila Samuel, M.E. Carvalho, E.G. Rossi, A.M.M. Gouveia, C.M. Reis, M. Grinberg, J.A.F. Ramires. *Heart Institute, Clinic, São Paulo, Brazil*

There is still some controversy concerning the evolution of pregnancy in women with valve prostheses. Our aim was to study the clinical course of women with valve prostheses during pregnancy and identify possible prognosis factors.
Methods: We studied 125 pregnant women with valve prostheses: 91 with bioprostheses (BP)(mean age=26.5±5.7)and 34 with mechanical prostheses(MP)(mean age= 25.5±6.4.During gestation we assessed the prostheses-related clinical events as congestive heart failure; thrombo-embolism; infective endocarditis; reoperation and maternal death; and prostheses dysfunction as stenosis, rupture, calcification, thrombosis and/or vegetation. Routine pre-natal care included echodopplercardiogram and substitution of coumadin by heparin during the first trimester and after 36 weeks of gestation in MP group.
Results: Ninety-two (73.6%) patients had an uneventful course. The events are summarised in table. Four maternal deaths were due to prostheses dysfunction (calcification in BP and thrombosis in MP).There were 117 (92.8%) alive newborns, 30 of them premature babies, and two with fetal neurological malformation, both from mother who suffered reoperation. Among the events the incidence of heart failure($p=0.02$), prostheses dysfunction ($p=0.02$) and reoperation ($p=0.03$) were higher in BP group. The incidence of total events was higher in pregnancy which occurred after 60 months from prostheses implantation for BP (43.3% vs 16.4%) and MP (50.0% vs 10.0%) ($p<0.01$).

Incidence of events during study

Events n/%	HF	IE	Thromb	Dysfunction	Reoperation	Death
BP 91pts	17/18.9*	3/3.0	5/5.5	16/17.6*	12/13.2*	3/3.3
MP 34pts	0/0	1/2.9	4/11.7	1/2.9	2/5.9	1/2.9

*$p<0.05$. HF-heart failure;IE - infective endocardites; Thromb-thrombosis and embolism episode; dysfunction- prostheses valve dysfunction; reoperationduring gestation; death - maternal death.

In conclusion: Pregnancy in patients with valve prostheses, both mechanical or bioprostheses, was associated to substantial maternal and fetal risks. Prostheses dysfunction and reoperation were more frequent in bioprotheses group. Worse maternal prognosis, for both groups, was related to the time delay from prostheses implantation to gestation.

P3442 Fibrinolysis of mechanical prosthetic valve thrombosis. A single center study about 127 cases

R. Roudaut, C. Courtault, S. Lafitte, M.F. Roudaut, J.M. Perron, X. Pillois, C. Jaïs, P. Coste. *Hôpital Cardiologique, Pessac, France*

Fibrinolytic treatment of prosthetic heart valve thrombosis (PHVT) appears to be an attractive alternative, to surgery, but is still controversial because of the risk of embolism. Therefore, we analyzed the results of fibrinolysis in a large group of PHVT. **Methods:** 110 consecutive patients presenting with 127 instances of PHVT (79 mitral, 46 aortic, 1 tricuspid and 1 mitro-tricuspid) were treated with fibrinolytic treatment in the same center between 1978 and 2001. The diagnosis of PHVT was established by fluoroscopy and/or echocardiography. Obstructed valves consisted of 79 bileaflet valves and 48 tilting disc, and fibrinolytic agents of streptokinase (SK) 49 cases, urokinase (UK) 41 and rtPA 37 times. A second fibrinolytic treatment was consecutively infused in 38 patients and a third in 11. The efficacy of treatment was assessed by well established hemodynamic parameters derived from echo as well as by clinical evaluation. **Results:** Complete resolution of hemodynamic abnormalities was seen in 90 (71%) episodes, partial resolution in 22 (17.3%) and no change in 15 (11.8%) after one or several consecutive fibrinolytic regimen. The efficacy of SK and rtPA, as the initial fibrinolytic agent was superior to UK in terms of valve reopening $p = 0.06$. Sixteen patients died (11.8%), death was significantly higher in NYHA functional classes III and IV. An haemorragic complication was observed in 6 pts (4.7%), nineteen (15%) documented embolic events occurred during fibrinolytic treatment (8 stroke, 6 TIA, 5 peripheral arterial). Finally, PHVT reccured in 24 (18.9%) cases treated with fibrinolysis.
Conclusion: The results of this extensive single center experience indicates that fibrinolytic treatment is effective in most cases of PHVT regardless of prosthesis or site involved. SK and rtPA are superior to UK in terms of valve reopening. However, a substantial incidence of embolism, haemorrhage and death occurred with lytic therapy of PHVT, limiting its application to patients at high risk with alternative treatment.

P3443 Report of erectile dysfunction after therapy with beta-blockers is related to patient knowledge of side effects and is reversed by placebo

A. Silvestri, P. Galetta, E. Cerquetani, G. Marazzi, R. Patrizi, F. Frascà, M. Fini, G.M.C. Rosano. *San Raffaele, Internal Medicine, Roma, Italy*

Patients with cardiovascular diseases (CVD) frequently complain of erectile dysfunction especially when treated with beta-blockers. In order to assess whether the effect of beta-blockers on erectile dysfunction is, in part related to patient knowledge of the drug side effects 96 male patients with CVD entered a double-blinded parallel study. Thirty-two patients atenolol 50 mg (A) without knowledge of the drug they were administered, 32 received A knowing that the drug was a beta-blocker and 32 received A knowing that the drug they were taking was a beta-blocker and that it could have given erectile dysfunction. After 3 months patients were administered a quality of life questionnaire containing questions about erection. The incidence of erectile dysfunction was 3% in the group not knowing which drug they were taking, 16% in the group knowing that they were receiving a beta-blocker and 30% in the group also knowing the side effects of the drug ($p<0.01$). Sildenafil citrate and placebo were equally effective in reversing erectile dysfunction in all but one patient. In conclusion in male patients with CVD the report of erectile dysfunction after therapy with beta-blockers is largely related to patient knowledge of the drug side effects as it is almost always completely reversed by placebo.

P3444 Identification of 17 new mutations associated with catecholaminergic polymorphic ventricular tachycardia (CPVT) and their phenotypic variation

A. Postma[1], I. Denjoy[2], M. Alders[1], J. Kamblock[3], V. Lucet[4], C. Bezzina[1], A. Wilde[1], P. Guicheney[5]. [1]*AMC, Exp. and Molecular Cardiology, Amsterdam, Netherlands;* [2]*Hôpital Lariboisière, Service de Cardiologie, Paris, France;* [3]*Centre de Cardiologie de Taaone, Service de Cardiologie, Tahiti, French Polynesia;* [4]*Centre de Cardiologie Infantile, Les Loges en Josas, France;* [5]*INSERM U523, Institut de Myologie, Paris, France*

Background: Catecholaminergic polymorphic ventricular tachycardia (CPVT) is a rare arrhythmogenic disorder. It is characterized by normal QT intervals and adrenergic induced ventricular tachyarrhythmias, which lead to syncope and sudden death in young patients with structurally normal hearts. So far, autosomal dominant missense mutations in RYR2, the gene encoding the cardiac ryanodine receptor type 2, and an autosomal recessive missense mutation in the cardiac calsequestrin gene (CASQ2), have been reported to be responsible for this disease. **Methods:** We collected 35 CPVT probands and their family members from France and Netherlands. The phenotypes were ascertained by ECG and stress test. Probands were screened by exonic PCR amplification and uni-directional sequencing. After positive identification of an aberrant sequence, at least 200 control alleles were screened using SSCP or RFLP. **Results:** We have identified 13 new missense mutations in the RYR2 gene of CPVT probands. All these mutations occur at evolutionary conserved positions across the RyR proteins of multiple species. The mutations appear to be grouped into three distinct regions, suggesting a functional importance of these regions for all RYR genes. In addition, sequencing of the cardiac calsequestrin gene (CASQ2) revealed four new mutations: two nonsense of which one is homozygous, one splice site and one missense mutation. Two CASQ2 mutations have an autosomal dominant and two have a recessive mode of inheritance. The 13 RYR2 mutations show a high degree of penetrance, apart from two families, which have incomplete related penetrance. In contrast the CASQ2 mutations including the nonsense mutations show reduced penetrance.
Conclusion: We found 17 new mutations in the RYR2 and CASQ2 genes in 35 CPVT families. This indicates the feasibility of pre-symptomatic detection of CPVT. Furthermore, we report the first homozygous nonsense mutation of CASQ2 as well as autosomal dominant mutations. In addition we can now compare the inter- and intra phenotypic variations of CPVT between the various RYR2 and CASQ2 mutations.

P3445 Typical slow-fast nodal re-entry tachycardia in paediatric age: utility and risk of radiofrequency catheter ablation

B. Sarubbi, Michele D'Alto, Barbara Mercurio, Raimondo Calvanese, Maria Teresa Palladino, Maria Giovanna Russo, Raffaele Calabrò. *Monaldi Hospital, Pediatric Cardiology, Naples, Italy*

Background: Typical slow-fast nodal re-entry tachycardia (NRT) is a common rhythm disorder in children and in young adults. Radiofrequency catheter ablation (RFCA) procedure has a potential increasing risk due to the small dimension of AV node, the little distance of fast and slow pathways and the growth of cardiac structures.
Methods: In the last 12 month, 14 patients (6M/7F aged 11±2.4 years) underwent electrophysiological study (EPS) + RFCA for NRT All procedures were performed in general anaesthesia. Vascular accesses used in all patients were: right femoral and right subclavian veins.
Results: Time of procedure, including anaesthesia induction, was 70±15 min. Time of radiation exposure was 15±5min. In all patients we targeted the slow pathway with a combined anatomical and electrophysiological approach. RF delivery sites were: point 9-10 in 9 pts and point 7-8 in 4 pts. Accelerated junctional rhythm was observed in 8/13 pts. Basal AH (67 ± 18 msec) and HV (39 ± 2.8) intervals and Wenckebach point (<319 ± 51) were unmodified after procedures. Follow up: All patients performed a non-invasive evaluation 30 days after RFCA. Echocardiography and Holter-ECG were normal; no arrhythmia was induced during stress test. Three months after RFCA we performed a control EPS. In one pts there was a recurrence of NRT, so a new RF delivery was required. In 5/14 pz no tachycardia could be induced, although a ono-to-one anterograde slow pathway has been documented.
Conclusion: RFCA is a highly-effective tool for NRT even in paediatric age.

P3446 Effect of glycoprotein IIb/IIIa receptor inhibition on troponin release in elective percutaneous coronary intervention after pretreatment with aspirin and clopidogrel

B. Lengenfelder, J. Strotmann, S. Held, G. Ertl, W. Voelker, A. Bonz. *Universitätsklinik, Cardiology, Würzburg, Germany*

Objective and background: The present study was designed to investigate 1) the amount of troponin T release after non-acute, elective PCI in patients pretreated with aspirin and clopidogrel and 2) the effect of additional glycoprotein (GP) IIb/IIIa receptor inhibiton on troponin T release in detail.
Methods: The TOPSTAR - trial is a double blind, randomized, placebo-controlled prospective trial on 109 patients with stable angina pectoris undergoing elective PCI. All patients were pretreated with aspirin and clopidogrel. After bolus application PCI was performed followed by an 18 hour continuous infusion of the study medication. Primary endpoint of the study was incidence and amount of release ischemic paramters (troponin T (TnT) and creatinkinase (CK, CK/MB)) after elective PCI.
Results: Platelet function was inhibited by 90% throughout administration of tirofiban. Within the first 12 hours after PCI Troponin release was detected in 63% of the patients receiving placebo (P) and in 40% of the patients receiving Tirofiban (T) ($p<0.05$), within 24 hours in 69% (P) and 48% (T) ($p<0.05$) and after 48 h in 74% (P) vs. 58% (T) ($p<0.08$) of the patients. No differences were observed regarding major bleeding, intracranial bleeding or non-hemorrhagical strokes. After 9 months a reduction of combined death/myocardial infraction/target vessel revascularisation could be observed in the tirofiban group ((T) 2.3% vs. (P) 13.04%, $p<0.05$).
Conclusion: TnT release occurs after successful intervention in 74% of the patients after 48 hours undergoing elective PCI even after pretreatment with aspirin and clopidogrel. The glycoprotein IIb/IIIa receptor antagonist Tirofiban is able to decrease the incidence of troponin release after PCI significantly in this patient population probably due to improved myocardial macro- and microcirculatory perfusion and might influence long term outcome.

ATRIAL FIBRILLATION TREATMENT

P3447 Catheter ablation of drug induced atrial flutter: impact on atrial fibrillation recurrences and quality of life

H. Bielik, J. Schrickel, N. Shlevkov, A. Yang, J.O. Schwab, R. Schimpf, B. Lüderitz, T. Lewalter. *University of Bonn, Department of Medicine-Cardiology, Bonn, Germany*

Background: Radiofrequency (RF) catheter ablation of isthmus-dependent, antiarrhythmic drug (AAD)-induced atrial flutter (AFL, "hybrid-therapy") is clinically relevant in the treatment of atrial fibrillation (AF). The aim of this study was to analyse the long-term preventive efficacy of this "hybrid-therapy" and its effect on AF-symptoms and quality of life (QoL).
Methods: Thirty-two patients (pts; age: 65.0±7.2 years; 9 women; left ventricular ejection fraction: 62.8±15.2%; structural heart disease (14), idiopathic AF (18)) were monitored after isthmus-ablation of AAD-induced AFL and continuation of this AAD treatment for AF-recurrences over a mean follow-up of 21.6±9.7 months. AF characteristics and symptoms as well as QoL before and after ablation were retrospectively evaluated by the "SF-36"-questionnaire, "symptom checklist" and "AF severity scale".
Results: 7 of 32 pts (21.8%) remained free of AF recurrences after hybrid therapy. From 25 of 32 pts (78.2%), who demonstrated AF-recurrences during follow-up, 19 (76%) demonstrated a decrease in frequency of symptomatic AF-episodes, from 5.8±5.9 before to 0.4±0.8 episodes/week after ablation ($p<0.05$). A significant decrease in AF episodes duration was documented in 17/25 pts (68%), from 7.0±1.8 to 3.3±1.7 on an episode duration scale from 0 to 9. The symptom checklist demonstrated a significantly attenuated AF-symptomatology in 17/25 pts (68%) following ablation (44.2±27.5 versus 20.3±13.0 scores, p=0.006). Furthermore, in the study population 7 out of 8 categories of the SF-36 questionnaire were significantly improved; only the bodily pain score did not reach significant improvement.
Conclusions: The pharmacological and ablative hybrid therapy was a "curative" treatment in 21.8% of entered study population, however 78.2% of patients demonstrated AF-reoccurrences during long-term follow-up. Hybrid-therapy significantly reduced the mean number and duration of symptomatic AF-episodes as well as AF-correlated symptoms in patients with AF-recurrences. 4. This approach resulted in an significant QoL-improvement. Even when this variant of hybrid therapy for AF treatment is semicurative, it offers a clinically valuable tool in selected patients.

P3448 Fluctuations of autonomic tone before onset of paroxysmal atrial fibrillation

M. Zimmermann[1], M. Bettoni[2]. [1]*Hôpital de La Tour, Cardiovascular Department, MEYRIN, Switzerland;* [2]*Hôpital de La Tour, Cardiovascular Department, MEYRIN, Switzerland*

Background: Mechanisms favouring the occurrence of paroxysmal atrial fibrillation (PAF) are complex and poorly defined. This study was designed to analyse dynamic changes in autonomic tone preceding the onset of PAF in a large group of unselected patients.
Methods and Results: Holter tapes from 77 consecutive patients (63 male, 14 female, mean age 58 ± 12 yrs) with PAF were analysed. A total of 147 episodes of sustained PAF (>30 min) were recorded and submitted to time-domain and frequency-domain heart rate variability (HRV) analysis. Six periods were studied using repeated measures ANOVA: the 24-hour period, the hour preceding PAF, and the 20 minutes prior to PAF divided into four 5-minutes periods. In the time-domain, a linear decrease in mean RR interval from 925 ± 16 to 906 ± 16 ms ($p<0.0002$) was observed before onset of PAF together with a significant increase in SDNN from 65 ± 4 to 70 ± 4 ms ($p<0.02$). In the frequency-domain, a significant increase in high-frequency (HF, HF-NU) components was observed before PAF ($p<0.001$ and <0.0001 respectively), together with a progressive decrease in low frequency components (LF, LF-NU) components ($p<0.0001$ and < 0.004 respectively). The LF/HF ratio showed a linear increase until 10 minutes prior to PAF followed by a sharp decrease immediately before PAF, suggesting a primary increase in adrenergic tone followed by a marked modulation towards vagal predominance. No difference was observed in these HRV changes between patients with "lone" PAF and patients with structural heart disease, nor between diurnal and nocturnal episodes of PAF.
Conclusion: The occurrence of PAF greatly depends on variations of the autonomic tone with a primary increase in adrenergic tone followed by a abrupt shift towards vagal predominance and this pattern is observed both in patients with "lone" atrial fibrillation and in patients with structural heart disease.

P3449 Seasonal variability and impact of non-cardiac factors on clinical presentation and management of AF in the emergency department (GEFAUR-2)

A. Martín, C. Del Arco, P. Laguna, P. Gargantilla on behalf of the GEFAUR-2 investigators. *Spanish Society for Emergency Medicine, Scientific Committee, Madrid, Spain*

PURPOSES: To determine and analise the influence of seasonal variability and the impact of non-cardiac factors (mainly respiratory tract infections, obstructive pulmonary diseases and its treatment) on the clinical features, management strategies and outcome of patients(pts) with atrial fibrillation(AF) in the Emergency Department(ED).METHODS: Prospective multicenter observational case-control study performed in the ED of 12 Hospitals in Madrid, Spain in Feb-2001. All patients with AF diagnosed in an ECG obtained in the medical area of the ED were included. Clinicoepidemiological data, management,outcome and patient's destination were recorded.Control group: GEFAUR-1 (prospective multicenter study performed in the same EDs,Jul-2000 with the same methodology,1178 pts).RESULTS: 301 pts were included, mean age 75y. There were a higher prevalence of males (48 vs.40%, p=0.01, OR=1.35) and ischemic heart disease (45 vs.30%, $p<0.001$, OR=1.9) in winter although overal structural cardiopathy (54 vs.47%, p=0.04,OR=1.3), hypertensive cardiopathy (16vs.9%,p=0.02,OR=1.95) and pts unabled(47% of the disabled vs. 30%, p=0.002,OR=2.68) were more frequent in summer.Dyspnea (34vs.28%,p=0.03,OR=1.33), chest pain (22 vs.13%,$p<0.001$, OR=1.85)dizziness (15 vs.10%,p=0.02,OR=1.53) and casual finding (5 vs.2%,p=0.002, OR=2.4) were more frequently the main presenting symptom in winter. There were a higer number of AF > 48h duration in summer (50vs.40%) and of unknown duration in winter (40vs.29%,p=0.01,OR=2.13). Stroke prevention was more frequently performed in winter (44 vs.37%, p=0.03, OR=1.31) due to anticoagulation (32 vs.23%, p=0.002, OR=1.56). Admission was more frequent in winter (54 vs.46%, p=0.002, OR=1.48), due to cardiac and thromboembolic complications ($p<0.001$). No differences were found on age, on previous AF, stroke, diabetes, thyrotoxicosis, hypertension, other heart diseases or current treatment for AF,on diagnosis of heart failure, hemodynamic compromise or secondary (non cardiac) AF(4%, mainly related with fever), on rate control/cardioversion strategies,in the relieving of the symptomatology,or ED length of stay.CONCLUSIONS:Fever is the main non-cardiac factor related with AF in the ED.Non-cardiac factors have no influence on clinical presentation and management of AF.Seasonal variability influences clinical presentation (ischemic heart disease and its related symptomatology), AF duration, Stroke prevention and admission rate (all of them more prevalent in winter). However, its impact on the overal management of AF in the ED is lesser than currently assumed.

P3450 Propafenone-sotalol: which is preferred in atrial fibrillation, for the maintenance of normal sinus rhythm

N.E. Igoumenidis[1], G.E. Kochiadakis[1], M.I. Hamilos[1], P.G. Tzerakis[1], N.C. Klapsinos[1], K.E. Vardakis[1], E.A. Zacharis[1], P.E. Vardas[2]. [1]*Heraklion University Hospital, Cardiology Dept., Heraklion, Crete, Greece;* [2]*Heraklion University Hospital, Cardiology, Heraklion, Greece*

The aim of this prospective, randomized, single blind, trial was to compare the long-term efficacy and safety of propafenone and sotalol, in maintaining normal sinus rhythm in patients with recurrent, symptomatic atrial fibrillation.
Methods: We studied 143 consecutive patients (70 men, mean age 62.9 ± 9.3 years) with recurrent, symptomatic atrial fibrillation. After restoration of normal sinus rhythm, 73 were given propafenone (450 mg/day) and 70 received sotalol (320 mg/day). End point of the study was recurrence of atrial fibrillation or occurrence of side effects necessitating discontinuation of medication. Follow up clinical evaluations were conducted at the 1st, 2nd, 4th and 6th month and at 3-month intervals thereafter. The proportion of patients remaining in sinus rhythm without side effects was calculated for the two groups using the Kaplan-Meier method.
Results: The two groups were comparable in terms of sex, age, left atrial size, left ventricular ejection fraction, pattern of AF, percentage of patients with underlying heart disease and time from initial diagnosis of AF.
The average follow up time for the non end-point patients was 26 ± 11 months for the propafenone group and 19 ± 10 months for the sotalol group.
Thirty-seven of the 73 patients (50.68%) receiving propafenone relapsed to atrial fibrillation after an average of 7 ± 6 months, compared to 47 of the 70 patients (67.14%) given sotalol, after an average of 7 ± 5 months (x^2: 4.82, $p< 0.028$). Five patients on sotalol (all of them in normal sinus rhythm) and 5 patients on propafenone (3 of them in normal sinus rhythm) experienced side effects necessitating withdrawal of medication. (x^2: 6.26, p: 0.0123 for atrial fibrillation-side effects free patients). Sex, age, atrial fibrillation pattern and left atrial diameter did not influence progression to atrial fibrillation-side effects in either group.
Conclusions: Propafenone is more effective than sotalol in the long-term prevention of side effects-free recurrent symptomatic atrial fibrillation.

P3451 Long-term results of hybrid therapy for the management of recurrent atrial fibrillation

M. Rivero Ayerza, M. De Zutter, P. Geelen, F. Provenier, P. Brugada. *OLV Hospital, Cardiovascular Center Aalst, Aalst, Belgium*

Objective: With the purpose of maintaining sinus rhythm in patients (pts) with recurrent atrial fibrillation, sometimes antiarrhythmic drugs (AAD) convert atrial fibrillation (AF) into atrial flutter (AFL). Combination of AAD and radiofrequency ablation (RFA) of the right atrial isthmus, has become a treatment option for these patients. Effectiveness of this treatment and determinants of AF recurrence during long term follow up are yet to be established.
Methods and Results: We analysed clinical and electrophysiological data of 100 consecutive pts with history of recurrent AF, who underwent isthmus RFA of AAD induced AFL. Mean age was 63±1.1 years and 78% of pts were male. Unsuccessful RFA (18%) was significantly higher (RR=2.17) in pts with atypical AFL. Mean follow up was 514±41 days. AFL recurred in 19% of the pts and AF as a sole arrhythmia in 23%. Sixty percent of pts were free of AF and AFL during follow up. Six percent of patients required implantation of a permanent pacemaker. Age, gender, type of AFL, presence of structural heart disease (43%), left ventricular ejection fraction (51±2%) and left atrial dimensions were not predictive of AF recurrence.
Conclusion: 1) Hybrid pharmacological and ablative therapy is effective in maintaining sinus rhythm during long term follow up in pts with recurrent AF and AAD induced AFL. 2) No clinical or electrophysiological variable predicts long term AF recurrence.

P3452 Dual defibrillator improves quality of life and decreases resource utilization in patients with drug refractory atrial fibrillation

R. Ricci[1], A. Quesada[2], C. Pignalberi[1], M. Disertori[3], A. Capucci[4], A. Raviele[5], N. Grovale[6], M. Santini[1]. *[1]San Filippo Neri Hospital, Cardiology Department, Rome, Italy; [2]General Hospital, Cardiology Department, Valencia, Spain; [3]S.Chiara Hospital, Cardiology Department, Trento, Italy; [4]Civile Hospital, Cardiology Department, Piacenza, Italy; [5]Civile Hospital, Cardiology Department, Mestre, Italy; [6]Medtronic Italia, Clinical, Rome, Italy*

Aim of the study was to evaluate the impact of the dual defibrillator on quality of life and resource utilization in patients with drug refractory atrial fibrillation (AF) with no prior ventricular arrhythmias.
Methods: 40 patients (28 M, mean age 64±10) received a dual defibrillator Medtronic 7250. AF was persistent in 24 (60%) and paroxysmal in 16 (40%). 13 (32.5%) had sinus bradycardia. 26 were in NYHA class I, 11 in class II, 3 in class III.
Results: The follow-up lasted 12±6 months (range 3-28). 34 patients (85%) had AF recurrences. 1652 atrial episodes were detected and treated by the device. Anti-tachy-pacing success rate was 77% on atrial tachycardia (AT) and 32% on AF. Atrial shock was 84% successful on AT and 90% on AF. No patient had sustained ventricular arrhythmias. Comparing the year after implant with the year before, external cardioversions decreased from 2.1±2.3 to 0.1±0.3 and hospitalizations due to AF from 1.5±2.1 to 0.4±0.8 (p<0.01, both. In Table 1 Symptom Checklist Questionnaire results at pre-implant and after 12 months are reported, while Table 2 shows the SF36 Quality of Life questionnaire results.

Table 1. Symptom Checklist Questionnaire results

Item	Number	Frequency	Severity
Pre-Implant	8.6±3.0	16.9±11.0	15.8±10.5
12 months	6.3±3.1	13.0±10.3	10.6±6.1
p	<0.05	<0.05	<0.05

Table 2. SF36 QoL scores

Item	A	B	C	D	E	F	G	H
Pre-implant	64	30	75	59	45	79	69	67
12 months	84	77	83	58	55	79	73	64
p	<0.05	<0.01	ns	ns	ns	ns	ns	ns

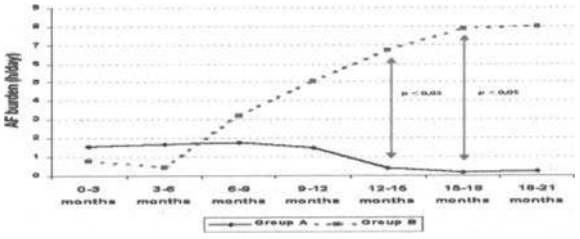
A = Physical functioning; B = Role physical; C = Bodily pain D = General health; E = Vitality; F = Social functioning; G = Role emotional; H = Mental health.

Conclusions: Dual defibrillator was effective in treating drug refractory AF and had a favourable impact on patient quality of life and resource utilization.

P3453 Early atrial shock delivering reduces atrial fibrillation burden and hospitalizations in patients wearing a dual defibrillator

R. Ricci[1], A. Quesada[2], J. Roda[2], M. Disertori[3], A. Capucci[4], A. Raviele[5], N. Grovale[6], M. Santini[1]. *[1]San Filippo Neri Hospital, Cardiology Department, Rome, Italy; [2]General Hospital, Cardiology Department, Valencia, Spain; [3]S.Chiara Hospital, Cardiology Department, Trento, Italy; [4]Civile Hospital, Cardiology Department, Piacenza, Italy; [5]Civile Hospital, Cardiology Department, Mestre, Italy; [6]Medtronic Italia, Clinical, Rome, Italy*

Aim of the study was to evaluate the impact of early atrial shock delivering on atrial fibrillation (AF) burden and hospitalizations in patients without ventricular tachyarrhythmias.
Methods: 40 patients (28 M, mean age 64±10) with drug refractory AF received a dual defibrillator Medtronic 7250. 24 (60%) had persistent AF and 16 (40%) paroxysmal AF. During the year before implant, they had on average 2.1±2.2 external cardioversions and 1.5±2.0 hospitalizations due to AF. One month after implant they were divided in two groups (20 patients each): group A, who accepted atrial shocks, were assigned to early delivering of atrial shock after AF onset, either automatically, by using patient activator, or in hospital, manually delivered within 12 hours; group B, who did not accept shocks, had antitachypacing therapies activated but atrial shock switched off. The groups did not differ in pre-implant characteristics.
Results: The follow-up lasted 12±6 months (range 3-28). 34 patients (85%) had AF recurrences. AF burden (hours/day) during the follow-up (months) is showed in the picture below. Hospitalizations due to AF decreased from 1.8±2.6 to 0.3±0.4 (p<0.05) in the group A and from 1.2±1.3 to 0.6±1.2 (p=n.s.) in the group B.



Burden trend.

Conclusion: In patients wearing a dual defibrillator early delivering of atrial shock reduced AF burden and AF related hospitalizations. Prevention of atrial remodeling may explain our results.

P3454 Proportion of symptomatic and asymptomatic episodes of atrial fibrillation after catheter ablation

A. Erdogan[1], J. Carlsson[2], T. Neumann[2], J. Sperzel[2], M. Schlapp[3], B. Schulte[2], J. Neuzner[2], H.F. Pitschner[2]. *[1]Justus-Liebig-University of Giessen, Cardiology, Giessen, Germany; [2]Kerckhoff Klinik, Cardiology, Bad Nauheim, Germany; [3]AD Elektronik, Wetzlar, Germany*

Background: The detection of asymptomatic episodes of atrial fibrillation (AF) is essential for assessment of success rate. The proportion of asymptomatic patients with further persistent AF after catheter ablation is still unknown.
Patients/Methods: Highly symptomatic patients (n=30, age 55± 5.8 years) with refractory paroxysmal AF lasting 5.6 ± 5.2 years and 32± 15 attacks within 3 months before ablation were included. Patients with cardiovascular diseases except arterial hypertension were excluded. Catheter ablation of AF was performed by creating linear lesions or isolation of pulmonary veins. After catheter ablation of AF the patients were investigated with a new event-recorder system (CardioRec, AD-Elektronik, Wetzlar, Germany) featuring both automatically triggered and patient activated recording.
Results: The event-recording was performed for 3.9 ± 1.5 weeks after catheter ablation (mean follow-up time 15.9 ± 2.5 months). 17/30 patients had further symptomatic attacks of paroxysmal AF while 10 patients had clinically no further attacks of paroxysmal AF and 5 (18%) asymptomatic patients with recurrent AF could be detected by automatically triggering mode of the event-recorder.
Conclusion: After catheter ablation of AF asymptomatic attacks of AF may still exist. For assessment of success after catheter ablation of AF the detection of asymptomatic episodes is essential. The use of an automatic event-recorder system for verification of the success rate is recommended.

P3455 Which patients are more likely to be cardioverted in the emergency department when atrial fibrillation arises? The GEFAUR-1 study group

C. Del Arco, A. Martín, P. Laguna, P. Gargantilla on behalf of The GEFAUR-1 investigators. *Spanish Society for Emergency Medicine, Scientific Committee, Madrid, Spain*

Purposes: To analyse cardioversion eligibility criteria of patients with atrial fibrillation(AF) in the Emergency Department(ED),to determine the therapeutic regimens for AF in the ED. To study the risk factors, clinicoepidemiological data and other selection criteria related with each sinus rhythm restoration (SRR) strategy.
Methods: Prospective multicenter observational study performed from Jun, 15 to Aug, 1 2000 in the ED of 12 referral hospitals in Madrid, Spain. All medical patients with AF achieved in an ECG obtained in the ED were included. Epidemiological and clinical data, risk factors for AF, previous and ED treatments, symptomatology, outcome and destination from the ED were recorded. No management recommendations were made. A multivariate analysis was performed to identify the variables related with SRR in the ED.
Results: 1178 episodes of AF were recorded.There were 246(21%) eligible patients for cardioversion (those with AF duration <48 hours).In this cardioversion-eligible group, SRR was attempted in 119 (42%) patients. In the resting 143(58%) cardioversion eligible patients, SRR was not attempted due to the following causes: Spontaneous cardioversion (36%), Physician's rejection (13%) and disability (3.5%) Only one patient rejects the procedure. Cardioversion-attempted patients were significantly younger (51% of patients >75y. vs. 80%) and had a higher heart rate(12% of patients<100 bpm vs. 36%, p<0.01). There were no significant differences between the two groups when previous antiarrhythmic therapy, structural cardiopathy or current heart failure were analysed. SRR related variables: hemodynamic compromise (OR= 6.3, CI 95%: 1.13 - 35.5), sex (male: OR= 1.98 CI 95%: 1.034 - 3.79), advanced age (OR=0.95, CI 0.93-0.98) and a higher heart rate (OR=1.02). SRR strategies were pharmacological in 88% of cases(success rate of 79%) and electrical(direct-current) in 5%(response rate 85%, no complications recorded).Most used drugs were amiodarone(43% of cases),flecainide(26%) and propafenone(18%).
Conclusions: 1) SRR is not attempted in the ED in most of eligible patients, despite the high success rate observed. 2) DC cardioversion in the ED remains anecdotical, although its efficacy and safety is clearly superior. 3) Most used antiarrhythmics are amiodarone and Ic-class drugs. 4) Hemodynamic instability is the main determinant of cardioversion in the ED. 5) A young man with paroxysmal AF has more likelihood to be cardioverted in the ED than a woman or an old man in the same situation. Factors as hypertension or stroke have no influence on the decision of SRR.

P3456 Verapamil in prevention of early recurrences of atrial fibrillation. Final results of the VERAF study

G.L. Botto[1], G. Belotti[2], A. Cirò[3], V. Ziacchi[4], M. Romanò[5], M. Marzegalli[6], A. Sagone[1], A. Politi[1] on behalf of the VERAF Study Group. [1]*Sant' Anna Hospital, Cardiology Dept, Como, Italy;* [2]*Treviglio Hospital, Cardiology Dept., Treviglio, Italy;* [3]*San Gerardo Hospital, Cardiology Dept., Monza, Italy;* [4]*Desenzano Hospital, Cardiology Dept., Desenzano, Italy;* [5]*Santa Corona Hospital, Cardiology, Garbagnate M.se, Italy;* [6]*Maggiore Hospital, Cardiology Dept., Milan, Italy*

Background: Atrial electrical remodeling caused by rate-induced intracellular calcium overload is one of the causes that produce early recurrences of atrial fibrillation (AF)after resumption of sinus rhythmn (SR). Calcium antagonists could theoretically limit atrial remodeling thus leading to a better outcome after cardioversion.
Aim of this prospective, multicenter, randomized study was to evaluate the effect of verapamil (VER) on efficacy of electrical cardioversion (EC) of persistent AF and on incidence of arrhythmia relapse.
Methods: Two hundred-fourteen patients (pts) (mean age 68±9 years) with persistent AF (mean arrhythmia duration 154±105 days), NYHA functional class I-II, left ventricular ejection fraction > 0.40 (mean value 0.55±0.07), were randomized to receive standard therapy (STD) (N=108) or STD + VER 80 mg t.i.d. (N=106), associated to anticoagulation, 3 weeks before and 4 weeks after EC (4 pts were excluded from the study). No additional antiarrhythmic drugs were given. In 6 (6%) pts in VER group, and in 47 (44%) pts in STD, additional digoxin (DIG) was given to control ventricular rate (p<0.0001). We considered end-point of the study the reversion to SR before EC, the inability to stop AF (EC Failure), early relapse of AF within 7 day after EC (ERAF), late relapse between 8-30 days after EC (LRAF), and the persistence of SR 1 month after EC (SR).

	Reversion SR	EC failure	ERAF	LRAF	SR
VER	20/103 (19%)	11/83 (13%)	19/72 (26%)	7/72 (10%)	46/72 (64%)
STD	10/107 (9%)	13/97 (13%)	51/84 (61%)	9/84 (11%)	24/84 (29%)
p value	0.059	NS	<0.0001	NS	<0.001

Results: The two groups were comparable in terms of the mean clinical variables considered. The result are reported in the table.
Immediate recurrence (within 1 hour) were lower in VER group compared to STD group (3/72 pts, 4% vs 18/84 pts, 21%; p=0.004). There was no difference between pts who were taken or not DIG in STD group. VER regimen was 40 t.i.d. in 14/106 pts (13%) pts because of dyspnea (5 pts), bradycardia (4 pts), fatigue (5 pts).
Conclusion: Stand alone VER around EC is effective in reducing early recurrence of AF. The effect is maximum for immediate recurrence reduction. Concomitant use of DIG in pts not treated with VER does not interfere with EC outcome.

P3457 The effect of exercise to P-wave dispersion and its evaluation as a predictor of atrial fibrillation

Z. Yigit, M. Ersanli, H. Akdur, B. Okcun, D. Guzelsoy, O. Guven. *Institue of cardiology, Istanbul, Turkey*

Prolongation of p wave time and increase of its dispersion is an independent predictor of paroxysmal atrial fibrillation. In patients (pts) with paroxysmal atrial fibrillation (PAF), as in healthy people, exercise augment sympathetic activity and therefore cause the development of atrial fibrillation. The aim of this study was to evaluate the effect of exercise to p wave dispersion and to predict the development of atrial fibrillation.
Methods: 198 pts (93 women, 105 men; 59±11 years) having the diagnosis of PAF were included in the study. The left atrial diameter of all these pts was more than 4 cm. 155 pts (72 women, 83 men, 58.8±10.8 years), with left atrial diameter more than 4 cm and without PAF were taken as control group. Symptom limited exercise test with modified Bruce protocol was applied to all pts. Rest, maximum exercise and end exercise 1, 3 and 5 minutes 12 derivations ECG was taken in all pts.The velocity of ECG was adjusted to 50 mm/sec; shortest and largest p wave durations were measured and p wave dispersion was calculated.
Results: 6 of 198 PAF pts with AF with exercise were excluded from the study. The mean left atrial diameter was 4.41±0.58 cm in PAF pts and 4.38±0.48 in control group. No differences were found between PAF pts and the controls in exercise time (10.4 ± 3 vs 11 ± 2.7 min); METs (7 ± 1.7 vs 7.3 ± 1.7); resting HR (79 ± 15 vs 80 ± 10 bpm); peak HR (147 ± 23 vs 147 ± 16 bpm); recovery 1 HR (126 ± 19 vs 128 ± 13 bpm); recovery 3 HR (109 ± 16 vs 108 ± 10 bpm); recovery 5 HR (88 ± 12 vs 86 ± 9 bpm). The differences in p wave dispersions with exercise were shown in table.

Differences in p wave dispersion

	PAF pts (n=198)	Controls (n=155)	p value
Resting p dispersion (msec)	75 ± 30	52 ± 20	0.001
Peak p dispersion (msec)	69 ± 12	53 ± 23	0.001
Recovery 1 p dispersion (msec)	69 ± 16	45 ± 20	0.001
Recovery 3 p dispertion (msec)	76 ± 26	54 ± 20	0.001
Recovery 5 p dispertion (msec)	70 ± 26	55 ± 25	0.001

Conclusion: In PAF pts p wave dispersion is significantly longer in rest, maximum exercise and recovery time.

P3458 Atrial fibrillation occurrence after radiofrequency catheter ablation of atrial flutter. Results from the Venetian multicentric study

E. bertaglia[1], A. Bonso[2], G. Pastore[3], L. Corò[4], A. Proclemer[5], R. Mantovan[6], M. Carone[7], P. Pascotto[1]. *[1]Ospedale Civile, Cardiologia Dipt., Mirano, Italy; [2]Ospedale Umberto I, Cardiologia, Mestre, Italy; [3]Ospdale Civile, Cardiologia, Camposampiero, Italy; [4]Ospedale Civile, Cardiologia Dipt., Conegliano, Italy; [5]Ospedale Civile, Cardiologia, Udine, Italy; [6]Ospedale Ca'Foncello, Cardiologia, Treviso, Italy; [7]Ospedale Civile, Cardiologia, S.Vito al Tagliamento, Italy*

Background: Atrial flutter (AFL) and atrial fibrillation (AF) frequently coexist in clinical practice. Both arrhythmias may share the same underlying pathology. Thus, elimination of AFL might not prevent the occurrence of AF during long-term follow-up. Aim of this prospective multicentric study was to evaluate the time to onset of AF during a long-term follow-up in a large cohort of patients (pts) with typical AFL treated with transisthmic radiofrequency catheter ablation (RCA).
Methods: We evaluated 383 pts (75% male, mean age 61.7±11.1 years) who underwent RCA for paroxysmal (52%) or persistent/permanent (48%) AFL. In 239 pts (62%) AF was present before RCA: 34% of these pts had predominantly AF. In 124 patients (32%) class IC drugs (propafenone and flecainide) or amiodarone converted AF into AFL.An underlying structural heart disease was present in 182 pts (48%). The mean left atrial diameter was 43±6 mm, and the mean left ventricular ejection fraction was 59±10%. RCA was performed using a combined anatomic and electrophysiological approach. The target of ablation was the creation of a bi-directional transisthmic block. After ablation, pts underwent outpatient examination after 1 month, and thereafter each 6 months. During follow-up, the incidence of AF was evaluated after 6, 12, 24, 36, and 48 months.
Results: Bi-directional transisthmic block was obtained in 367 pts (96%). Complications were observed in 6 pts (1.6%), including 2 permanent AV block (0.5%). During a mean follow-up of 20.5±12.4 months, relapse of AFL was recorded in 41 pts (11%): 31 pts underwent another successful RCA. Three pts (0.8%) died. At the end of follow-up, 33% of pts with a successful RCA referred AF: paroxysmal in 20%, persistent or permanent in 13%. The incidence of AF increased continuously during the follow-up: AF was present in 24% after 6 months, in 36% after 12 months, in 42% after 24 months, in 52% after 36 months, and in 48% after 48 months.
Conclusions: RCA of AFL is successful and safe. It is useful in pts with coexisting AF, too. However, the evolution of the atrial electrical disease implies that during long-term follow-up AF will occur in a large number of pts.

P3459 Effect of slow pathway ablation/modification on the fast pathway properties in patients with atrioventricular nodal reentrant tachycardia

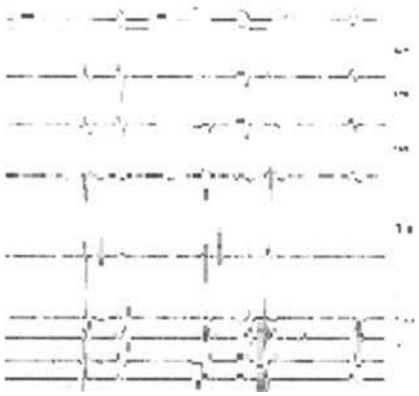
M. Zimmermann. *Hôpital de La Tour, Cardiovascular Department, MEYRIN, Switzerland*

Radiofrequency (RF) catheter ablation of the slow pathway (SP) is considered as the treatment of choice for definitive cure of atrioventricular nodal reentrant tachycardia (AVNRT). Modification of AV node conduction by RF current application in the perinodal tissue has been rarely systematically analysed or reported. This study was performed to assess the effect of RF ablation or modification of the SP on the fast pathway properties in a large cohort of unselected patients (pts).
Methods: 223 consecutive pts (149 female; 74 male; mean age 51 ± 16 yrs; heart disease in 28/223) submitted to RF ablation for AVNRT were included in this study. SP ablation was anatomically and electrophysiologically guided using conventional techniques.
Results: Success (defined as AVNRT noninducibility at the end of the procedure) was obtained in 221/223 cases (99%) with a median of 5 RF applications. Complete SP ablation was observed in 96/223 (43%) and SP modification in 127/223 (57%) cases. RF application in the SP region resulted in a significant shortening of the effective refractory period (ERP) of the fast pathway (293 ± 58 ms after RF vs 327 ± 64 ms before RF, $p<0.0001$). Such an effect was observed in the subgroup of pts with SP modification (292 ± 60 ms vs 329 ± 63 ms, $p<0.0001$) and in the subgroup of pts with SP ablation (294 ± 57 ms vs 325 ± 65 ms, $p<0.0001$). Maximal 1:1 AV conduction was also significantly influenced by RF application in the SP region (174 ± 27 bpm before RF vs 171 ± 25 bpm after RF, $p<0.001$) whereas AH interval was not (78 ± 20 ms vs 78 ± 21 ms, $p=0.92$).
Conclusion: In pts with AVNRT, a significant shortening of the ERP of the fast pathway is observed after RF application in the region of the SP and this effect is present both in patients with SP ablation and in patients with SP modification. Further studies are needed to elucidate the mechanisms underlying this observation (vagal withdrawal? modification of electronic influences?).

P3460 Focal atrial fibrillation arising from persistent superior vena cava: mapping and radiofrequency ablation

M. Landolina, F. Cantù, G M. De Ferrari, F. Frattini, S. Foresti, B. Petracci, E. Lucca, P. Moretti. *Policlinico S.Matteo-IRCCS, Cardiology Dept., Pavia, Italy*

Focal atrial fibrillation (AF) can be initiated by premature atrial contractions (PACs) from pulmonary veins (PVs) and less frequently from superior vena cava, crista terminalis and ligament of Marshall (LOM). RF ablation of focal AF originating from persistent left superior vena cava (LSVC) has never been described. We report the case of a pt who underwent EPS for episodes of paroxysmal AF unresponsive to AA drugs. The pt had a persistent LSVC inserting in the posterolateral CS. The rhythm was sinus (SR) interrupted by frequent PACs that initiated episodes of AF. Double potentials were recorded in persistent LSVC close to insertion in CS (Fig 1, LSPV: left superior PV). In SR, an initial far-field atrial component is followed by a late sharper LSVC component, whereas during PACs the sharp potential is preceding the atrial component indicating that LVSC was the site of PACs origin. Two RF applications caused the disappearance of PACs and of LSVC potential. During follow-up (12 mos), the pt was free of PACs and episodes of AF without AA drugs.



Conclusions: we describe the unique case of successful ablation of focal AF arising from persistent LSVC. The involvement of this structure in triggering AF is not surprising, as the LOM, a common site of origin of focal AF, is the embryological remnant of LSVC.

P3461 How reliable are symptoms for detection of atrial fibrillation in clinical routine? Results of the PAFAC trial

T. Fetsch[1], R. Engberding[2], H.P. Koch[3], J. Lukl[4], M. Oeff[5], H. Trappe[6], N. Treese[7], G. Breithardt[8] on behalf of the PAFAC Study Group. *[1]University Hospital of Münster, Dep. of Cardiology and Angiology, Münster, Germany; [2]City Hospital of Wolfsburg, Dep. of Cardiology, Wolfsburg, Germany; [3]Abbot/Knoll Germany, Ludwigshafen, Germany; [4]General Hospital, Dep. of Cardiology, Olomouc, Czech Republic; [5]General Hospital, Dep. of Cardiology, Brandenburg, Germany; [6]University of Bochum, Marienhospital, Dep. of Cardiology, Herne, Germany; [7]Marienhospital, Dep. of cardiology, Osnabrück, Germany; [8]University Hospital of Münster, Dep. of Cardiology and Angiology, Münster, Germany*

The PAFAC Trial (Prevention of Atrial Fibrillation After Cardioversion) is a prospective, double-blind, randomized, placebo-controlled study. In 39 months, 1,182 pts. showing documented chronic atrial fibrillation (AF) were included in 99 centers in Germany and in the Czech Republic. After successful cardioversion, 848 pts. could be randomized to either sotalol, quinidine + verapamil or placebo. Endpoints were either documented AF recurrence or death of any kind. All pts. were followed until an endpoint occurred or the end of the trial was reached. The mean follow-up period was 249 ± 315 days. All pts. received a personal small ECG recorder (Tele ECG) and were asked to record and transmit via telephone at least 1 ECG per day during the total follow-up. All ECGs were immediately analyzed in a central unit. Only AF recurrences documented by ECG were assumed as valid, independent of related symptoms. In case of AF, a fax was sent immediately to the investigator, initiating an extraordinary visit of the pt. Subsequently, a Holter recording was performed to discriminate between paroxysmal and chronic AF. In addition, the pt. was asked for associated symptoms (irregular heart beats, dizziness, tachycardias, syncopes) at the time of primary AF recording.

A total of 191,103 Tele ECGs were recorded and transmitted, of which 95% were valid for complete analysis. In 572 pts. (67%) at least 1 episode of AF was documented,in 352 pts. (42%) AF was subsequently defined as chronic. Irregular heart beats occurred in 23%, dizziness in 7%, tachycardias in 13% and syncopes in <1% of all documented AF episodes. Altogether, 70% of documented AF recurrences occurred completely asymptomatic and have occasionally been detected by daily Tele ECG monitoring. There is a tendency towards higher rates of symptomatic episodes in case of paroxysmal AF. The data suggest a correlation between higher heart rates and the occurrence of symptoms, only.

With respect to these findings it is questionable, whether associated symptoms are still valid parameters for a reliable detection of AF in clinical routine, especially if they are the basis of decisions for therapeutic strategies (e. g. immediate cardioversion without anticoagulation).

P3462 Flecainide but not sotalol causes post-repolarization refractoriness in the fibrillating atrium of patients with long-lasting atrial fibrillation

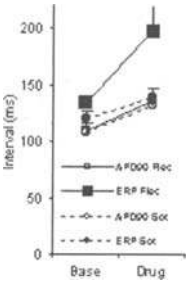
P. Kirchhof[1], M. R. Franz[2], M. Engelen[3], L. Eckardt[3], S. Rolf[3], M. Ribbing[3], G. Breithardt[3], W. Haverkamp[3]. *[1]University Hospital Münster, Cardiology and Angiology Department, Münster, Germany; [2]VA and Georgetown University Medical Center, Cardiology and Pharmacology, Washington DC, United States of America; [3]Cardiology and Angiology and IfA, Münster, Germany*

Potassium and sodium channel blockers may terminate atrial fibrillation (AFib) and prevent its reinitiation after cardioversion. In addition to prolonging action potential duration (APD), sodium channel blockers may induce post-repolarization refractoriness (PRR). Whether these drug effects are present in the fibrillating atrium is not known. We thus studied the effects of Flecainide (Flec) and Sotalol (Sot) in the fibrillating human atrium.

[Image] In 12 patients with persistent AFib (11male, 58 ±17 yrs, 27±24 mo duration of AFib), we simultaneously recorded monophasic action potentials (MAP) from the right atrial appendage and septal right atrium at baseline and 15 minutes after IV administration of Sot (1.5mg/kg) or Flec (2 mg/kg). Effective refractory periods (ERP) were determined by delivering extra stimuli at increasing coupling intervals (5ms steps) until local capture was reproducibly documented. APD was measured at 70% (APD70) and 90% (APD90) repolarization. PRR was calculated as ERP-APD90.

Flec and Sot both prolonged APD (APD70: Flec 110 ±7 vs 88 ± ms*, Sot 106 ± 6 vs 88 ± 6 ms*; APD90: Sot 131 ± 8 vs 108 ±6 ms*, Flec 137 ± 10 vs 109 ± 7 ms*, *p < 0.05). Sot prolonged ERP slightly more than APD (ERP: 119 ± 8 vs 139 ± 8 ms*), whereas Flec induced marked PRR (mean 54 ms*, ERP: 133 ± 6 vs 197 ± 22 ms*, figure).

Conclusions: Sot and Flec prolong APD in the fibrillating human atrium. Flec but not Sot also induces PRR. Both of these effects contribute to wave length prolongation. PRR may explain the effectiveness of Flec to prevent reinitiation of AFib after cardioversion.



Effect of Sot and Flec on APD and ERP.

P3463 Bisoprolol and sotalol in treatment of recurrent atrial fibrillation in patients with coronary artery disease. Bisoprolol is beyond comparison

K.G. Adamian, A.V. Astvatsatrian, A.L. Chilingarian, S.I. Vardanian, T.R. Astvatsatrian. *Institute of Cardiology, Myocardial Infarction, Yerevan, Armenia*

To compare long- and short-term efficacy and safety of bisoprolol (B) and sotalol (S) in maintaining sinus rhythm (SR) in pts with recurrent atrial fibrillation (AF) with documented coronary artery disease (CAD).

Methods: 128 pts (39 female, mean age 57± 12 yrs) with recurrent AF, 60 were given S and 68 B, after restoration of (SR). Pts randomized to S began with 80 mg twice daily and B 5 mg once daily. The dose was individually increased to the highest well-tolerated dose. All of them were on standard and similar therapy. The proportion of pts relapsing in AF with/without side effects was calculated for the two groups using the Kaplan-Meier method.

Results: 41 of the 60 (68.3%) pts receiving S relapsed to AF after an average of 7.1±6.5 months, compared to only 8 of the 68 (11.8%) pts given bisoprolol, after an average of 8.3±8.7 months ($p < 0.0003$). 7 pts (all of them on S) experienced side effects necessitating immediately withdrawal of medication, nevertheless 6 of them are still in normal SR. The proportion of AF/side effects free pts at the 1-year follow-up examination in the B group was higher than in S group (34% vs 26%), and 2 years later the results was more than double (29% vs 12%, for B and S respectively).

Conclusions: Long- and short-term efficacy of B is highly superior to S for the maintenance of SR in pts with recurrent AF with CAD and about side effects B is beyond comparison.

P3464 Factors determining long-term maintanace of sinus rhythm after successful cardioversion of persistent atrial fibrillation

D. Kosior[1], D. Wretowski[1], J. Kochanowski[1], P. Scislo[1], D. Rabczenko[2], A. Torbicki[3], G. Opolski[1]. *[1]Warsaw University of Medicine, Dept. of Cardiology, Warsaw, Poland; [2]Institute of Higiene, Dept. of Biostatistic, Warsaw, Poland; [3]Institute of Pulmonary Diseases, Dept. of Internal Medicine, Warsaw, Poland*

Long term maintenance of sinus rhythm (SR) after successful cardioversion of persistent atrial fibrillation (AF) carries lower risk of stroke and may avoid the risks associated with anticoagulation. We sought to determine the clinical and echocardiographic predictors of maintained SR during one year follow-up period.

Methods: Our study population comprised 219 patients (pts) (F/M 80/139; mean age 61.4±17.6); 109 of them (F/M 35/74; mean age 61.1±7.2) were randomized to SR restoration and maintenance with serial antiarrhythmic drug usage for whom clinical, transthoracic echocardiographic (TTE) and exercise test (ExT) variables were recorded prior to CV. The relation between those variables and SR maintenance at one year was examined. Generalized additive logistic regression was used to investigate impact of selected variables on long-term SR maintenance. Variables of interest were age, gender, echo parameters such as long, short axis of LA, LA and RA area, shortening fraction and LV end diastolic diameter, time of atrial fibrillation duration NYHA functional class and concomitant diseases. Binary variables (gender and sex) were represented in model as dummies. Impact of other parameters on long term SR maintenance and significance of its non-linear shape was tested. For parameters in which non-linearity of association was not significant relative risk associated with one unit of this variable increase was computed. For non-linear parameters, after inspection of plot of its dependence was linear selected. Than regression was performed on data from this intervals and specific for this interval relative risks associated with one unit of analyzed variable increase were computed.

Results: SR was presented in 64.4% pts at one year. For quantities variables series of generalized additive logistic regression models with one parameter of interest adjusted for age and sex was fitted. Linearity of dependence of echocardiographic and ExT parameter of interest with ID success was tested. Increased left atrium area >28 cm^2; $p<0.04$; RR 1.64 (1.12-2.64), and increase of FS value in ranges between 26-40%; $p<0.003$; RR 1.31 (1.06-1.72), were significantly associated with SR maintenance after 12 months observation period.

Conclusion: Among all considered variables only left atrium area and shortening fraction seem to be good predictors of SR maintenance after successful CV of persistent AF in one year follow-up.

P3465 Effects of diltiazem and esmolol on cycle length and spontaneous conversion of atrial fibrillation

C. Sticherling[1], H. Tada[2], H. Oral[2], F. Pelosi[2], B.P. Knight[2], S.A. Strickberger[2], F. Morady[2]. [1]Free University of Berlin-UKBF, Dept. of Cardiology, Berlin, Germany; [2]University of Michigan Medical Center, Dept. of Internal Medicine, Cardiology, Ann Arbor, Michigan 48109-0022, United States of America

Background: Patients with atrial fibrillation (AF) frequently receive calcium channel blockers (CCB) for ventricular rate control. There is evidence that CCB also exert direct effects on the atrium and prolong the duration of AF. Esmolol (Esmo) is not known to have any direct effects on the atrium. The purpose of this study was to compare the acute effects of intravenous diltiazem (Dilt) and Esmo on the cycle length (CL) and conversion rate of pacing-induced AF.
Methods and Results: In 41 adults without structural heart disease (13 male, age 44±17 years, LVEF 0.6±0.03) AF was induced by rapid atrial pacing. After 3 mins, pts were randomized to to receive either i.v. Dilt 0.25 mg/kg i.v. over 2 mins followed by a 1.7 mg/min infusion over 13 mins (n=13), i.v. Esmo 500μg/kg followed by 50-200 μg/kg/min over 14 mins (n=15), or 0.3 ml/kg saline (Plac, n=11). If AF converted spontaneously within 8 mins, AF was reinduced. AF persisting for >15 mins was cardioverted electrically. After 8 mins, the AF-CL shortened to a significantly higher degree in the Dilt group than in the Esmo group or the Plac group (table). At the same time, the ventricular CL prolonged significantly in the Dilt group (523±115 ms vs 850±214 ms, P<0.001) and the Esmo group (508±86 ms vs 571±79 ms, P<0.001). Spontaneous termination of AF occurred significantly less often in the Dilt group (3/13 pts, 23%) than in the Esmo group (10/15 pts, 67%, P<0,05) and the Plac group (10/13 pts, 77%, P<0.01).

Table: Changes in AF-CL (ms)

	Dilt	Esmo	Plac
Minute 1	183±19	169±28	189±35
Minute 8	140±19*	165±24	173±37
P	0.001	0.6	0.005

*P<0.05 vs Plac

Conclusion: Dilt, but not Esmo, shortens the AF-CL and lowers the probability of spontaneous conversion of recent-onset AF to sinus rhythm. These suggests that the use of diltiazem for acute rate control may unwittingly prolong the duration of recent-onset AF.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR – CLINICAL AND TECHNICAL ASPECTS

P3466 Effects of implantable cardioverter-defibrillator therapy on survival in chronic heart failure patients awaiting for transplantation

M.T. La Rovere[1], M. Gnemmi[1], S. Capomolla[1], O. Febo[1], A. Caporotondi[1], M. Ceresa[1], A. Mortara[2], F. Cobelli[1]. [1]Fondazione "S.Maugeri", IRCCS, Cardiology Dept., Montescano, Italy; [2]Policlinico di Monza, Cardiology, Monza, Italy

The impact on survival of ICD therapy has been evaluated in 506 CHF patients (pts) awaiting heart transplantation (HXT) from 1992 to 2001. Fifty-one pts (92% male) were implanted because of ventricular fibrillation (VF) (n=34) or sustained ventricular tachycardia (SVT) (n=17). Age and LVEF were similar between pts with and without ICD (51±10 vs 53±10 yrs, 24±9 vs 25±6%) while NYHA class and wedge pressure were significantly lower in ICD patients (2.5±0.6 vs 2.9±0.7, 17±8 vs 22±9 mmHg, p<0.01). During a mean follow-up of 18 months (range 0.13-118) 33 ICD patients were appropriately shocked for fast VF or VF. Ten patients (20%) died for heart failure or were urgently transplanted including 6 who were previously shocked. Death for heart failure or urgent HXT occurred in 151 no-ICD patients (33%) and sudden presumably arrhythmic death in 52 (11%). In no-ICD pts those with arrhythmic deaths could not be identified based on traditional risk factors. Survival curves for total cardiac mortality are displayed below for: A) ICD patients, B) no-ICD patients, C) ICD patients censored at the time of the first appropriate shock.
Conclusion: These data suggest that ICD, in a high risk CHF population, markedly improves both survival and the chance of receiving HXT. Risk stratification is needed to select those CHF pts who may benefit most from primary prevention with ICD.

P3467 Heart rate turbulence in patients with implanted cardioverter-defibrillators

W. Zareba[1], A. Erdogan[2], A. Berkowitsch[2], J.P. Couderc[1], J.P. Daubert[1], H. Pitschner[2]. [1]University of Rochester, Cardiology, Rochester, United States of America; [2]Kekhoff Klinik, Bad Neuheim, Germany

Background: Heart rate turbulence, reflecting baroreflex sensitivity, has recently been described as predictor of cardiac events in postinfarction patients. The aim of this study was to determine prognostic significance of heart rate turbulence in patients with implantable cardioverter-defibrillators (ICDs).
Methods: In 63 high-risk patients with decreased left ventricular function and ICDs, a short-term (10-minute) high-resolution ECG recording was performed after which patients were followed for 25 months on average with cardiac death as primary endpoint and ICD shock or cardiac death as secondary endpoint. Heart rate turbulence was evaluated using turbulence slope and turbulence onset parameters computed in 29 of those patients who presented with at least on premature beat during 10-minute ECG.
Results: During 25-month follow-up, cardiac death occurred in 9 (31%) whereas ICD shock or cardiac death occurred in 15 (52%) of 29 patients. The turbulence slope was significantly smaller in patients with than without cardiac death (0.049±0.038 vs. 0.116±0.081, respectively; p=0.034), whereas turbulence onset did not differ significantly between two groups. None of heart rate turbulence parameters was significantly different when comparing patients with and without secondary endpoints.

HRT and Outcome in ICD Patients

	Alive (n=20)	Death (n=9)	p value
Ts (ms/RR)	0.116±0.081	0.049±0.038	0.034
To (%)	-0.003±0.039	0.004±0.012	0.378
	Event-free (n=14)	Cardiac Death or ICD Shock (n=15)	
Ts (ms/RR)	0.104±0.072	0.090±0.080	0.534
To (%)	0.004±0.038	-0.004±0.029	0.896

Values in parentheses are standard deviations

Conclusions: These observations indicate that heart rate turbulence slope is predictive for cardiac death in ICD patients with left ventricular dysfunction. However, lack of significant association between heart rate turbulence and secondary endpoints may suggest that compromised baroreflex sensitivity may indicate increased risk of non-arrhythmic cardiac events.

P3468 Primary prevention of sudden cardiac death following myocardial infarction: how many patients are candidates for an implantable cardioverter-defibrillator?

T. Brüggemann, C. Ehlers, D. Andresen. Vivantes Klinikum Am Urban, Dept. of Cardiology, Berlin, Germany

Prophylactic implantation of an ICD improves survival in high risk pts. with remote MI. The MADIT trial showed a significant benefit for pts. late after MI with poor ejection fraction (EF), nonsustained ventricular tachycardia (nsVT) on Holter ECG and inducible but not drug-suppressible sustained VT. Recently presented results indicate that pts. with low EF alone (<=30%) late after MI benefit from a prophylactic ICD. Other primary prevention trials are on its way also studying high risk pts. early after acute MI. We showed in a previous study that only a very small group of pts. with remote MI (0.2%) fulfills the strict MADIT criteria. However, the portion of potential ICD-candidates in unselected groups of post MI pts according to the proposed criteria is unknown.
Method: We applied various noninvasive criteria as used in the different primary prevention trials to a consecutive series of 790 post MI pts. <75 years (males 76%, mean age 59±10 yrs.) from our MI data base. Medical history: previous MI 17%, diabetes mellitus 19%, arterial hypertension 46%, smoker 57%. Clinical data: anterior MI 45%, transmural MI 80%, thrombolytic therapy 59%, PTCA 39%, ACVB 11%. Risk stratification was performed by EF and Holter ECG prior to discharge (10±6 days after MI). Risk groups were defined according to the following criteria: EF<=35% + nonsustained ventricular tachycardia (nsVT) on Holter ECG, EF<=30%, EF<=35% + mean HR>=80/min on Holter, and nsVT>=150/min on Holter.
Results: Using EF<30 the number of ICD candidates within the post MI population was as high as 18.4% (145/790). Under application of EF<35+HR>80 we found 10% (79/790) ICD candidates. Combining EF<35 with nsVT revealed a group of 4.4% (35/790). If selection was done by nsVT>150 3.5% (28/790) fulfilled this criterion.
Conclusion: The results of primary prevention trials in post MI pts. will substantially increase indications for prophylactic ICDs. However, the increase highly dependends on the criteria used.

P3469 The use of Implantable cardioverter-defibrillators in patients with hypertrophic and arrhythmogenic right ventricular cardiomyopathy. A large national database

A. Proclemer[1], G. Cicuttini[2], D. Gregori[2], P.M. Fioretti[1]. [1]"S. Maria della Misericordia" Hospital, Cardiology, Udine, Italy; [2]IRCAB Foundation, Udine, Italy

Background: Non randomized multicenter studies have demonstrated the usefulness of ICD treatment in particular subgroups of patients with hypertrophic cardiomyopathy (HCM) and arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVD). The large application of those studies and the guidelines on the ICD use are not well known.
Aim: To assess the implant rate of ICD in patients with well-defined diagnosis of HCM and ARVD in the 58 million Italian population and to compare the main epidemiological data and clinical characteristics of the two groups.
Methods: All the data were collocated by EURID forms in the Italian ICD Registry. The study population included all the patients treated by ICD between 01-07-1997 and 31-12-2000.
Results:

	HCM	ARVD	p
Estimated Prevalence	1:500	1:1000-10.000	N.S.
N° implants (% on the overall)	156 (29%)	127 (2.35%)	N.S.
Centers (% on the overall)	80 (30.42%)	63 (23.96%)	N.S.
Average age	56	48	N.S.
Male	115 (74%)	96 (76%)	N.S.
NYHA Class I-II	123 (79%)	109 (86%)	N.S.
LVEF >50	71 (46%)	68 (54%)	N.S.
Amiodarone	54 (34%)	44 (34%)	N.S.
Ventricular Tachycardia	85 (35%)	92 (72%)	0.003
Ventricular Fibrillation	49 (32%)	20 (15.7%)	0.004
VT and VF	5 (3%)	11 (8%)	N.S.
Syncope/Presyncope	82 (53%)	57 (45%)	N.S.
Cardiac Arrest	30 (19%)	17 (13%)	N.S.
Palpitations/ Other	33 (21%)	48 (38%)	0.017
Prophylactic ICD	10 (7%)	5 (4%)	N.S.

Conclusion: The ICD implant rate in patients with HCM and ARVC appears still limited in a large single country of European population considering the prevalence of the two syndrome. About 1/3 of the Italian centers are involved in this activity. Ventricular fibrillation is the main indication in patients with HCM, while ventricular tachycardia is more frequent in ARVC. The prophylactic ICD use concerns less than 10% of cases.

P3470 Incidence of spontaneous atrial and ventricular tachyarrhythmias in patients with a defibrillator and a history of atrial tachyarrhythmias

A. Schuchert[1], C. Wollmann[2], M.A. Aydin[1], M. Kühl[3], T. Meinertz[1] on behalf of the VENTAK PRIZM AVT Investigators. [1]University-Hospital Hamburg-Eppendorf, Department of Cardiology, Hamburg, Germany; [2]University Hospital Münster, Department of Cardiology, Münster, Germany; [3]Guidant, Brussels, Belgium

The aim of the prospective study was to evaluate the incidence of spontaneous atrial and ventricular tachyarrhythmias in patients with a history of spontaneous atrial and ventricular tachyarrhythmia. Inclusion criteria were a standard indication for the implantation of a cardioverter defibrillator (ICD) and at least one documented spontaneous atrial tachyarrhythmia within the last year.
Methods: Patients received the dual-chamber ICD VENTAK PRIZM AVT (Guidant). The device has new algorithms that differentiate atrial flutter from atrial fibrillation, have separate therapy options for the treatment of atrial flutter and atrial fibrillation (Antitachycardia Pacing (ATP) and/or shock therapy), and have diagnostic functions that allow a selective storage of spontaneous atrial and ventricular tachyarrhythmias (16 min with intracardiac electrograms and annotated event markers).
Results: The study included 84 patients in 22 European and one Canadian center (64 ± 13 years, male n = 62, coronary artery disease n = 49, LVEF 45 ± 15%). Paroxysmal atrial tachyarrhythmias in combination with monomorphic ventricular tachycardia had 56 patients, paroxysmal atrial tachyarrhythmias and ventricular fibrillation 21 patients and 7 devices were implanted for paroxysmal atrial tachyarrhythmias only. Follow-ups were at predischarge, 1,3 and 6 months after implantation. During a cumulative implanted duration of 503 months the device documented 5717 spontaneous atrial episodes in 58 (69%) patients and 2630 spontaneous ventricular episodes in 45 (53%) patients. Both atrial and ventricular spontaneous episodes during a mean follow-up duration of 2.1 months had 32 (38%) patients. The spontaneous atrial tachyarrhythmias were successfully terminated by ATP in 1602 episodes and by shock therapy in 44 episodes. The remaining episodes terminated spontaneously. Of the spontaneous ventricular episodes, 305 were successfully terminated by ATP and 201 by shock therapy. The remaining episodes terminated spontaneously.
Conclusions: Patients who receive an implantable defibrillator and with a history of atrial tachyarrhythmias have a high incidence of spontaneously atrial tachyarrhythmias after device implantation. These patients are also at high risk of suffering from ventricular arrhythmias (38%). Spontaneous atrial tachyarrhythmias can be successfully diagnosed and treated with ICD's that offer options to selectively detect and treat atrial tacharrhythmias.

P3471 Comparison between automatic nocturnal and manual shocks in patients with drug refractory atrial fibrillation treated with a dual defibrillator

A. Quesada[1], R. Ricci[2], M. Disertori[2], S. Campos[1], A. Capucci[2], F. Atienza[1], A. Raviele[2], M. Santini[2]. [1]H. General Universitario de Valencia, Cardiology, Valencia, Spain; [2]H. San Filippo Neri, Rome, Italy

Background: The Medtronic 7250 is an implantable atrial (dual) defibrillator (ICD) with multiple programmable therapies options. Ventricular therapies back up allows programming the atrial shocks in an automatic fashion. The differences of this automatic strategy with manual one are unknown.
Aim: The aim of the study has been to evaluate whether there are long term differences with automatic or manual shocks in the atrial fibrillation (AF) temporal course and clinical status of ptes with dual ICD for refractory AF.
Methods: 40 Pts (28 M, mean age 65±10)with symptomatic, drug refractory AF (60% persistent, 40% paroxismal) received a Medtronic 7250 ICD. Preventing and antitachycardia pacing therapies were activated. 14 (35%, group A) pts accepted automatic shock therapy, programmed as 1 single, over night, maximal energy (27 J) shock by episode. In the other 26 ptes (65%, group B)device shocks were delivered by a physician in the hospital. AF burden (AF hours by week), number of episodes, efficacy, ERAF, tolerability, symptoms and QoL data has been evaluated to study the impact of the automatic shocks. All patients completed 1 year of follow-up.
Results: In both groups, dual ICD decreased AF burden, number and duration episodes. However during some periods significant differences in AF burden were found due to longer duration of AF episodes in group B.Tolerability of automatic shocks was high with only one patient needing a temporal interruption, and was related to the success of the therapy and mainly with the rate of the shocks
Conclusion: Automatic shocks seem reduced more effectively AF burden during burden.Tolerance is good when they are delivered as only 1 shock during nightime.

P3472 Do implantable cardioverter-defibrillator patients really live longer? A reassessment after 10 years

C. Wollmann[1], J. Köbe[2], I. Berner[2], R. Gradaus[2], G. Breithardt[2], D. Böcker[2]. [1]Universitätsklinikum, Medizinische Klinik und Poliklinik C, Münster, Germany; [2]Universitätsklinikum Münster, Medizinische Klinik und Poliklinik C, Münster, Germany

Background: In 1993, we published the results of 107 patients (pts.) treated with an ICD in combination with endocardial defibrillation leads (Böcker et al, JACC 1993). The purpose of this study was to investigate the long-term follow-up (FU) of these patients.
Patients and Methods: The follow-up of 107 pts. (86% male; 68% CAD, 17% DCM; EF 40%±15; VF 29%, sustained VT 50%, VT and VF 18%), implanted between October 1989 and March 1992, was studied 10 years after ICD implantation (November 2001).
Results: After a follow-up of about 10 years, 54 pts. (50%) out of the 107 are still alive. 4 pts. (3,74%) underwent heart transplantation (mean 61,1 months after first ICD implantation), of whom 3 are still alive.
Death occurred after a mean of 56 months (median 54± 36). Cause of death was sudden in 6 pts. (9% of all deaths) after 62±35 months and progressive pump failure in 28 pts. (53%) after 53±34 months. Thirteen pts. (25%) died from a non cardiac cause. The cause of death remained unknown in 2. Three pts. died within 30 days after first ICD implantation, 2 of them after failed implantation of an endocardial lead system.
Thirty-four pts. (33%) had VF or fast VT >240 bpm, 84 pts. (81%) sustained VT. However, 19% of the pts. had neither VF nor VT-episodes. Inappropriate ICD therapies occurred in 34 pts. (33%), the majority of which were caused by atrial fibrillation with fast AV-conduction.
Lead-related problems requiring repeated surgery were a common finding, occurring once in 50% of the patients and more than once in 10%. The majority of the lead problems included the Pacing/sensing part of the lead, followed by insulation problems and infections. The high-voltage circuit was included only in a minority of the patients. Only 2 pts. had a dysfunction of the ICD itself.
Conclusions: ICD treatment reduces the sudden death rate even during long-term follow-up to .5%/year and, thus, improves the prognosis of the treated patients. Progression of pump failure is the leading cause of death in this patient cohort. The incidence of lead dysfunction requiring repeated surgery is high while dysfunctions of the device itself are a rare finding.

P3473 Syncope in implantable cardioverter-defibrillator pacemaker dependent patients

D. Cavaco[1], P. Adragão[1], C. Aguiar[1], J. Neves[2], M. Abecasis[2], F. Morgado[1], D. Bonhorst[1], R. Seabra-Gomes[1]. *[1]Hospital Santa Cruz, Department of Cardiology, Carnaxide, Portugal; [2]Hospital de Santa Cruz, Department of Cardiothoracic Surgery, Carnaxide, Portugal*

Background: With the current Automatic Gain Control (AGC) implantable cardioversor defibrillators (ICDs), maximum sensitivity is programmed to guarantee ventricular fibrillation detection. Ventricular oversensing may allow inappropriate tachyarrhythmia detections and therapy and pacing inhibition. The incidence of ventricular oversensing is unknown. Its consequences in pacemaker dependent patients are dangerous. **Objectives:** To evaluate ventricular oversensing frequency in pacemaker dependent patients, with AGC ICDs implanted. **Population:** We studied 8 ICD pacemaker dependent patients (P), (4.8% of all AGC ICDs implanted in our department). Six P had a dual chamber ICD (3 with ventricular resynchronisation) and 2 P single chamber ICDs. **Results:** Four P suffered (at least 1) syncope in follow up, and one died suddenly, corresponding to 63% of P with serious complications. The device interrogation in these patients showed: oversensing episodes (false detection of VF) followed by pacing inhibition and shock - 3 P; absence of arrhythmia detection - 2 P. The P that died (dual chamber ICD with resynchronisation) was among the latter (the autopsy excluded lead dislodgment and was not conclusive as to the cause of death) **Conclusions:** Oversensing in this population seems frequent and may constitute a high potential risk. Precautions should be taken as to the choice of the device in pacemaker-dependent patients. Better sensing systems, eventually with tachy and brady independent sensing may pssibly contribute to solve these problems.

P3474 Reliability and clinical benefits of a new subthreshold non-invasive shock lead integrity test

A. Schuchert[1], J. Winter[2], T. Meinertz[1] on behalf of the Reliance Investigators. *[1]Univ. Hospital Hamburg-Eppendorf, Dept. of Cardiology, Hamburg; [2]Heinrich Heine Univ., Dept. of Cardiovascular Surgery, Düsseldorf, Germany*

The integrity of the defibrillation lead is crucial for the proper function of implanted cardioverter/defibrillators. Serial measurements of the shock lead impedance are the most reliable non-invasive method to verify the integrity. The current approach is to deliver an at least 1 J shock. As this is painful for the patient, deep sedation is mandatory. The aim of the prospective study was to compare a new subthreshold measurement for shock lead impedance with the standard measurement. **Methods:** The study included 123 patients (60±13 years, 82% male, 71% coronary artery disease, ejection fraction 38±16%) who received in 25 European centers either a Prizm DR (n=73) or VR (n=50, Guidant, St. Paul, MN, USA) defibrillator. The defibrillator was connected to the single coil (models 0127/0128; n = 39) or dual coil (models 0147/0148; n = 84) Endotak Reliance defibrillation lead. The defibrillator delivers for the shock lead integrity test a <1 mJ subthreshold pulse through the single coil or dual coil lead and the defibrillator housing (can). The current density of the test pulse is 1/100th of a pacing pulse. Non-invasive shock lead impedance was measured for the defibrillation vectors from the distal coil to the proximal coil and can as well as from the distal coil to the can. The standard measurement for shock lead impedance was with a 17J shock. **Results:** The shock lead impedance for the vector from the distal coil to the proximal coil and the can was 42 ± 5 ohms (95% confidence interval (CI): 41 - 44 ohms) with the lead integrity test and and 41 ± 4 ohms (±95% CI: 39 - 43 ohms) with a high-energy shock (p = 0.13).The shock lead impedance for the vector from the distal coil to the can was 63 ± 7 ohms (±95% CI: 60 - 66) with the lead integrity test and 60 ± 8 ohms (±95% CI: 56 - 64 ohms) with a high-energy shock (p = 0.44). The vector from the distal coil to the can had a significant higher shock lead impedance than from the distal coil to the proximal coil and the can (p=0.001). **Conclusions:** The new subthreshold shock lead integrity test measured a shock lead impedance similar to the standard measurement with the delivery of the high-energy shock. This non-invasive test is a useful diagnostic method as it allows serial measurements of the shock lead impedance during follow-up without the need for sedation.

P3475 Chronic values of shocking lead impedance compared to impedances at implant – Results of the LIT study

C. Unterberg-Buchwald[1], S. Stiller[2], L. Binner[2], D. Pfeiffer[3], D. Stockman[4], D. Schmitz[5], U. Appl[6], G. Grossmann[2] on behalf of Investigators of the lead integrity test study. *[1]Univ. Hospital, Goettingen, Germany; [2]Univ. Hospital, Ulm, Germany; [3]Univ. Hospital, Leipzig, Germany; [4]A.Z. Middelheim, Antwerp, Belgium; [5]St. Johannes Hospital, Dortmund, Germany; [6]Guidant, Diegem, Belgium*

Background: To test the integrity of the shocking lead a shock must be delivered. Low energy sub threshold test shocks allow to evaluate the shock lead integrity, without being painful to the patient. In the present study we evaluated the Lead Integrity Test (LIT) in VENTAK PRIZM I and II ICDs (Guidant, St. Paul, MN, USA) at implant and during follow-up.

Method: 132 Patients (81,1% male, mean age 61.1 ± 13.8 years, LVEF 43.6 ± 16.1%) with an ICD indication were included in the study. 113 completed all procedures. At implant the LIT was compared against low energy test shocks. At predischarge (PHD) and after 3 months the lead impedance was evaluated again using the LIT.

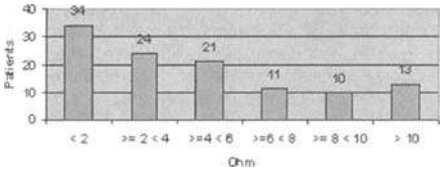
Results: LIT delivers significant lower values than the low energy shock at implant (see table). The acute lead impedance measured at PHD is significantly lower than the impedance measured at implant ($p < 0.0001$). The chronic impedances are not significantly higher than the impedances at implant.

Impedance values

	Implantation	Predischarge	3-months - Follow-up
1.1 J ICD - shock	54.1 ± 13.7 Ohm		
LIT	50.0 ± 12.3 Ohm p < 0.009	46.1 ± 9.9 Ohm	51.2 ± 11.7 Ohm

Values as mean ± standard deviation

The median difference between the impedance at implant and the chronic impedance value is 3.8 Ohm (see picture).



Difference from implant value at 3 months follow-up.

Conclusion: The lead integrity test is a useful and reliable tool to verify the proper function of the defibrillation lead and improves patient comfort and tolerance.

P3476 Complete device removal together with reimplantation of a new device is the optimum management of infected pacemaker and implantable cardioverter-defibrillator leads

T. Padder[1], F. Padder[2], B. Kantharia[1], G. Panjrath[3], A. Ivanov[1], M. Albatani[1], S. Ahmad[3], S. Kutalek[1]. *[1]Hahnemann University Hospital, Cardiac Electyrophysiology, Philadelphia, United States of America; [2]mcp hahnemann university hospital, cardiology, philadelphia, United States of America; [3]Hahnemann University Hospital, Nuclear Cardiology, Philadelphia, United States of America*

Background: Pacemaker and ICD infection is a life-threatening situation. The incidence of infection in these devices ranges from 1.3-12.6%. However optimum management of these infected devices is yet to be defined. Taylor et al, Trinkle et al and Lee et al have emphasized the conservative treatment of infection without total device removal. Our approach has been total removal of the infected device with reimplantation of new device after proper antimicrobial therapy.

Objective: To come up with a standard protocol for the management of infected pacemaker and defibrillator leads.

Method and Results: between 9991-2001,180 consecutive patients with 320 leads satisfied the criteria of device related infection and underwent device explantation. Infection was defined as presence of warmth, erythema, swelling, edema and pain along with positive culture from blood, device, device pocket, or lead.145 patients had pacemaker and 35 patients had ICD's. The study included 130 male and 50 female patients. The mean age of the patients was 66±15 years (range 20-92 years.). Early infection (<6 months) was found in 31% patients and late infection (>6 months) was observed in 69% patients. The mean implant duration was 52 months (range 2- 264 months). Infection was found to be local in 56% patients, systemic in 21% patients, erosion in 18% and vegetation in 9% patients. Infection was caused by Staphylococcus in 82%, Enterobacter 5%, Pseudomonas 5%, Streptococcus 5% and 1% each by Candida, Citrobacter, Corynebacterium, and Propionibacterium. Complete device removal was achieved in 171 (95%) patients. 150 (84%) patients had reimplantation of the new device at the same center after antimicrobial therapy. During follow up of 36 months only two (1%)patients had reinfection of the reimplanted device. The overall complication rater was 4%.

Conclusion: Complete extraction of the infected device followed by an antimicrobial therapy of choice is a safe and effective way of management of these device related infected devices. Reimplantation of the new device could be done after two consecutive r negative cultures and negative TEE. Although our study was non-randomized it provides substantial insight into successful management of infected device in a large population.

P3477 Non-invasive optimization of the atrioventricular delay in patients under biventricular pacing

T. Deneke, S. von Dryander, P.H. Grewe, T. Lawo, T. Fadgyas, C. Müller, B. Calcum, B. Lemke. *Bergmannsheil Bochum, Department of Cardiology, Bochum, Germany*

Biventricular (BiV) pacing has evolved as a promising add on therapeutic tool in patients with chronic heart failure. In addition to systolic improvement diastolic resynchronisation may be achieved by optimizing the atrioventricular timing.
Methods: 16 patients (ejection fraction 29±6%, end diastolic left ventricular diameter 65±5mm) received a BiV implantable cardioverter defibrillator (Medtronic InSync™). Doppler echocardiographic evaluation of diastolic and systolic flow durations were performed for different atrioventricular (AV) delays (30ms to 150ms) and different stimulation sites (left ventricular (LV), right ventricular (RV) and BiV). The optimal atrioventricular delay for each stimulation site was calculated using the Ritter-Lemke formula.
Results: QRS duration narrowed during BiV pacing from 208±37ms to 169±16ms. The mean optimal AV delay was calculated to be 117±36ms (60 to 180ms) for BiV, 102±30ms (65 to 150ms) for LV and 75±35ms (50 to 125ms) for RV pacing with wide interindividual differences. Optimized BiV pacing produced the shortest pre-ejection intervals (PEP) (150±44ms) and longest ejection duration (EP) (269±35ms) as parameters of improved systolic inter- and intraventricular contractile synchrony compared to LV (PEP 169±35ms, EP 262±35ms) or RV (PEP 182±28ms, EP 256±46ms) pacing. Diastolic right and left cardiac filling times were longest during BiV pacing. Compared to the mean of the non-optimal AV delays diastolic optimization improved preejection and ejection intervals and prolonged diastolic filling duration independent to the stimulation site.
Conclusions: Individual programming of BiV pacing devices for optimizing hemodynamic benefit is needed because of widely differing electro-mechanical delays. Optimization not only improves diastolic ventricular filling but also increases systolic functional parameters. Compared to monoventricular pacing BiV stimulation increases mean EP (+1% versus LV and +3% versus RV pacing) and shortens PEP (-13% versus LV and -22% versus RV). BiV stimulation prolongs mean diastolic left cardiac filling compared to LV (+12%) or RV (+9%) pacing.

P3478 A rhythm discrimination algorithm based on rate-branch and morphology discrimination in dual chamber cardioverter-defibrillators

G. Boriani[1], M. Biffi[1], A. Dall'Acqua[2], P. Silvestri[2], C. Martignani[1], L. Frabetti[1], R. Zannoli[1], A. Branzi[1]. *[1]Inst of Cardiology, Bologna, Italy; [2]St. Jude Medical Italy, CRMD, Milan, Italy*

Morphology Discrimination (MD) is a discriminator based on QRS morphology analysis implemented in St. Jude Medical dual-chamber implantable cardioverter defibrillators (ICD). In these devices detected events are firstly classified according to atrial (A) and ventricular (V) median rates (Rate Branch); then a series of discriminators,i.e. MD and Stability if V rate < A rate or MD and Sudden Onset if V rate = A rate, analyse the rhythm according to definite criteria and to different diagnostic logic for ventricular tachycardia (VT) diagnosis (i.e. requiring "any" or "all" the specific discriminators indicating VT, respectively). All rhythms are classified as VT if V rate > A rate.
The accuracy of Photon DR diagnostic algorithm was evaluated on 645 detections occurred in 25 patients during a follow-up of 15±4 months.
All the detected events (645 overall) were reviewed and classified as: 79 atrial fibrillation (AF) episodes, 53 atrial tachycardias, 62 atrial flutter, 203 sinus tachycardias, 234 VTs and 14 ventricular fibrillation episodes.
Overall, specificity on 397 supraventricular arrhythmias (SVT) was 73.5% (292/397) with the diagnostic logic "any" and 90.9% (361/397) with the diagnostic logic "all". Sensitivity on VT episodes was 100% and 98.7% (231/234) with "any" and "all", respectively. In detail, with the diagnostic logic "any", specificity was 88.6% for AF, 0% for atrial tachycardia, 40.3% for atrial flutter and. 97.0% for sinus tachycardia. With the diagnostic logic "all" specificity was 92.4% for AF, 54.7% for atrial tachycardia, 93.5% for atrial flutter and 99.0% for sinus tachycardia.
The use of Morphology Discrimination was crucial for improving the specificity of Rate Branch algorithm. (without this discriminator the highest specificity achievable overall was 74.6%).
In conclusion, implementation of Morphology Discrimination in an ICD with atrial and ventricular sensing, in combination with a Rate-Branch classification system, allows attainment of a very high specificity in discriminating detected events, with maintenance of 98.7-100% of sensitivity for ventricular tachyarrhythmias. With this algorithm the advantage in rhythm discrimination is strictly dependant on use of Morphology Discrimination algorithm, since a marked increase in specificity results from addition of this discriminator to the conventional discriminators (i.e. Sudden Onset and Stability). The net increase in specificity is particularly relevant in discrimination of regular supraventricular tachyarrhythmias (i.e. atrial flutter, atrial tachycardias).

P3479 Low incidence of inappropiate shocks in a dual chamber cardioverter defibrillator: an analysis of a cohort of 197 patients

R. Schimpf[1], N. Sadoul[2], C. Henry[3], C. Wolpert[4], B. Lüderitz[1]. *[1]University of Bonn, Dept. of Cardiology, Bonn, Germany; [2]Hopital Brabois, Department of Cardiology, Nancy, France; [3]Ela Medical, Le Plessis-Robinson, France; [4]University of Mannheim, Department of Medicine, Mannheim, Germany*

One of the most frequent reasons for inappropiate shocks in ICD recipients is atrial fibrillation (AF). Therefore the aim of this study was to assess the number and causes of inappropiate shocks in dual-chamber ICD patients. Special attention was paid on all atrial fibrillation episodes and the effect of programming a slow VT-zone.
Methods: A cohort of 197 patients (pts) and their episodes were reviewed (177 males, 64 ± 10 years, left ventricular ejection fraction = 39 ± 16%) implanted with a dual chamber ICD (Defender IV, Alto DR, Ela Medical, France). Fifty-one pts had a previous history of an atrial arrhythmia. All devices were programmed with 2 VT zones starting at 100 bpm and a VF zone. Shock therapy in the slow VT zone was left to the investigator's judgement. All pts had PARAD or PARAD+ detection algorithm programmed. All documented episodes were retrieved from the memory of the device at each follow-up. The investigator and a group of experts when equivocal reconfirmed whether therapy delivery was adequate or inadequate. Results: During a mean follow-up of 5.6 months, 93/197 pts experienced 434 treated episodes. Among those, 95 episodes were treated by shock in 45 pts. Of the 95 episodes 83 were clinical VT of VF in 38 pts. In 9 pts, 12 episodes were inappropriately treated: 6 episodes of ventricular artifacts (5 pts, 3 with lead problemns, 2 with external interference), 2 episodes of T wave oversensing (1 pts) and 2 AF episodes inappropiately classified as VT (2 pts). Among the 233 AF episodes (25 pts) that were not associated with shocks, 25 (8 pts) triggered ATP therapy without deleterious effect. Therapy was appropiately withhold in 208 (88%) of AF episodes.
Clinical Implication: 1. Only 1% of all ICD-recipients and 4% of all shock treatments were caused by misdiagnosis of atrial fibrillation. 2. Inappropiate shocks were mainly related to ventricular lead problems.

P3480 Assessment of defibrillation via the middle cardiac vein in pigs

J. Paisey, P. Roberts, S. Allen, J. Morgan. *SUHT, Cardiothoracic, Southampton, United Kingdom*

Background: Conventional electrodes placed in middle cardiac vein (MCV) have previously been shown to reduce the defibrillation threshold (DFT) compared to standard electrode configurations in pigs. We have further evaluated DFT reduction in the same setting but using custom built bi-filament defibrillation electrodes {ELA Recherché, Paris, Fr} (placed in MCV) with novel design features intended to optimise energy delivery and defibrillation efficacy.
Methods and Results: In 9 pigs (61.3±4.3 kg) defibrillation electrodes were deployed under fluoroscopic control, into right and left branches of MCV. VF was induced (4sec bursts 50Hz AC). 2 animals could not be resuscitated from VF by external shocks after failed internal defibrillation and were excluded from analysis. In 1 MCV anatomy was unsuitable for electrode deployment (venous anatomy defined by contrast injection). A customised guide catheter selectively cannulated venous radicles for defibrillation electrode placement. The DFTs of the following configurations were evaluated using a binary search method:

DFT by configuration

Configuration	RV to Can	RV to SVC+Can	RV+MCV to Can
DFT (Joules)	22.8±7.3	21.9±7.6	13.1±5.1

$p<0.05$ RV to can vs RV + MCV to can

Conclusion: The addition of a bifilament electrode in separate branches of MCV reduces DFT by 43% compared to conventional configurations. Optimisation of electrode design may further reduce defibrillation requirements.

P3481 14–20% of patients with an implantable cardioverter-defibrillator indication may benefit from resynchronisation therapy

S G. Molhoek[1], J J. Bax[2], L. van Erven[2], E E. van der Wall[2], M J. Schalij[2]. [1]Leiden University Medical Center, Cardiology, Leiden, Netherlands; [2]Leiden University Medical Center, Cardiology, Leiden, Netherlands

Treatment of congestive heart failure (CHF) aims for symptomatic relief and reduction of mortality. An implantable cardioverter defibrillator (ICD) prevents sudden death in patients at high risk, whereas recent data suggest that biventricular (BV) pacing in patients with CHF may improve functional status. The combination of these 2 treatments may be synergistic. It is unknown however, what percentage of patients with an ICD indication are potential candidates for BV pacing.
Accordingly, we retrospectively analyzed all patients who received an ICD, for eligibility of BV pacing. Based on the available literature, established criteria for BV pacing included NYHA class III or IV (> 6 months), dilated cardiomyopathy of any origin and a QRS duration >120 ms. Patients in NYHA class II with a left ventricular ejection fraction (LVEF) <30% and QRS >120 ms were also considered eligible. The incidence of potential exclusion criteria, including atrial fibrillation (AF), RBBB and PR interval <150 ms, was also assessed.
Results: 195 consecutive patients received an ICD from June 1996 till July 1999 at our hospital. There were 159 men and 36 women, with a mean age of 59 ± 13 years. Underlying cardiac disease was ischemic (66%), idiopathic dilated cardiomyopathy (CM) (13%), primary CM (8%) and miscellaneous in 13% of the patients. Indications for ICD implantation were out hospital cardiac arrest (52%), ventricular tachyarrhythmia (46%) and preventive (2%). In the 195 patients the mean LVEF was 36 ± 17.
The incidence of severe CHF (NYHA class III/IV) was 19% (37 patients); 32 (16%) patients were in NYHA class II with an LVEF <30%. Of these 69 patients, 39 had a QRS duration >120 ms (18 LBBB, 9 RBBB, 12 intraventricular conduction delay). Thus, a total of 39 (20%) patients were eligible for BV pacing in addition to an ICD. When patients either in chronic AF or with RBBB were excluded, this number was reduced to 27 (14%). None of the patients had a PR interval <150 ms (mean 196 ± 31ms, range 160 - 260).
In conclusion, 14-20% of patients with an ICD indication may also benefit from BV pacing. Screening for eligibility of BV pacing should be considered in patients with CHF scheduled for ICD implantation.

ATRIAL FLUTTER – ABLATION

P3482 Catheter ablation of the right atrial cavo-tricuspid isthmus in patients with paroxysmal atrial fibrillation

C. Mewis, L. Küffner, H.R. Neuberger, K. Kettering, R.F. Bosch, L. Seipel, V. Kühlkamp. *Medizinische Klinik III, Cardiology Dept., Tübingen, Germany*

Patients with paroxysmal atrial fibrillation (pAF), who develop atrial flutter during treatment with class IC drugs, benefit from a cavo-tricuspid ablation of the isthmus. It is unknown whether patients with AF may also benefit from this procedure independently of the occurrence of drug related atrial flutter. Therefore we included in this study highly symptomatic patients with pAF. At least one month prior to the ablation patients underwent twice Holter-monitorings and event recordings. All patients were instructed to record their arrhythmia episodes. The documentation of atrial flutter led to the exclusion of the patients. After the ablation all recordings were repeated the subsequent 6 months. If the patient took any antiarrhythmic drug before the procedure, the drug was continued the whole follow-up period.
Results: 25 patients with pAF were included into the study (age: 55±9 years), 4 patients suffered from structural heart disease (EF 55 ± 8%). None of the patients had dilated atria in the echocardiography. In all patients the isthmus ablation was successfully performed. During the follow-up of 6±3 months 12/25 patients reported to feel an significant improvement of arrhythmia symptoms. They reported less frequent and less severe episodes of AF. Patients benefitted most from ablation if the episodes of AF prior to the intervention occurred with a heart rate > 100 b/min. ECG pattern such like polymorphic (flutter-like) p-waves during AF were not predictive for the patient outcome. Conclusion: Almost 50% of the patients with pAF benefit from a cavo-tricuspid isthmus ablation. Macroreentry circuits around the tricuspid annulus seem to play an important role in sustaining AF. Thus a minimal linear lesion within the cavo-tricuspid annulus might be an alternative less aggressive symptomatic approach in patients with pAF than multiple linear lesions or focal ablation procedures.

P3483 Impact of first-line radiofrequency ablation in patients with atrial flutter on the risk of subsequent atrial fibrillation

A. Da Costa, N. Zarquane, C. Romeyer, B. Samuel, A. Khiel, E. Faure, A. Cerisier, K. Isaaz. *CHU, Service De Cardiologie, Saint Etienne, France*

Background: Radiofrequency ablation (RFA) of Atrial Flutter (AFlu) has been effective for short and intermediate term arrhythmia control. However, it is unknown if first-line RFA will alter the intermediate-term risk of developing atrial fibrillation (AFib). Objectives. The aim of this study was to evaluate the long term risk of subsequent AFib after RFA in two groups of pts with lone AFlu, Group I: first-line RFA therapy and Group II: RFA after at least one drug therapy failure. Lone AFlu excluded prior evidence of AFib. Methods. During 24 months, 161 consecutive patients (66±12 years; 29 females) with counterclockwise A Flu were considered eligible, 92 pts in GpI (68±12 years) and 69 pts in GpII (65±11 years). RF-ablation with an 8-mm-tip catheter was performed by the same operator and the end-point was to obtain a bi-directional block. Results: The mean follow-up for the entire population was 15±9 months and cumulative risk of AFib was analyzed by use of the Kaplan-Meier method and by the log-rank test. Clinical presentation, electrophysiologic data, results of RF ablation and follow-up were as following in the two groups (*p<. 05): flutter duration since-onset (1.9±3 vs 28±31 months; p<.0001), structural heart disease (40 vs 40.5%; ns), left ventricular ejection fraction (58±12 vs 61±10%; ns), left atrial size (43±7 vs 41±6mm; ns), cavo-tricuspid isthmus dimension (40±10 vs 37±11 mm; ns), bi-directional block (98.9 vs 94.2%; ns), RF application (12.4±.12 vs 12.1±12 minutes; ns), AFL recurrence (4.3 vs 7.2%; ns), discharge with antiarrhythmic agents (10/92 vs 14/69; p=.4), mean follow-up (14±8 vs 16±9 months; ns), atrial fibrillation occurrence (6.5% vs 11.5%; p=.4). No complication were noted in the two groups. Conclusions. This study suggests that first-line therapy of AFlu with RF ablation does not alter the intermediate-term risk of subsequent AFib.

P3484 Safety of the complete line between the tricuspid ring and the inferior vein cava during the ablation of the cavotricuspid isthmus

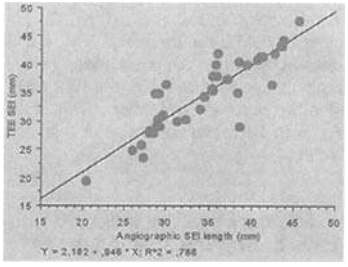
J.G. Rebollo[1], A. Madrid[1], G. Pena[1], M.G. Bueno[1], I. Marin[1], P. Cabeza[1], J. Peng[1], C. Moro[2]. [1]Ramon y Cajal, Arrhythmia, Madrid, Spain; [2]Alcala University, Medicine, Alcala, Spain

Complete linear atrial ablation is necessary to achieve successful ablation of atrial flutter. Experimental studies have shown that deeper and wider lesions can be safely performed using 8 mm or irrigated-tip catheters. However, the lesions created by these catheters may be more than 10 mm in diameter and depth. The potential advantages of these catheters would include a quicker ablation, with a higher success rate. However, the potential damage to the tricuspid valve or inferior vena cava has not been evaluated.
Twenty-seven pigs (weighing between 26 and 52 Kg) were ablated. Standard RF ablation was performed with a steerable 4-mm tip, 7 Fr catheter, Marinr, (Medtronic Inc., Minneapolis, USA). The RF Generator was Atakr II, Medtronic. The application was carried out in a temperature-controlled mode, targeting 70°C. The Irrigated tip catheter was a Chilli (Cardiac Pathways). We used 50 watts, temperature-controlled mode, 50°C. The 8 mm Catheter was a Conductor from Medtronic, the power used was 100W. The three types of ablation were chosen randomly. After 1 week, the animals were slaughtered. A total of 187 radiofrequency applications were made in 26 animals, using the three different catheters (10 Irrigated, 8 standard, 8 catheters 8 mm).
The size of the lesion was greater with the irrigated tip catheters and the 8 mm than with standard. The line of anatomic isthmus block was documented. Completely transmural lines were found in 14 animals. The lesion appeared as a discoloured greyish red oval area, sharply demarcated from the adjacent healthy endocardium. In 7 animals (1 Irrigated, 4 with 8-mm catheters, 2 standard), the lesions extended to the right ventricle and the tricuspid valve. The tricuspide valve was severely damaged in 2 pigs and with mild lesions in 5. The animals with tricuspid lesions had a higher maximal power (59± 27 Watts versus 51 ± 24 watts) and temperature (63± 4°C versus 55± 11 °C), p < 0.001. The Low Energy Measurement (LEM), was also higher (0.55±0.24 versus 0.35±0.29, p 0.001), indicating a greater pressure contact of the catheter.
Conclusions: The tricuspid valve may be severely affected by the application of radiofrequency during the ablation of atrial flutter. This fact was particularly documented after using high energy (100 Watts) with 8-mm catheter (50% cases), but can be produced after using usual energy with standard catheter (20% cases). In order to avoid this damage, it is neccessary to avoid applications inside the right ventricle.

P3485 Anatomic evaluation of inferior vena cava-tricuspid isthmus: correlation between angiography and transthoracic echocardiograpy

A. Da Costa, E. Faure, C. Romeyer, B. Samuel, A. Khiel, A. Cerisier, K. Isaaz. *CHU, Service De Cardiologie, Saint Etienne, France*

Background: In patients with common atrail flutter, bidirectional conduction block across the sub.eustachian isthmus (SEI) often requires excessive radiofrequency applications due to the length of this region. Gaining information about SEI length can guide the ablation approach (catheter choice). Anatomic evaluation is generally performed by right atrial angiography (RAA), however this technique is invasive, expensive, time consuming, and special equipment is required with contrast injection. We hypothesized that transthoracic echocardiography (TTE) may constitute an alternative to RAA. Objectives. The aim of this study was to assess the value of TTE in comparison with RAA, the gold standard. Methods. This study prospectively included 41 consecutive pts (65±13 years; 4 women) presenting a common atrial flutter and referred for ablation over 4 months period. The SEI length was measured as the distance from the lateral margin of the tricuspid annulus to the inferior vena cava origin in the subxiphoid view. RAA was performed in right anterior oblique view (25°) and the SEI was measured between the inferior vena cava and the lower hinge point of the tricuspid valve. Results. TTE was feasible in 39/41 pts (95.3%). SEI length correlation coeffitients between the two methods were 0.89 ($p<.0001$).



Correlation graph.

Conclusions: This study demonstrates that non invasive measurement of SEI length by TEE is feasible and highly correlated with the angiographic approach. TTE can be used to assess SEI length before ablation of atrial flutter gaining information about catheter ablation choice.

P3486 A non-fluoroscopic real-time 3D-navigation system allows easy and safe treatment of typical atrial flutter

M. Niehaus, T. Nasilowski, M. de Sousa, T. Korte, J. Tebbenjohanns. *Hannover Medical School, Dept. of Cardiology And Angiology, Hannover, Germany*

The ablation of the cavotricuspid isthmus using radiofrequency (RF) is a well established procedure for treatment of isthmus dependent typical atrial flutter. Nevertheless, fluoroscopy times are high and recurrence rate remains significant. The new non-fluoroscopic intracardiac navigation system (LocaLisa3, Medtronic) allows for the first time a real-time localization of up to 4 additional catheters without fluoroscopy. Furthermore this navigation system allows exact marking of the ablation position and online controlling of the catheter's position even during RF application. This enables the physician to induce an accurate and continous lesion.

Methods: Twenty-two consecutive patients with typical atrial flutter scheduled for isthmus blockade were included. 11 patients were treated conventionally (point-by-point lesions in the septal isthmus, Marinr-4mm,70°,70W), 11 patients were ablated with the same method combined with the LocaLisa (LL)-system.

Results: The fluoroscopy time of the LL-group (8.8±4.42) min was significantly reduced compared with the control group (18,3±12 min, $p<0.01$). The duration of the procedure was 120 ±38min in the control group versus 140 ±44min ($p>.05$) in the LL-group. The efficacy of the ablation to create a complete isthmus blockade was higher using the LL-system: In 9/11 patients of this group the isthmus blockade was complete after the first lesion while in all patients of the control group gap mapping guided additional RF applications were necessary. Moreover the complication rate was lowered in the LL-group: No complication was found in the LL-group, while a temporary AV-block III appeared in 1 patient of the control group.

Conclusions: The real time 3D-navigation system LocaLisa 3 improves the safety of isthmus blockade for typical atrial flutter. The system provides easy documentation of the RF-lesions and re-navigation to former localized gaps without additional fluoroscopy. Therefore, it reduces significantly the fluoroscopy time with insignificant increase of procedure times.

P3487 Outcome of atrial flutter ablation: results from the venetian multicenter study

R. Mantovan[1], E. Marras[1], E. Bertaglia[2], A. Proclemer[3], A. Bonso[4], R. Vertlato[5], L. Corò[6], P. Stritoni[1]. *[1]Cardiovascular Department, Treviso, Italy; [2]Cardiovascular Department, Mirano (VE), Italy; [3]Cardiovascular Department, Udine, Italy; [4]Cardiovascular Department, Mestre (VE), Italy; [5]Cardiovascular Department, Camposampiero (PD), Italy; [6]Cardiovascular Department, Conegliano (TV), Italy*

Radiofrequency transcatheter ablation is a well-established procedure for atrial flutter treatment. However early and late outcome of this technique has not been fully investigated in large cohort of patients.

Methods: Radiofrequency ablation of atrial flutter was performed in 417 consecutive patients (103 female, 314 male; mean age 62 years, range 21-86) in six cardiology centers of Northeast of Italy from 1997 to 2001. Eight-mm tip catheter was employed in 337 cases, irrigated tip in 28 cases, 4mm tip in 27 cases, and 4+4mm tip in 25 cases. Inferior isthmus ablation (between tricuspid anulus and inferior vena cava) was performed in 322 patients (77%), while septal isthmus (between tricuspid anulus and coronary sinus ostium) or both isthmus ablation was performed in 95 patients (23%). Successful procedure was considered when bi-directional isthmus block was achieved.

Results: Success was achieved in 367 cases (88%). Success rate was lower using 4 mm catheter tip (52% vs 84% [4+4mm], 89% [irrigated], 91% [8mm]; $p<0.001$) and in earlier years (70% [1997], 87% [1998], 87% [1999], 90% [2000], 95% [2001]; $p<0.01$). Complications occurred in 7 patients (1.6%): 1 patient had polymorphic ventricular tachycardia during the procedure, 4 patients developed vascular complication in early post-interventional period, 2 patients (0.5%) developed complete AV block during the procedure requiring pace maker implantation. Both patients with AV block underwent septal isthmus ablation (2.1%), while no AV block occurred in patients who only underwent inferior isthmus ablation ($p<0.05$). During a mean follow up of 19 ± 36 months, atrial flutter recurred in 41 patients (9.8%). Recurrence rate was significantly higher in patients who underwent ablation with 4 mm tip comparing with 8 mm, irrigated or 4+4 mm tip catheter (11/27, 41% vs 27/337, 8%, 2/28, 7% and 1/25, 4% respectively; $p<0.001$).

Conclusions: Our data confirm that transcatheter radiofrequency ablation is a safe and effective technique for atrial flutter treatment. Four mm catheter tip should be avoided in order to increase the success and to reduce the recurrence rate. Moreover septal isthmus ablation should be avoided due to a small but significantly higher risk of complete AV block.

P3488 Ablation of typical atrial flutter using ultra sound 3D RPM mapping – long-term results

S.G. Spitzer, L. Karolyi, C. Hansen, T. Otto. *Institute of Cardiovascular Research, Dresden, Germany*

RPM is a non-fluoroscopic electro-anatomical mapping system for ablation of typical atrial flutter. In this series of 15 patients (CL 221.7 ± 20.8 ms, EF 58.2 ± 7.9%, LA 43.5 ± 4.4 mm), the ultrasound multi-transducer catheters of the RPM Mapping System (Cardiac Pathways, Realtime Position Management ™ System) were securely placed in the coronary sinus and at the right ventricular apex. The movement of the cooled steerable ablation catheter (Cardiac Pathways, Chilli rpm ™) which is also equipped with ultrasound transducers, could be depicted on the monitor at any time. Several guiding marks were set in the right atria and thus, defined the subsequent lesion lines (i.e. sinus coronarius, V. cava inferior, septal tricuspid annulus). In all 15 patients bi-directional block was achieved after 10.2 ± 6.3 single applications. The total time of intervention amounted to 102 ± 31 min. There was a strong learning curve with regard to the reduction of x-ray exposure time (last 5 patients 4.9 + 2.1). No complications occurred. The mean follow-up period was 13.9 ± 5.5 months. Rhythm follow-up data show 90% sinus rhythm, 10% atrial fibrillation, and no new recurrence of typical atrial flutter.1 patient died (non-cardiac death).

Isthmus ablation with ultrasound navigated catheters is feasible and safe. After a learning phase, the precision of linear lesions was improved and fluoroscopic exposure time considerably reduced.

P3489 Catheter-based cryoablation of atrial flutter: chronic success rate comparable to RF ablation and a painless procedure

C. Timmermans[1], G.M. Ayers[2], S. Philippens[1], H.J.G.M. Crijns[1], L.M. Rodriguez[1]. [1]*Academic Hospital Maastricht, Cardiology, Maastricht, Netherlands;* [2]*CryoCor Inc., San Diego, United States of America*

Background: Radiofrequency (RF) ablation of type I atrial flutter (AFL) has a high procedural success rate (96%) and low recurrence rate (6-9%). However, RF ablation of the right atrial isthmus (RAI) can be painful. The aim of this study was to assess the acute and chronic efficacy and procedural pain for cryoablation (cryo) of AFL.
Methods: Thirteen pts (52 ± 11 years, 11 men) with AFL (AFL only = 4; atrial fibrillation organized into AFL under antiarrhythmic drugs: class IC = 7, amiodarone = 2) underwent cryo of RAI using point-by-point applications. Mean left atrial size and LVEF was 45 ± 6 mm and 58 ± 10%. Cryo was performed with the CryoCor cryoablation system using a pre-cooler and N2O as refrigerant. Cryothermia was delivered twice, for 4 minutes, at each site along the RAI. Pain was evaluated after every application using a visual analogue scale ranging from 0 to 100.
Results: All pts were successfully ablated at a median of 8 sites (median 16 applications) along the RAI with nadir temperatures between -71 and -90°C (mean -83.4 ± 5.7°C). The fluoroscopic and procedural time was 35 ± 14 min and 3.9 ± 1.1 h. Pts did not perceive pain during the freezes. After a mean follow-up of 5 ± 3 months no recurrences of AFL occurred.
Conclusions: The acute and chronic success rate obtained with cryo of the RAI for AFL is at least as high as that seen with RF ablation. Furthermore, cryo of RAI is painless.

P3490 Irrigated-Tip versus 8-mm-Tip catheters for ablation of atrial flutter in patients with cavo-tricuspid isthmus > 35 mm. A randomized study

A. Da Costa, B. Samuel, A. Khiel, C. Robin, C. Romeyer, E. Faure, K. Isaaz. *CHU, Service De Cardiologie, Saint Etienne, France*

Background: Radiofrequency ablation (RFA) lesions are expected to be deeper with a Cooled RFA catheter (cRFA) and longer with a conventional 8mm tip catheter in patients with common atrial flutter (AFlu). It has been demonstrated that cavo-tricuspid isthmus (CTI) length may influence RFA duration. Randomized studies comparing these two RFA catheters are lacking, especially when CTI is broad. Objective. The purpose of this prospective study was to compare the efficacy and safety of these catheters for AFlu ablation in a sub-group of patients with Cavo-Tricuspid Isthmus > 35 mm. Methods. Forty-nine consecutive patients were screened and a right atrial (RA) angiography was performed before RFA. Population was divided in two groups, pts with CTI > 35 mm (n=23) and pts with CTI < 35 mm (n=24). Informed consent was not obtained from 2 pts. Patients with CTI > 35 mm were randomized to ablation with 8-mm thermocouple catheter (Saint-Jude medical) (Gp I; n=12) or irrigated 5-mm-tip thermocouple catheter (Cordis Webster Thermocool) (Gp II; n=11). RFA using an 8 mm tip ablation catheter (Boston Scientific) was performed in pts with CTI < 35 mm. The same operator performed all procedures. A 12-pole catheter was positioned in the lateral RA (LRA: pole 11-12) along the isthmus (pole 7-8; 5-6; 3-4) with its distal electrode pair in the coronary sinus origin (CSO; pole 1-2) to assess during pacing (600 ms cycle length) from pole 11-12 and pole 1-2 the complete bi-directional block. When the complete bi-directional block was not obtained after 30 minutes of RF application, a crossover was required. Results: Clinical presentation and results of RF ablation were as following between GpI (70±6 years) and GpII (70±10 years): history of AFib before ablation (4/12 vs 4/11; ns), structural heart disease (5/12 vs 7/11; ns), LV EF (59±11 vs 56±14%; ns), left atrial size (47±7 vs 49±9 mm), cavo-tricuspid isthmus dimension (39±3 vs 40±3 mm; ns), bi-directional block (96.2 vs 100%; ns), RF application (18±19 vs 20±16 minutes; ns), fluoroscopic time (19.8±16 vs 19.8±19 minutes; ns), recurrence of bi-directional block within 30 min (1/12 vs 4/11; ns), RF failure (0/12 vs 1/11; ns), crossover (3/12 vs 2/11; ns). No complication occurred. Conclusions. Preliminary results of this prospective pilot study demonstrate a similar success between cRFA and 8 mm tip catheter when Cavo-Tricuspid Isthmus is >35 mm.

P3491 Incidence, mechanisms and treatment strategies of atrial flutter following intraoperative radiofrequency ablation of atrial fibrillation (IRAAF)

A. Dorszewski, H. Kottkamp, U. Wetzel, P. Schirdewahn, G. Hindricks. *University of Leipzig, Heartcenter, Cardiology, Leipzig, Germany*

Intraoperative radiofrequency ablation has evolved a highly effective curative therapy for atrial fibrillation (AF). The IRAAF treatment concept (induction of contiguous left atrial lesion lines between the mitral annulus and the ostia of the pulmonary veins) was applied in 387 patients (pts.), in 129 pts. with AF as primary indication (group I), in 117 pts. in conjunction with minimal invasive mitral valve repair or replacement (group II), in 46 pts. with mitral valve surgery via stemotomy (group III) and in 95 pts. with other cardiac surgeries (group IV). In all pts. of group I and II the procedure was performed via minimal invasive surgical techniques (right lateral mini-thoracotomy). Freedom of AF at 6 months follow-up was 97% in group I and 87% in group II. However, 5% of pts. of group I and 7% of pts. of group II developed recurrent episodes of atrial flutter during longterm follow-up. Invasive electrophysiologic study with non-fluoroscopic mapping technology (Carto, Biosense Webster) was performed in 12 pts.. Cycle length of atrial flutter was 271±48 ms. In 3 pts. the arrhythmia mechanism was isthmus related typical atrial flutter although the surface-ECG indicated atypical flutter. These pts. underwent successful isthmus ablation. In 6 pts. left atrial re-entry evident from detailed entrainment mapping was the arrhythmia mechanism. Using 3D-electromagnetic mapping the complete left atrial re-entrant circuit could be mapped and reconstructed. Gaps in the IRAAF-lesion lines giving rise to left atrial re-entry were identified and radiofrequency application to the gap sites terminated the tachycardias in 5 of 6 cases. One pt. presented with left atrial re-entry and with typical atrial flutter, both treated successful with ablation. In 2 pts. ectopic atrial tachycardias (EAT) were revealed. In the one case the EAT originated in the AV-nodal area and in the other case in the region of the crista terminalis. Both EATs were successfully ablated. Conclusions: Atrial flutter following intraoperative ablation of AF occurs in approximately 10% of pts. treated. In the majority the flutter is due to gaps in the induced lesion lines. These gaps can be identified using 3D-electromagnetic mapping and radiofrequency ablation of gap sites cures pts. from atypical flutter. However, even if the surface-ECG suggests atypical flutter, isthmus related flutter may be present. The atypical appearance of the flutter waves in the surface-ECG in these pts. may be explained by an unusual left atrial activation due to the intraoperatively induced lesion lines.

CONTROL MECHANISMS IN MYOCARDIAL HYPERTROPHY

P3492 Unchanged expression of marker proteins of the calcineurin pathway in rats overexpressing the mouse renin gene (TG (mREN-2)27)

H. Diedrichs, C. Mei, B. Bölck, R.H.G. Schwinger. *University of Cologne, Clinic III for Internal Medicine, Cologne, Germany*

Cardiac hypertrophy is an adaptive response to many cardiac diseases with an increased afterload. While the hypertrophic response is initially a compensatory mechanism, sustained hypertrophy can lead to dilated cardiomyopathy and heart failure.
It has been argued, that various stimuli (e.g. endothelin, RAAS) finally lead to cardiac hypertrophy via a calcineurin dependent pathway. It has also been shown that in transgenic mice expressing activated forms of calcineurin or transcription factor NF-AT3 an inhibition of the calcineurin phosphatase activity with cyclosporin A (CyA) stopped the development of cardiac hypertrophy. Nevertheless, other studies failed to show an influence of CyA on the development of cardiac hypertrophy (e.g. in rats wit aortic banding).
To further elucidate the role of the calcineurin pathway in the development of cardiac hypertrophy we measured the expression of marker proteins of the calcineurin pathway (calcineurin, NF-AT3, GATA4) and the calcineurin activity in transgenic rats (TGR, n=10) with hypertension induced myocardial hypertrophy because of an overexpression of the mouse renin gene (TG(mREN-2)27). As control group we used age matched Sprague-Dawley rats (n=10).
Western blotting showed no significant diference in protein expression of calcineurin (TGR 86 ±9,9 DU, control 91 ±2,4 DU=Densitometric Units), GATA4 (TGR 13,6 ±0,9 DU, control 9,9 ±1,8DU) or NF-AT3 (TGR 100,5 ±1,0 DU, control 98,1 ±1,5 DU). The rt-PCR confirmed the equivalent results between TGR and control group on mRNA level. In addition we measured the calcineurin activity with a phosphatase assay and found no difference between TGR and control, too. In conclusion, we could not find an activated calcineurin pathway in transgenic compared to Sprague-Dawley rats.
Thus, at least in this renin overexpressing rat model, cardiac hypertrophy may result from a calcineurin independent stimulation.

P3493 Differential regulation of the calcineurin genes in human cardiac hypertrophy and in ischaemic and dilated cardiomyopathy

J. Bass, U. Gemke, R. Pregla, A. Steege, A. Doller, H.R. Zurbrügg, R. Hetzer, V. Regitz-Zagrosek. *Deutsches Herzzentrum Berlin, Berlin, Germany*

In some animal models of cardiac hypertrophy and heart failure, the dimeric phosphatase calcineurin (Cn) is upregulated in the myocardium. Its targeted inhibition prevented myocardial hypertrophy and failure. The isoforms of the catalytic subunit CnAalpha, beta and gamma and CnB are differentially regulated by hypertrophic stimuli. In order to characterize different forms of human myocardial hypertrophy, we determined the CnAalpha, CnAbeta(β) and CnB mRNA together with markers of hypertrophy (ANP, BNP) in samples from patients with cardiac hypertrophy due to aortic stenosis and with heart failure due to dilated (DCM) and ischemic cardiomyopathy (ICM).

We measured CnAalpha, CnAβ, CnB, ANP and BNP mRNA in left ventricular samples taken during aortic valve surgery from 10 patients with aortic valve stenosis (AS, n=10, LV EF: 44 ± 6%) and from explanted failing hearts from patients with DCM (n=27) and ICM (n=7) after informed consent. As controls, 15 unused donor hearts with normal systolic function were used. mRNA was quantitated by real-time PCR (PE 5700). Target gene mRNA was related to the stably expressed GAPDH mRNA from the same sample. Data are given as medians; Kruksal Wallis and Wilcoxon tests were used.

Differential upregulation of the isoforms of the catalytic subunit CnA was found. CnAalpha was sign. increased in AS (194% of con, $p<0.05$), but not in DCM (120%) and not in ICM (102%). CnAβ mRNA was increased in AS (215%) and DCM (188%, $p<0.0.01$ both), but not in ICM (126%). The regulatory subunit CnB exhibited a tendency towards a decrease in AS (50% of con, ns) and ICM (79%, ns) with a great interindividual variability. In contrast, CnB was significantly upregulated in DCM (292%). ANP and BNP mRNA were upregulated in AS and DCM, but correlated only weakly with the Cn genes.

The regulation of CnA and CnB genes and their subunits is different in human cardiac hypertrophy, ICM and DCM and may represent a useful marker for the transition from compensated hypertrophy to heart failure or even a clue for their differentiation at a molecular level.

P3494 Pressure-overload cardiac hypertrophy in mice with a gene-targeted disruption of the NADPH oxidase subunit gp91phox

J. Byrne, D.J Grieve, J.K Bendall, A.C Cave, A.M Shah. *GKT School of Medicine, Cardiology, London, United Kingdom*

Increased oxidative stress is suggested to be involved in the pathophysiology of left ventricular hypertrophy (LVH). We have previously shown that a phagocyte-type NADPH oxidase that generates reactive oxygen species (ROS) is expressed in the heart and plays a pivotal role in the cardiac hypertrophic response to angiotensin II. In this study, we investigated the response to pressure overload in gene-modified mice lacking the gp91phox subunit of NADPH oxidase (which is critical for ROS generation) and matched wild-type controls (C57/BL6J).

Adult male wild-type and gp91phox knockout mice (16-20g) underwent suprarenal abdominal aortic banding (8.0 nylon suture tied around a 29 gauge needle; ~70% constriction) or sham surgery. One week post-surgery, the LV/body weight ratio was ~25% higher in wild-type bands versus shams (3.91 ± 0.13 vs 3.14 ± 0.11; $P<0.05$) and ~27% higher in banded gp91phox-/- mice versus shams (4.29 ± 0.05 vs 3.38 ± 0.11; $P<0.05$; n=4 per group). At 2 weeks post-op, LV/body weight ratio was 42.5% higher in banded wild-types (4.57 ± 0.29 vs 3.21 ± 0.07) and 43.2% higher in banded knockouts (4.87 ± 0.18 vs 3.4 ± 0.07) versus respective sham controls. Expression of atrial natriuretic factor mRNA (semi-quantitative RT-PCR) was higher ($P<0.05$) in both banded groups relative to their sham controls (wild-type: 16.7 ± 2.1 vs 2.3 ± 0.1 densitometric units; gp91phox knockouts: 19.3 ± 3.6 vs 2.9 ± 1.5 units). NADPH-dependent O2- production was measured in LV homogenates by lucigenin (5μM)-enhanced chemiluminescence. Wild-type banded mice had higher O2- production cf. the sham group (3.85±0.24 vs 2.77±0.31 arbitrary light units; P=0.07, n=6). The banded gp91phox-/- animals also had a similar increase in O2- production compared to their sham controls (5.82 ± 0.55 vs 2.88 ± 0.52 arbitrary light units; $P<0.05$). NADPH-dependent O2- production was inhibited by the flavoprotein inhibitor diphenyleneiodonium in all groups but not by L-NAME.

Conclusion A similar increase in LV mass is seen in both wild-type and gp91phox-deficient mice in response to pressure overload. The increase in LV NADPH oxidase activity in banded gp91phox-/- mice suggests that a non-gp91phox-containing oxidase contributes to ROS production during pressure overload. Whether this ROS production is involved in the development of LVH merits further study.

P3495 Heart rate variability in two different patterns of left ventricular hypertrophy and geometry

C. Gürgün, A. Abbasaliyev, M. Zoghi, O. Yavuzgil, U. Ertürk. *Ege University, Cardiology, Izmir, Turkey*

In this study, we investigated the heart rate variability (HRV) indexes in two different types of left ventricular hypertrophy (LVH) model as in patients with hypertrophic cardiomyopathy (HCM) and essential hypertension. There were 25 patients (m/f: 11/14, mean age: 48±9) in HCM group, 25 patients (m/f: 10/15, mean age: 51±7) in hypertensive left ventricular hypertrophy (HLVH) group and 25 healthy subjects (m/f: 12/13, mean age: 50±4) in control group. After the echocardiographic examination, all patients underwent 24 hours Holter ECG monitoring for the assessment of HRV indexes (pNN50, RMSSD and SDNN). The SDNN, RMSSD, pNN50 values from the HRV indexes are compared for the three groups (HCM, HLVH and control groups), differences between groups are found reasonable. SDNN (msec), RMSSD (msec), pNN50 (%) values (130.56±17.6, 28.4±10.4 and 6.5±4.0 respectively) in HCM group were found significantly lower than the control group (156.1±27.7, 44.1±19.8 and 12.8±8.1 respectively, $p<0.05$). There was no significant difference between HLVH and control groups for the SDNN index of HRV (137.8±33.6 versus 156.1±27.7 msec). However RMSSD and pNN50 indexes reflecting parasympathetic tonus were found as reasonably lower in HLVH group than control group (30.8±13.0 versus 44.1±19.8 msec and 8.1±6.3 versus 12.8±8.1%, respectively, $p<0.05$). No significant difference for the HRV indexes was detected between the HCM and HLVH groups. We couldn't find any relationship between HRV indexes and left ventricular outflow track obstruction, arrhythmias and syncope in HCM and HLVH patients. There was negative correlation between parasympathetic parameters of HRV and left atrial dimensions in HCM group, but not for HLVH group.

	HCM	HLVH	CONTROL	P
Heart Rate(msec)	76±9	73±14	75±8	n.s.
Mean RR(msec)	761.3±70.2	780.5±90.8	795.1±79.1	n.s.
SDNN(msec)	130.5±17.6	137.8±33.6	156.1±27.2	0.004
RMSSD(msec)	28.4±10.4	30.8±13.0	44.1±19.8	<0.001
PNN50(%)	6.5±4.0	8.1±6.3	12.8±8.1	0.002

In conclusion; HRV indexes are decreased in patients with left ventricular hypertrophy. The shape of hypertrophy doesn't seem to have an effect on HRV indexes. HRV parameters could not be used as predictors of the arrhythmias and syncope in patients with HCM or HLVH.

P3496 Different actions of irbesartan and atenolol on cardiac repolarisation in hypertensive left ventricular hypertrophy

K. Malmqvist, T. Kahan, M. Edner, L. Bergfeldt, T. Kahan, M. Edner, L. Bergfeldt. *Danderyds Hospital, Cardiology, Stockholm, Sweden*

Purpose: Left ventricular hypertrophy (LVH) is associated with a substantial risk for malignant arrhythmias and sudden death. The effects of antihypertensive therapy on QT dispersion, which reflects cardiac repolarization heterogeneity, in relation to changes in left ventricular mass are not well studied.

Subjects and Methods: Ninty two hypertensive patients with LVH were randomized double-blind to receive the angiotensin II type 1 receptor blocker irbesartan (n=44) or the beta1-receptor blocker atenolol (n=48) for 48 weeks. An age and gender matched control group consisted of 37 hypertensive subjects without LVH. Echocardiography and electrocardiogram(standard 12 lead, 50 mm/s)were performed at 0, 12 and 48 weeks. QT intervals were measured with a digitizing table by one person in a blinded fashion.

Results: Left ventricular mass index related to QT dispersion ($r=0.34$, $p<0.001$) and the duration of ventricular repolarization (the JT interval) but not the depolarization (the QRS interval) was dependent on the degree of LVH. The reduction in left ventricular mass was greater by irbesartan than by atenolol (-27±28 vs. -15±21 g/m^2 at 48 weeks, $p=0.021$), by similar reductions in blood pressure. Irbesartan decreased QT dispersion (from 56±24 to 45±20 ms at 48 weeks; $p<0.001$), and QTc dispersion (from 57±24 to 44±19 ms at 48 weeks; $p<0.001$). In contrast, atenolol had minor effects. Thus, decreases in QT and QTc dispersions were greater by irbesartan than by atenolol ($p=0.001$ and $p=0.011$, respectively), also when changes in left ventricular mass, blood pressure and heart rate were included in multivariate analyses.

Conclusion: Heterogeneity of ventricular repolarization is related to the degree of myocardial hypertrophy. Irbesartan, but not atenolol, reduces QT and QTc dispersions independent of changes in left ventricular mass, blood pressure, or heart rate. Thus, irbesartan may induce structural and electrical remodeling in a direction that could decrease the risk of fatal events in hypertensive patients.

P3497 Angiotensin II increases cell-matrix-interaction by activation of integrin-associated kinases in cardiac fibroblasts

K. Graf, P. Stawowy, M. Graefe, R. Gebker, F. Blaschke, E. Fleck. *Deutsches Herzzentrum Berlin, Cardiology, Berlin, Germany*

Activation of the cardiac renin angiotensin system is leads to proliferation of cardiac fibroblasts and myocardial fibrosis. Angiotenin II (AngII) induces synthesis of matrix- and adhesion proteins by cardiac fibroblasts. We have demonstrated that receptors for matrix proteins, integrins, are induced in a model of cardiac hypertrophy. In the present study we investigated the effect of AngII on β1-integrin mediated adhesion and cell contractility on collagen I (Col1), collagen III (Col3) and fibronektin (Fn) in cardiac fibroblasts from adult rat hearts (CFBs). Adhesion and cell contractility (measured by a spreading assay) is mainly mediated via auf β1-Integrin on these meatrices. A blocking antibody against β1-Integrin (50μg/mL) inhibited adhesion by 55% (Col3) and 85% (Col1, Fn). Spreading was blocked to comparable amount by this antibody. Treatment of CFBs with 1 μM AngII for 2 to 48 hours induced a concentration-dependent increase of adhesion to Col1 (2.2-fold, $p<0.01$), Col3 (1.9-fold, $p<0.01$) and Fn (2.4-fold, $p<0.01$). These effects have been blocked by the selective AT1 receptor-blocker irbesartan, but not by the AT2 receptor-blocker PD 123319. The effect of AngII was prevented by MAP Kinase inhibitor PD98059 and the PI3kinase inhibitor Wortmanin, which inhibits the activation of AKT. The effects of AngII were associated with the activation of integrin-assocoaited kinases. AngII induced the phosphorylierung of FAK (2-fold, $p<0.05$), Pyk2 (4-fold, $p<0.01$), AKT (3-fold, $p<0.05$) and MAP Kinase (5-fold, $p<0.01$) in CFBs. However, there was no significant change of β1-integrin mRNA in CFBs, nor an increased expression of β1, alpha1, alpha2 and alpha5-integrins after stimulation with AngII detected by flow cytometry. These data indicate, that the effect of AngII on adhesion is mediated via MAP Kinase and AKT, and leads to an increase of β1-integrin binding activity (avidity) whithout effect the xpression levels of integrin receptor in cardiac fibroblasts.

P3498 Changes in anisotropy associated with cellular architecture, and connexin43 expression in a guinea-pig model of left ventricular hypertrophy

W. Hussain[1], P.M. Patel[1], P. Carey[1], N.J. Severs[2], D.J. Sheridan[1], C.H. Fry[3], N.S. Peters[1]. [1]*Imperial College, St Marys Hospital, Cardiac Electrophysiology, London, United Kingdom;* [2]*Imperial College, London, United Kingdom;* [3]*University College, Institute of Urology, London, United Kingdom*

We have previously reported changes in conduction velocity and a reduction in anisotropy in left ventricular hypertrophy (LVH), and hypothesised that this results from changes in the topology of gap junctional coupling and cellular architecture as the principal determinants of intercellular conduction. LVH was induced in guinea pigs by a constrictive clip on the thoracic aorta. Papillary muscles were excised from banded and sham-operated animals 50 to 250 days post-operation. Conduction velocity (CV) was measured (by multiple intracellular impalements) in the longitudinal and transverse axes. Quantitative confocal immunodetection of Cx43 in 6 randomly selected highly confocal (<1mm) slices was performed. Cellular architecture was studied using serial sections. In LVH, there was an increase in cell size (LVH 407.5±106.4mm^2 and sham 278.3±76.2mm^2 $p=0.0027$), cell-to-cell contacts from 5.67±0.97 to 8.11±1.28 ($p<0.0001$) and in the number of intercalated disks per cell (8.22±2.16 to 10.22±1.22 $p<0.002$). However, the number of contacts between any two individual cells decreased from 1.46±0.34 to 1.24±0.15($p<0.02$). There was no change in the proportion of end-to-end connections or the number of intercalated disks per cm in both axes. In LVH Cx43 expression per cell correlated ($p<0.0001$ $r=0.76$ $n=20$) with an increased transverse conduction velocity (29.3 ± 9.6 cm/s vs. 20.5± 4.5 $p=0.007$) and with a corresponding decrease in transverse resistivity ($p<0.003$ $r=0.47$ $n=22$). However, there was no association between Cx43 expression per cell and either the reduced longitudinal conduction velocity (72.8±15.5 to 63.6±11.1 $p<0.05$) or the increased longitudinal intracellular resistivity (776±279 vs 411±124 $p<0.05$).

In LVH, an increase in transverse conductance resulting from an increase in cell to cell contacts, intercalated disks, cell size and Cx43 expression is associated with a corresponding increase in transverse conduction velocity and reduced anisotropy.

P3499 Electrophysiological remodelling in the diabetic heart: prevention by angiotensin II receptor blockade

P. DePaoli, L. Raimondi, G. Lonardo, R. Pirisino, A. Mugelli, E. Cerbai. *University of Firenze, Dept. Pharmacology, Firenze, Italy*

Electrophysiological abnormalities of the myocardium have been identified in diabetes, likely related with an increased risk of arrhythmias and sudden death. An upregulation of local renin angiotensin system occurs in human and rat diabetic heart. Since chronic stimulation of angiotensin II receptors (AT1) leads to cardiac remodeling in several physiopathological settings, we investigated the possible beneficial effect of AT1 blockade in a rat model of diabetes-related cardiomyopathy.

Methods: We analyzed the electrophysiological properties of ventricular cardiomyocytes (VCM) from diabetic rat hearts, with or without treatment with 20 mg/Kg/day losartan (LOS). Diabetes was induced by a single injection of streptozotocin (STZ, 55 mg/kg). One group of rats received LOS (STZ+LOS) in the drinking water beginning from 1 week before diabetes induction up to 3 weeks later. Age-matched rats, treated (Ctr+LOS) and not treated with LOS (Ctr), were used as controls. LOS treatment did not affect body weight, plasma glucose levels and water consumption of diabetic and control animals. Patch-clamped VCM were superfused with a normal Tyrode's solution (to measure action potential, AP) or appropriately modified Tyrode's solutions (to measure transient outward current, TO).

Results: Membrane capacitance, an index of cell size, was similar in all groups. Action potential duration at 90% repolarization (APD90) was significantly prolonged in STZ compared to Ctr rats (144±13 ms, n=28, vs. 106±10 ms, n=28, $p<0.05$). All the other AP parameters were unchanged. APD prolongation was paralleled by a significant decrease of maximum TO density in the STZ group (Ctr: 19.3±2.4 pA/pF, n=23; STZ: 12.6±1.4, n=34 pA/pF) ($p<0.05$). Pretreatment with LOS did not affect AP profile in Ctr rats, but significantly shortened its duration in diabetic rats: APD90 was 100±11 ms in STZ+ LOS rats (n=20; $p<0.05$ vs. STZ). The effect was comparable also at higher driving rate (1 Hz instead of 0.2 Hz), APD90 being 153% of Ctr in STZ cells and 113% of Ctr in STZ+LOS cells ($p<0.05$ vs. STZ). Normalization of APD by LOS was accompanied by restoration of TO density, which recovered to 18.7±1.8 pA/pF in STZ+LOS (n=36, $p<0.05$ vs. STZ). Time constant of TO recovery from inactivation was similar in Ctr (33.1 ms), STZ (36.2 ms) and STZ+LOS rats (35.9 ms).

Conclusions: these results demonstrate that AT1 blockade protects the heart from the development of electrophysiological alterations typically associated with diabetes, and suggest that it may represent a new therapeutic strategy against the arrhythmogenic risk in this setting.

P3500 Increased production of reactive oxygen species in hypertrophied myocardium: in vivo study by microdialysis technique

E. Ruuge[1], E.A. Gorodetskaya[1], E.I. Kalenikova[1], A.N. Murashev[2], O.S. Medvedev[3]. [1]*Cardiology Research Center, Institute of Experimental Cardiology, Moscow, Russian Federation;* [2]*RAS, Institute of Organic Chemistry, Pushchino, Russian Federation;* [3]*Moscow State University, Faculty of Basic Medicine, Moscow, Russian Federation*

There has been considerable interest in the role of reactive oxygen species in the pathogenesis of myocardial injury. The aim of our study was to investigate the production of oxygen free radicals in the myocardium of Wistar and Wistar-Kyoto rats and SHR-SP using microdialysis technique.

Methods: Experiments were carried out on anaesthetized open-chest male rats ventilated with oxygen from room air supplement. The linear microdialysis probe was inserted in the left ventricle wall and then perfused at the rate of 3 il/min with Ringer solution containing sodium salicylate. 2,3-dihydroxybenzoic acid (2,3-DHBA) produced in the reaction of oxygen radicals with salicylate was measured in dialysis samples by high-performance liquid chromatography and used as an indicator of the rate of oxygen radical production in myocardium.

Results: Dialysate sampling started 60 min after the probe implantation, and the baseline level of 2,3-DHBA was established in each experiment. Some quantity of 2,3-DHBA was always present in the perfusion fluid due to the exogenous salicylic acid oxidation. Mean baseline values of 2,3-DHBA in dialysate samples were not notably different (112±8.7%, n = 5) from the values of 2,3-DHBA in perfusion fluid in Wistar-Kyoto rats, but were significantly lower (87±3.2%, n = 6, $p < 0.03$) in Wistar rats and significantly higher (154±1.1%, n = 7, $p < 0.001$) in SHR-SP. We believe that this is the first report of in vivo registration of the elevated basal level of reactive oxygen species in hypertrophied myocardium of SHR-SP by high-sensitive microdialysis technique. The basal 2,3-DHBA in SHR-SP was positively correlated ($r = 0.83$, $n = 7$, $p < 0.05$) with degree of left ventricle hypertrophy expressed as a ratio of left ventricle weight to the body weight.

Conclusion: The results of our experiments demonstrate that the left ventricle hypertrophy in SHR-SP is accompanied by considerably higher rate of oxygen radical production.

GENE POLYMORPHISM IN CORONARY ARTERY DISEASE

P3501 PLA gene polymorphism in patients with acute coronary syndromes

E. Papp[1], L. Czopf[1], Z.S. Márton[1], E. Szabados[1], E. Magyar[1], I. Juricskay[1], B. Melegh[2], K. Tóth[1]. *[1]University of Pécs, School of Medicine, First Department of Medicine, Pécs, Hungary; [2]University of Pécs School of Medicine, Department of Human Genetics, Pécs, Hungary*

Platelet glycoprotein IIb/IIIa receptor plays an important role in platelet aggregation. Glycoprotein IIIa is polymorphic (PLA1 and PLA2), and the PLA2 variant may be strongly associated with increased risk of acute coronary syndromes. The protective role of acetylsalicylic acid (ASA) in ischemic heart disease is well known. ASA resistance can be detected in about 30% of the population, thus we routinely measure platelet aggregation in patients with acute coronary syndromes. The aim of our study was to examine the prevalence of PLA2 allele in acute coronary syndrome patients with or without ASA or ticlopidine resistance and in the healthy population. Methods: Prevalence of PLA2 gene was examined in 103 consecutive patients (31 females, 72 males, age: 61.1 ± 13.0 years) with acute coronary syndromes and in the healthy population using polymerase chain reaction (PCR). 30 of the 103 patients (29.1%) were found ASA or ticlopidine resistant (14 females, 16 males, age: 66.1 ± 8.5 years). Results: PLA2 polymorphism was found in 39.8% of patients with acute coronary syndromes, in 50.0% of acute coronary syndrome patients with ASA or ticlopidine resistance and in 15.6% of the healthy population. The prevalence in both patient groups was significantly higher than the prevalence in the healthy population ($p<0.05$). Among patients with acute coronary syndromes those having ASA or ticlopidine resistance have a significantly higher prevalence of PLA2 allele than non-resistant patients ($p<0.05$). Conclusion: Our results support the hypothesis that the PLA2 allele occurs more frequently in patients with acute coronary syndromes especially in those with ASA or ticlopidine resistance.

P3502 Gender-specific gene environment interaction between CA repeat polymorphism of eNOS gene and homocysteine in acute coronary syndromes

V. Stangl[1], C. Meisel[2], M. Laule[1], I. Prauka[1], I. Roots[2], G. Baumann[1], K. Stangl[1]. *[1]Charité, Humboldt University, Cardiology, Campus Mitte, Berlin, Germany; [2]Charité, Humboldt University, Clinical Pharmacology, Berlin, Germany*

The CA repeat polymorphism in intron 13 of the endothelial nitric oxide (eNOS) is associated with an excess risk of coronary artery disease. We have recently shown in 1000 consecutive patients with angiographically confirmed coronary artery disease and 1000 age- and gender-matched control patients that the presence of one allele containing >=34 CA repeats is associated with an excess risk of coronary artery disease.

Hyperhomocysteinemia (Hhcy) interacts by several mechanisms with the NO system favouring endothelial dysfunction and vasospasm. Since Hhcy appears to be an independent cardiovascular risk factor for acute coronary events, we investigated a possible interaction between Hhcy and the eNOS CA repeat polymorphism.

The median value of homocysteine (Hcy) in our study population was 9.4 μmol/l. Accordingly we determined the relative risk of acute coronary events for Hcy values > 9.4 μmol/l and < 9.4 μmol/l at different CA repeat cut off values (>=35, >=36, >=37, >=38, >=39 CA repeats). For the entire CAD group (n=1000) acute coronary syndromes (ACS) were not significantly associated with the CA repeat number. However, in females with Hcy >9.4 μmol/l the relative risk for developing ACS increased significantly from 1.7 (confidence interval 0.7-4.3; not significant) at cutoff >= 35 Ca repeats, 4.9 (1.7-13.6; p=0.003) >=36 Ca repeats, 11.2 (2.9-41.9; p<0.001) at >=37 CA repeats, to 18.3 (1.9-173.2; p<0.006) at >=38 Ca repeats. This effect modification was not observed in men.

These data suggest a gender-specific gene environment interaction between the CA repeat eNOS polymorphism and homocysteine in ACS.

P3503 Acute-phase levels of plasminogen activator inhibitor-1 (PAI-1) and the 4G/5G PAI-1 promoter polymorphism

F. Andreotti[1], F. Burzotta[2], A. Di Castelnuovo[3], R. Schiavello[2], M.B. Donati[3], A. Maseri[2], G.F. Possati[2], L. Iacoviello[3]. *[1]Rome, Italy; [2]Catholic University, Cardiovascular Medicine, Rome, Italy; [3]M Negri Sud, Vascular Medicine and Pharmacology, S Maria Imbaro, Italy*

Background: The 4G/5G plasminogen activator inhibitor-1 (PAI-1) promoter polymorphism is known to modulate basal PAI-1 levels and to affect prognosis in severely traumatized patients. We hypothesized that the 4G/5G genotype might also influence the acute-phase levels of PAI-1 in patients undergoing coronary-artery surgery. As a secondary point, we assessed the association of PAI-1 genotype and PAI-1 levels with in-hospital course.

Methods: 111 stable patients with multivessel coronary artery disease undergoing elective coronary-artery by-pass grafting were investigated. Plasma PAI-1 activity and antigen levels were measured by ELISAs in samples taken before surgery, daily up to 72h, and at discharge. Serial levels of white-cell count, fibrinogen, C-reactive protein and interleukin-6 were also assessed. Plasma was collected in citrate with antiplatelet agents. Genomic DNA was extracted by standard procedures. The PAI-1 -675 4G/5G polymorphism was determined as previously described. Age >80 years, left ventricular ejection fraction <30%, urgent revascularization, renal, hepatic or respiratory insufficiency, active infection, and chronic anti-inflammatory therapy were reasons for exclusion.

Results: PAI-1 activity and antigen concentrations increased approximately two-fold after surgery, peaking at 48 hours. Carriers of the 4G-allele, compared with 5G/5G homozygotes, showed higher PAI-1 activity and antigen levels both preoperatively (P=0.007 and P=0.035) and after surgery. In multivariate analysis, 4G/5G genotype was the only significant modulator of postoperative PAI-1 activity (P=0.003) and the main significant modulator of postoperative PAI-1 antigen (P=0.013). The effect of genotype on PAI-1 was not specific for the acute-phase, as the interaction between time and genotype effects was not significant (i.e., higher postoperative levels reflected higher baseline values). PAI-1 concentrations (peak - baseline), but not PAI-1 genotype, correlated with length of stay in the intensive-care unit and in-hospital (P=0.0026 and P=0.0014 for PAI-1 activity, P<0.00014 and P<0.0001 for PAI-1 antigen), independently of age and of changes in white-blood cell count, fibrinogen, C-reactive protein and interleukin-6.

Conclusions: These data, in patients undergoing elective coronary-artery surgery, suggest that the 4G/5G polymorphism modulates basal PAI-1 concentrations and, as a consequence, the acute-phase levels of PAI-1. In these patients, postoperative PAI-1 concentrations appear to associate with length of stay in hospital, independently of other acute-phase changes.

P3504 The p22 phox gene polymorphism and altered coronary endothelial dependent vasodilator capacity

A. Darwish, Sahar A.F. Hammoudah. *Tanta university hospital, cardiac, Tanta, Egypt*

Oxidative stress in the vasculature induced by .O2- has been implicated in the pathogenesis of CAD. The sources of .O2- in the vasculature are diverse and include VSMCs, endothelial cells, and macrophages. C24T2T p22phox NADH/NADPH oxidase polymorphism result in substitution of Tyr for His residue 72 which might may modulate enzyme activity by affecting heme binding. Recent data suggest that the CYBA 242T allele is associated with the increased progression of coronary disease.

This study was designed to detect the association between C242T polymorphism of the p22phox gene and the endothelium-dependent vasodilator capacity of human coronary arteries through the assessment of endothelium-mediated flow-dependent dilation and nitroglycerin, which is endothelium-independent.

Methods and Results: NADH/DAPH oxidase p22 phox polymorphism was determined; in 80 patients; by restriction fragment length polymorphism (RFLP). The vasodilator function of the epicardial arteries were assessed by endothelium-mediated flow-dependent dilation and nitroglycerin, which is endothelium-independent. A significant blunted endothelium-dependent dilator response was found in carriers of the CC genotype of the C242T P22 phox polymorphism (n=37) (12.0+ 8.9 luminal area change Vs 16.9+9.7 P=0.007), which was by multivariate analysis, independent of other risk factors or atherosclerosis itself. Carriers of p22 phox CC genotype show also a trend towards decreased endothelium-independent dilation.

Conclusion: From the present study it could be concluded that, C242T polymorphism of the p22 phox gene is an important determinant of coronary endothelial vasodilator function that is independent of the presence or absence of atherosclerotic disease, as well as coronary risk factors.

P3505 Not the atherosclerotic burden nor progression of atherosclerosis explain the cardiac event rate in relation to the E/D298 ecNOS polymorphism

W.R.P. Agema[1], J.W. Jukema[2], M.P.M. de Maat[3], E.J.M. Feskens[4], A.H. Zwinderman[5], J.J.P. Kastelein[6], T.J. Rabelink[7], E.E. van der Wall[1]. *[1]Leiden University Medical Center, Cardiology, Leiden, Netherlands; [2]the Netherlands, Interuniversity Cardiology Institute, Utrecht, Netherlands; [3]TNO-PG, Gaubius Laboratory, Leiden, Netherlands; [4]National Institute of Public Health, Epidemiology, Bilthoven, Netherlands; [5]Amsterdam Medical Center, Clinical Epidemiology and Biostatitics, Amsterdam, Netherlands; [6]Amsterdam Medical Center, Vascular Medicine Dept., Amsterdam, Netherlands; [7]University Medical Centre Utrecht, Vascular Medicine and Nephrology, Utrecht, Netherlands*

Nitric oxide (NO) plays a central role in endothelium-dependent dilatation of coronary arteries. Endothelial constitutive nitric oxide synthase (ecNOS) is the key enzyme in determining basal vascular wall NO production. The E/D298 polymorphism in the gene coding for ecNOS has been associated with an increased risk for myocardial infarction (MI). We investigated the impact of this ecNOS polymorphism on progression of atherosclerosis and cardiovascular events in patients with coronary artery disease (CAD) and compared the frequency distribution to a sample of the general population.

Methods: Patients were enrolled in the REGRESS trial which studied the impact of pravastatin therapy on CAD. Progression of atherosclerosis was determined using quantitative coronary angiography measuring changes in mean segment diameter (MSD) and minimum obstruction diameter (MOD) at baseline and after two years. Controls without known CAD matched for gender and age were taken from the general population. A total of 755 and 574 subjects were genotyped in the patient and reference group respectively.

Results: The rare allele (D) was present in 38.9% (95%CI 36.0%-41.7%) of the normal population. The preliminary data show that the genotype distribution differed significantly between subjects with and without CAD (EE and ED vs DD: OR 1.55, 95%CI 1.12-2.14). Within the CAD group, patients with the EE genotype more often had a history of MI than patients with the DD genotype with heterozygotes having an intermediate risk: 51% vs 47% vs 32%, p=0.009. However, there was no relationship between genotypes and baseline atherosclerotic burden or progression of atherosclerosis (MSD/MOD) in either the placebo or the pravastatin group.

Conclusions: The ecNOS EE genotype is associated with previous MI in CAD patients. Furthermore, this genotype is associated with CAD compared to the general population. This phenomenon is most likely due to differences in vasoreactivity since differences in atherosclerotic burden and progression of coronary atherosclerosis were absent.

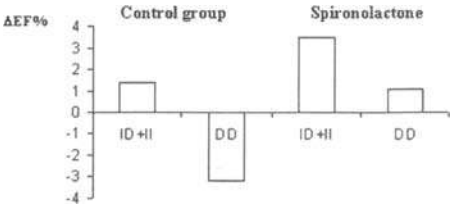
P3506 Angiotensin-converting enzyme gene polymorphism predicts the antiremodelling effects of spironolactone in chronic heart failure patients

M. Cicoira, A. Rossi, L. Zanolla, G. Golia, L. Franceschini, G. Brighetti, M. Pilati, P. Zardini. *Divisione Clinicizzata di Cardiologia, Dip scienze biomediche e chirurgiche, Verona, Italy*

Purpose: In chronic heart failure (CHF) spironolactone (SP) improves survival; preliminary studies suggest an effect of this drug on left ventricular function. We aimed at assessing the contributory role of the angiotensin-converting enzyme (ACE) gene polymorphism on the antiremodeling effects of SP in CHF patients.

Methods: We randomised 89 CHF outpatients already on chronic treatment with ACE-inhibitors to SP, 25 mg od (n=47), or control group (n=42). Patients underwent genetic analysis and an echocardiographic evaluation at baseline and at 12 month follow-up, with measurement of left ventricular end-systolic volume (ESV) and ejection fraction (EF).

Results: At baseline, mean EF was 34±7%, and mean ESV 176±86 mL. Twenty-three patients (26% of total) had a DD genotype, 50 (56%) had an ID genotype and sixteen (18%) an II genotype. EF improved after SP treatment only in patients with the ID or II genotype, while it significantly decreased in patients with the DD genotype in the control group (ANOVA, p=0.03;figure 1). ESV at follow-up decreased compared with baseline after SP treatment only in patients with the ID or II genotypes, while it did not change in patients with the DD genotype (-26±31mL and 0±30 mL, respectively) and did not change in the control group (II+ID genotype: -3±35 mL, DD genotype: 1±41mL) (ANOVA, p=0.06).



Conclusions: SP significantly improves left ventricular EF and has a borderline effect on ESV only in the ID or II genotype. In patients with the DD genotype, SP administration prevents worsening of contractile function over time. Our results suggest that the effects observed during aldosterone antagonism in CHF patients might be at least in part genetically determined.

P3507 Associations of HFE gene polymorphisms with pre-transplant diagnosis and the development of cardiac transplant related vasculopathy

H. A. Branford White[1], C.G. Densem[1], J.E. Fildes[1], A.K. Deiraniya[1], N. Yonan[1], N.H. Brooks[1], B.G. Keevil[2]. *[1]Wythenshawe Hospital, Transplant Centre, Manchester, United Kingdom; [2]Wythenshawe Hospital, Department of Biochemistry, Manchester, United Kingdom*

Ischaemic heart disease (IHD) is the most common indication for heart transplantation. Abnormal iron metabolism has been postulated as an important risk factor for IHD. Hereditary haemochromatosis is a genetic disorder of iron overload common amongst people of Northern European descent. The gene encoding haemochromatosis, HFE, contains two polymorphic regions, C282Y and H63D which influence iron metabolism. We investigated the prevalence of these polymorphisms in a cohort of cardiac transplant recipients. We also related the genotypes to the development of cardiac transplant related coronary vasculopathy (CV). Genomic DNA from 143 heart transplant patients was analysed for C282Y and H63D polymorphisms using polymerase chain reaction and single strand conformational polymorphism. This was related to the pre-transplant diagnosis using contingency testing. CV was diagnosed at routine surveillance coronary angiography. Kaplan Meier survival analysis and log rank testing was used to assess for significance. We found that of patients transplanted for end-stage heart failure 56.6% had a preceding diagnosis IHD; 43.4% had non-ischaemic cardiomyopathy. H63D and C282Y homozygotes made up 80.4% and 85.3% of the cohort respectively. H63D heterozygotes were over-represented in the ischaemic relative to non-ischaemic groups; 25.9% vs. 11.2% ($p<0.05$). No difference was found in the prevalence of C282Y heterozygotes; 16.0% IHD vs. 12.9% non-IHD (p=NS). However, C282Y heterozygotes were much less likely to develop post-transplant CV; 46.0% vs. 81.0% disease free at 5 years for CC and CY respectively (p=0.035). H63D had no influence on CV development. To conclude, heterozygosity for H63D may be a risk factor for the development of end-stage ischaemic myocardial dysfunction requiring transplantation. Previous studies report conflicting evidence on the effects of C282Y and coronary artery disease, however, we found that heterozygosity for the C282Y polymorphism may be protective against cardiac transplant related coronary vasculopathy.

P3508 A deletion in the transcriptional activator EYA4 leads to dilated cardiomyopathy with sensorineural hearing loss

J. Schönberger[1], H. Levy[2], J.B. Kim[2], E. Grünig[3], H. Katus[4], C.E. Seidman[2], J.G. Seidman[2]. *[1]University Hospital Wuerzburg, Department of Medicine, Wuerzburg, Germany; [2]Harvard Medical School, Department of Genetics, Boston, United States of America; [3]University of Heidelberg, Department of Medicine III, Heidelberg, Germany; [4]University Hospital Lübeck, Department of Medicine II, Lübeck, Germany*

25% of Dilated Cardiomyopathies are familial. The few gene defects identified so far, have led to the hypothesis that Dilated Cardiomyopathy is a disease of the cytoskeleton. We report for the first time about a mutation in a transcription factor (EYA4), which leads to a dilated cardiomyopathy accompanied by sensorineural hearing loss. A 5kb heterozygous deletion, which affects exons 9 and 10, presumably leads to a severe truncation of the EYA4 protein. This leads to the loss of the conserved EYA domain as well as a loss of a substantial part of the variable domain. In adult human tissue, EYA4 shows highest expression levels in cardiac and skeletal muscle. Recently described further carboxy-terminal truncating mutations in EYA4 lead to isolated Sensorineural Hearing Loss. We conclude, that the distal portion of the variable region contains a function, that is essential for the cardiac-specific activity of EYA4. EYA4 is one of the four vertebrate-specific orthologes of the Drosophila gene "eyes absent". A loss-of-function mutation in Drosophila eyes absent leads to programmed cell death of ocular precursor cells. As mutations in eyes absent lead to programmed cell death, we hypothesize that mutations in human EYA4 cause Dilated Cardiomyopathy and Sensorineural Hearing Loss through an impairment of apoptotic control.

GENE EXPRESSION

P3509 Differences in collagen I and III expression in atrial tissue of patients with atrial fibrillation with and without mitral valve disease

U. Wetzel, A. Boldt, J. Lauschke, J. Weigelt, G. Hindricks, A. Dorszewski, P. Schirdewahn, H. Kottkamp. *University Leipzig Heart Center, Electrophysiology, Leipzig, Germany*

Background: Collagen I and III, major components of the extracellular matrix, are increased in fibrotic tissues. Atrial fibrillation (AF) is a progressive disease associated with increased atrial fibrosis. AF usually turns paroxysmal (PAF) to chronic (CAF) with time. Histologically, most extensive atrial fibrosis could be shown in patients (pts.) with mitral valve disease (MVD) and CAF. We therefore postulated that atrial tissue expresses more collagen I and III in MVD than in lone AF. Additionally there should be lower levels of collagen I and III in PAF compared to CAF.
Methods and Results: Atrial tissue samples of pts. with lone AF (group I, n=47, 26 PAF, 21 CAF) and pts. with MVD (group II, n=44, 8 PAF, 31 CAF, 5 SR controls) were obtained during cardiac surgery for AF and/or MVD. Collagen I and III mRNA levels were measured by quantitative PCR (light cycler), protein levels by Western blotting techniques. Collagen I and III mRNA (26,6 (range 3,4-92,2) vs. 57,4 (range 4,9-175,0) and 10,3 (range 0,16-51,8) vs. 17,3 (range 0,3-97,8), respectively) and protein levels (0,6 (range 0,1-1,0) vs. 0,95 (range 0,4-1,5) and 1,2 (range 0,1-7,7) vs. 6,1 (range 0,1-49,0), respectively) were lower in group I but these differences were not statistically significant. Interestingly there were no differences between PAF and CAF pts. of group I and group II. Control pts. of group II express less collagen I and III mRNA and protein, although differences were also not statistically significant. Pts. with lone AF exhibit about the same levels of collagen I and III as pts. with MVD and SR.
Conclusions: Collagen I and III mRNA and protein levels are elevated in pts. with MVD as compared to lone AF. Since there was a similar degree of enhanced collagen expression in PAF and CAF, we conclude that fibrosis precedes AF. Further studies are needed to correlate these data to the histological degree of fibrosis.

P3510 BMP-10 is required for embryonic heart function

H. Neuhaus[1], L. Garner[2], V. Rosen[2], R.S. Thies[3]. *[1]University of Halle, Institute of physiological chemistry, Halle/Saale, Germany; [2]Genetics Institute, Cambridge, United States of America; [3]Geron Corporation, Menlo Park, United States of America*

Recently we identified a novel member of the TGF-b family, BMP-10 which is expressed exclusively in the trabeculated component of the developing mouse ventricle, beginning at d 9.0 p.c.
Shortly after formation of a single heart tube at approximately d 8.5 p.c. in the mouse the myocardium starts to differentiate into an outer compact myocardial layer and an inner spongy zone, the trabeculated myocardial layer. The function of this transient structure, the trabeculae, is presumably the maintenance of sufficient oxygenation and nutrient supply to the growing myocardium prior to the development of coronary arteries. During subsequent development, trabeculae are thought to coalesce, thereby forming the muscular portion of the interventricular septum and papillary muscles. Other observations demonstrated that the conduction rate is higher in trabeculae compared to compact myocardium. This was supported by the finding that connexin 40 and connexin 45 are more abundantly expressed in the trabeculae. Based on those and additional studies of gene expression patterns in the developing ventricles as well as on genetic studies, Moorman et al. suggest that the ventricular conduction system originates from the trabecular ventricular component.
We could show that after the initial expression of BMP-10 in the trabeculae BMP-10 expression changes during later development. After d 14.5 p.c. expression in the ventricle decreases and at the same time expression in the atrium increases. In the adult heart, BMP-10 expression is restricted to a small region in the right atrium containing the sino-atrial node. We further demonstrate that a null mutation of the heart specific BMP-10 gene results in a failure of the developing heart to trabeculate, leading to embryonic lethality caused by insufficient cardiac function. Taken together, these data suggest that BMP-10 might have a unique role during embryonic heart formation and, possibly, maintenance of the mature heart conduction system.

P3511 Promoter-analysis of muscle LIM protein (MLP): organ specific regulation by Nkx-2.5 and MyoD

B. Witzenbichler, R. Knoell, S. Knueppel, K. Warnke, H.P. Schultheiss. *University Hospital Benjamin-Franklin, Cardiology Dept., Berlin, Germany*

Introduction: Muscle LIM Protein (MLP) is an adaptor protein of the cytoskeletal apparatus, expressed exclusively in myokardium and skeletal muscle. Recent data using knock-out experiments suggest that MLP interaction with cytoskeletal filaments is important for ventricular compliance, and a disturbance of MLP function could lead to cardiomyopathy. Data regarding the regulation of organ-specific expression of MLP are not known to date. We therefore cloned and analysed the promoter region of MLP in order to investigate the regulation of MLP expression and to identify specific transcription factors.
Results: Cloning of a 3000 bp sequence upstream of the first exon (identified by 5'RACE) of the MLP genom into a luciferase expression plasmid resulted in a 40x increase in luciferase activity after transfection in 10T1/2-fibroblasts (mesnchymal precursor cells) and in C2C12 myoblasts compared to empty plasmid control, suggesting that the cloned sequence contained the putative MLP promoter region. Using deletion constructs the minimal promoter sequence could be narrowed to a -112/68 bp region; in shorter constructs luciferase activity was abolished. To identify regulatory transcription factors involved in striated muscle differentiation we performed cotransfection experiments with Nkx2.5 and Tbx, both being expressed during heart development, as well as with MyoD and Myogenin, expressed during skeletal myocyte differentiation. Whereas Tbx and Myogenin did not significantly affect MLP promoter activity, both Nkx2.5 and MyoD lead to a 8 to 10fold increase in promoter activity when cotransfected with MLP promoter, suggesting an important regulatory role for both transcription factors in MLP expression. To support this result we established a stable MyoD-expressing 10T1/2 cell line, which spontaneously forms myotubes; in these cells overexpression of MyoD was sufficient to switch on MLP expression, as shown by RT-PCR. Alternatively, overexpression of Nkx2.5 in 10T1/2 fibroblasts using an adenoviral construct could again induce MLP expression.
Summary: Our promoter analysis and overexpression experiments identified Nkx2.5 and MyoD as positive regulators of MLP expression. Since both transcription factors are expressed in an organ-specific manner, it can be argued that Nkx2.5 regulates MLP expression in heart, whereas MyoD induces MLP expression in skeletal muscle, at least during myocyte differentiation.

P3512 Endothelin and isoprenaline co-stimulation causes contractile failure in engineered heart tissue which is partially reversed by MEK inhibition

O. Zolk, F. Muenzel, T. Eschenhagen. *Universität Erlangen, Institut für Pharmakologie, Erlangen, Germany*

Background: Progression of heart failure is due in large part to activation of neurohormonal systems like the endothelin- (ET) and the sympathetic nervous system. ET-1- and catecholamine-evoked signaling decisively involves the MEK-ERK-pathway and is implicated in key pathological processes. We hypothesized that MEK inhibition could prevent development of contractile dysfunction following combined ET-1 and isoprenaline (ISO) stimulation in engineered rat heart tissue (EHT).
Methods and Results: EHTs reconstituted from neonatal rat cardiac myocytes were cultured in serum containing medium for 6 days and treated with ET-1 (10 nM) + ISO (10 nM) for additional 5 days in the presence or absence of the MEK-Inhibitor U0126 (10 μM, n=15 each group). Isometric force of contraction (FOC) was measured under basal conditions and with increasing concentrations of calcium (0.4-2.8 mM) and ISO (0.1-1000 nM). ET-1+ISO treated EHTs showed a significantly diminished increase in FOC (delta FOC) in response to ISO (0.17±0.02 vs. 0.38±0.04 mN, $p<0.05$). Moreover, contraction (T1, 73.1±3.0 vs. 54.8±2.0 ms, $p<0.05$) and relaxation times (T2, 89.8±4.1 vs. 62.8±2.4 ms, $p<0.05$) were significantly prolonged. Effects of ET-1+ISO were partially reversed by U0126, resulting in an increased delta FOC in response to ISO (0.23±0.02 vs. 0.17±0.02 mN $p<0.05$) and normalization of T1 (61.5±1.9 vs. 73.1±3.0 ms, $p<0.05$) and T2 (75.1±3.3 vs. 89.8±4.1 ms, $p<0.05$). U0126 significantly decreased rate of protein synthesis by 18%, as assessed by 14C-phenylalanine incorporation. However, cardiac myocyte phenotype, investigated by immunohistochemical staining of sarcomeric actinin, did not differ between treatment and control groups.
Conclusions: ET-1+ISO treatment caused contractile dysfunction in EHTs suggesting that coactivation of the ET and sympathetic nervous system could play an important role in the progression of heart failure. MEK inhibition with U0126 partially reversed contractile dysfunction and decreased protein synthesis in the EHT model. These data support a role for MEK/ERK in pathological cell signaling.

P3513 Efficient gene transfer in 24 h Langendorff-perfused neonatal rat hearts

S. Wiechert, F. Münzel, T. Eschenhagen. *FAU, Institut für Pharmakologie, Erlangen, Germany*

After completion of the human genome project there is increasing need for valid, trustworthy and simple screening systems for the functional analysis of these genes. In our study we demonstrate that it is possible to perfuse isolated neonatal rat hearts for >24 h and perform an efficient adenoviral gene transfer. We developed a modified recirculating Langendorff-system with constant flow (1 ml/min) and monitored perfusion pressure, force and frequency of contraction. Optimisation of the serum-free medium allowed an perfusion for up to 48 h with constant pressure. The weight of the native hearts was 35.2±1.2 and after 24 h 36.6±2.8 mg/g bodyweight, the weight of lyophilised native hearts 19.5±0.2% that of 24 h perfused 17.4±0.6% of wet weight (n=12 and 10, $p<0.05$). This suggests 10% oedema, a result that was confirmed histologically by H&E stained paraffin sections.
After mounting the hearts and 3 h of equilibration, function was measured under basal conditions and after perfusion with isoprenaline (0.1 μM). This procedure was repeated after 24 h in the same way (n=13). Results are shown in table 1.

Table 1: Contractile parameters (n=13)

	Frequency [bpm]	Force of contraction [mN]	Time of relaxation [ms]	Velocity of relaxation [N/s]
3 h Medium	130±14	2.1±0.4	125±5	28±5
3 h Isoprenaline	168±14	3.5±0.4	81±2	58±7
24 h Medium	131±10	4.3±0.5	137±5	48±5
24 h Isoprenaline	155±11	5.7±0.6	95±5	87±10

When hearts were perfused with recombinant, replication deficient adenovirus encoding beta-galactosidase or the green fluorescent protein at a moderate dose (200 mio biologically active virus), transfection efficiency reached 30-60%. The gene transfer did not affect contractile parameters, indicating lack of virus toxicity. In summary, we have developed a new in vitro model that allows to study functional consequences of transient gene transfer on contractile force under well defined conditions in the intact heart.

ANIMAL MODELS IN ATHEROSCLEROSIS

P3514 Increased atherosclerosis in LDL receptor-null mice lacking the CC-chemokine receptor 4

B.R. Kwak[1], G. Pelli[1], N.R. Veillard[1], F. Mulhaupt[1], R.W. James[2], C.A. Power[3], F. Mach[1]. [1]*University Hospital Geneva, Cardiology Division, Geneva, Switzerland;* [2]*University Hospital Geneva, Endocrinology and Diabetes, Geneva, Switzerland;* [3]*Serono Pharmaceutical Research, Geneva, Switzerland*

Immunologic and inflammatory responses play a crucial role in the development of atherosclerosis. Chemokines are a superfamily of small proteins involved both in routine leukocyte trafficking and in the activation and recruitement of specific cell populations to sites of inflammation and infection. CC-chemokine receptor 4 (CCR4), a high affinity receptor for the CC chemokines macrophage-derived chemokine (MDC) and thymus and activation-regulated chemokine (TARC), is expressed in the thymus and spleen, and also by peripheral blood T lymphocytes, monocytes, macrophages, platelets, and basophils. Recent studies have demonstrated a key role for CCR4 in lipopolysaccharide-induced endotoxic shock, but little is known on the role of this chemokine receptor in other inflammatory diseases. We have observed CCR4 expression in human atherosclerotic lesions. The purpose of this study was to examine the role of CCR4 in the development of atherosclerosis in vivo.
Atherosclerosis-susceptible LDL receptor-deficient mice were intercrossed with CCR4-deficient mice. Male double (CCR4-/-LDLR-/-) and single (LDLR-/-) knockout mice of 12 weeks old (n=6 per group) were fed a cholesterol-rich diet (1.25%) for 14 weeks. Atherosclerotic lesions were measured by computer image analysis measuring the extent of sudanophilic lesions within the thoraco-abdominal aorta and aortic root. Increase in serum lipid profiles (total cholesterol, triglycerides) did not differ between both groups.
The progression of atherosclerosis was significantly increased in the thoraco-abdominal aorta and aortic root of CCR4-/-LDLR-/- double knockout mice as compared to controls (LDLR-/- mice). For the thoraco-abdominal aorta, the lipid deposition was 21.3±4.5% and 11.2±2.2% for CCR4-/-LDLR-/- and LDLR-/- mice, respectively (mean±SEM, $p<0.05$). Similar results were obtained in aortic root analysis.
To our knowledge, this is the first demonstration that blocking a chemokine pathway increases the progression of atherosclerosis in vivo. Our results might point to a beneficial effect of the recruitement of a specific subset of inflammatory cells in the early phase of atherogenesis. This unexpected role for CCR4 in the development of artherosclerosis underlines the complexity of cellular interactions leading to this common disease.

P3515 The nitric oxide donor molsidomine favours features of atherosclerotic plaque stability during cholesterol lowering in rabbits

G.R.Y De Meyer[1], M.M. Kockx[2], M.W.M Knaapen[3], W. Martinet[1], D.M.M De Cleen[1], H. Bult[1], A. Herman[1]. [1]*University of Antwerp - UIA, Pharmacology, Wilrijk, Belgium;* [2]*General Hospital Middelheim, Pathology, Antwerp, Belgium;* [3]*HistoGeneX, Edegem, Belgium*

Atherosclerotic plaques with an unstable phenotype are characterized by a thin fibrous cap containing numerous macrophage-derived foam cells and few smooth muscle cells (SMC). A treatment decreasing the number of macrophages and/or increasing the number of SMC might favour plaque stabilization. Therefore, we investigated in the aorta of cholesterol-fed rabbits (0.3% cholesterol, 20 weeks) the effect of 4 weeks cholesterol withdrawal as such and in combination with the nitric oxide (NO) donor molsidomine (0.1 or 1 mg kg-1 day-1) on atherosclerotic plaque size and on macrophage and SMC content using (immuno)histochemical techniques. We also studied superoxide production (lucigenin assay) and the expression of extracellular superoxide dismutase (ecSOD) mRNA (quantitative reverse transcription-PCR), respectively.
Cholesterol treatment led to atherosclerotic plaque formation in the aorta, an increase in superoxide production, and a decrease in ecSOD mRNA as compared to normal aortas. Cholesterol withdrawal alone led to the formation of a thin subendothelial macrophage-free layer and significantly reduced both vascular cell adhesion molecule-1 (VCAM-1) expression and cell replication in the luminal part of the plaque. It did not affect plaque area, apoptosis, superoxide production, and ecSOD mRNA expression. Treatment with molsidomine (1 mg kg-1 day-1) during the cholesterol withdrawal period increased the thickness of the subendothelial macrophage-free layer consisting of SMC, and resulted in a normalisation of both the superoxide production and ecSOD mRNA expression by the aorta.
The latter findings demonstrate that cholesterol lowering combined with molsidomine treatment increases features of stable atherosclerotic plaques.
[1]

P3516 Angiotensin II accelerated atherosclerosis is attenuated in osteopontin deficient mice

D. Bruemmer[1], A.R. Collins[2], U. Kintscher[1], G. Noh[2], Y. Ozawa[2], E. Fleck[1], R.E. Law[2], W.A. Hsueh[2]. [1]*German Heart Institute, Dept. Cardiology, Berlin, Germany;* [2]*University of California, Division of Endocrinology, Los Angeles, United States of America*

Osteopontin (OPN) is large acidic phosphoprotein and acts through its arginine-glycine-aspartate (RGD) tripeptide integrin binding motif as an adhesion substrate and migration stimulus. These interactions with integrins result in activation of cell signaling pathways and regulation of gene expression. Angiotensin II (AII) is a potent inducer of OPN in the atherosclerotic vessel wall and overexpression of OPN has been identified in atherosclerotic lesions. We therefore hypothesized that OPN may play a key role in early and late changes associated with the development and progression of AII accelerated atherosclerosis. To test this hypothesis we bred OPN-/- with ApoE-/- mice to develop heterozygote ApoE-/-OPN+/- and homozygote ApoE-/-OPN-/- double knock-out mice. Three month old male ApoE-/-OPN+/- and ApoE-/-OPN-/- mice and ApoE-/-OPN+/+ littermate controls were infused with 2.5 μg/kg/min AII for 4 weeks. All 3 groups developed marked hypertension (systolic 160 mmHG vs. 100 mmHG in control animals). En face analysis of the thoracic aorta revealed a significant 65% decrease in atherosclerotic lesions in OPN deficient mice compared to ApoE-/-OPN+/+ littermate control mice (ApoE-/-OPN+/- 5.3%, n=9; ApoE-/-OPN-/- 5.1%, n=6; ApoE-/-OPN+/+ 15.3%, n=4). Real time RT-PCR confirmed that OPN mRNA expression was decreased by 50% in ApoE-/-OPN+/- mice and not detectable in ApoE-/-OPN-/- mice. Lipid profiles were similar in the 3 groups. Peritoneal macrophages from OPN deficient mice exhibited an impaired chemotactic response in transwell migration assays which could contribute to the diminished atherosclerosis observed in the OPN deficient mice. These data suggest that OPN is an important proatherogenic factor in the vessel wall. Approaches designed to inhibit OPN expression and/or adhesion in vasculature may provide a novel therapeutic strategy against atherosclerosis.

P3517 Increased vascular cell apoptosis and proliferation after balloon injury in p53 null mice

C M. Matter[1], M F. Villela Dantas[1], L. Ma[1], E. Hofmann[2], S-W. Ha[3], T F. Lüscher[1]. *[1]Cardiovascular Research, Institute of Physiology/Cardiology, Zurich, Switzerland; [2]Schneider, Bülach, Switzerland; [3]Jomed, Beringen, Switzerland*

A disequilibrium between vascular cell death and proliferation is a prominent feature in the response to vascular injury. A phase of marked medial apoptosis is known to initiate the process of balloon-induced lesion formation in large animals. At the molecular level, p53 is a known mediator of apoptosis and cell cycle arrest that is induced by DNA damage and has been associated with restenosis. However, a cause-effect between p53 and balloon-induced lesion formation is still unknown. We tested the hypothesis whether the lack of p53 would decrease apoptosis and enhance proliferation after balloon injury.
Balloon distension injury was performed in the non-dissected portion of the left proximal common carotid artery of p53-/- and wild-type C57Bl/6 (WT) male mice weighing 22.5 to 24.5g. Serial cross sections of the dilated segment of the carotid artery were obtained 3h, 1, 7 and 28d after balloon injury (n>7 for each group, mean±SD). Cellularity was determined by chromatin staining (DAPI) and DNA synthesis was assessed by BrdU labeling index (BrdU-I). Cell death and apoptosis were characterized by the typical nuclear morphology that was confirmed by TUNEL and active caspase-3 staining. Medial cellularity decreased early, then increased at d7 and 28 in a similar fashion in both strains. However, at 1d post injury, total medial cell count was lower in p53 -/- than in WT mice (38±20 vs. 59±13, $p<0.05$). Indeed, counts of cell death were higher in p53-/- than in WT mice at 3h (17±6 vs. 10±5, $p<0.05$), 1d (10±7 vs. 4±4, $p<0.05$), 7d (9±5 vs. 5±4, $p<0.05$) and 28d (8±8 vs. 1±1, $p<0.001$) post injury. On the other side, medial proliferation (BrdU-I) was also higher in p53 -/- mice at 7d (8±6 vs. 5±4, NS) and at 28d (0.9±1.2 vs. 0.6±1.0, $p<0.05$). Intima analysis revealed that its cellularity decreased sharply 3h post injury in both strains (4±2 vs. 5±3, NS), then increased more in p53 null mice at 7 (149±92 vs. 101±63, NS) and 28d (83±43 vs. 46±7, $p<0.001$). These findings were paralleled with an increased intimal proliferation rate in p53 null mice at 7d (11±10 vs. 4±3, $p<0.05$) that leveled off and became similar in both strains at day 28. Lumen areas and intima/media ratio were not different between the strains.
p53 null mice show a higher rate of cell apoptosis and proliferation after carotid balloon injury. The paradoxical increase in cell death in p53 -/- mice suggests a compensatory activation of p53-independent apoptosis pathways in these animals. The increase in cell proliferation in p53 knockout mice is likely due to the lack of cell cycle arrest mediated via p53.

P3518 Omapatrilat accelerates reendothelialisation and prevents fatty streak deposit in a novel model of mouse carotid injury

J. Roncalli[1], B. Garmy[2], C. Castano[2], L. Brouchet[2], R. Elhage[2], F. Bayard[2], J.F. Arnal[2]. *[1]CHU Rangueil, Cardiologie Dept., Toulouse, France; [2]Hôpital de Rangueil, INSERM U 397 et physiologie médicale, Toulouse, France*

Background: The importance of endothelial integrity was initially demonstrated by the facilitation of atherosclerotic lesion development in hypercholesterolemic animals models endothelial injury. We have previously shown that omapatrilat prevents spontaneous fatty streak deposit at the root of the aorta. We have evaluated the effect of omapatrilat, a dual ACE and NEP inhibitor, on the acceleration of reendothelialization in wild-type mice and the development of fatty streak in apolipoprotein E (apoE)-deficient mice after arterial injury.
Methods: Firstly, 2 groups of six male wild-type mice were given either placebo or omapatrilat 100 mg/kg/day. Reendothelialization was evaluated by staining the denuded areas with Evans blue. Secondly, 2 groups of six male apoE-deficient mice were given either placebo or omapatrilat 100 mg/kg per day after carotid injury for 3 months. The evaluation of fatty streak deposit was evaluated using red oil staining.
Results: 3 days after arterial injury, in wild-type mice treated with omapatrilat in mice demonstrated placebo accelerated reedothelialization compared to placebo (% of area remaining deendothelialized = 38.8 ± 1.5, vs = 46.9 ± 2, $p<0.005$). Placebo-treated apoE-deficient mice developed fatty streak deposit at the site of injured carotid, whereas the uninjured controlateral carotid artery demonstrated no lesion. In contrast, ApoE-deficient mice treated with omapatrilat had almost no fatty streak deposit 3 months after arterial injury.
Conclusion: Omapatrilat accelerates reendothelialization after carotid arterial injury in wild-type mice and protect the apoE-deficient mice from fatty streak deposit after arterial injury. The benefit of the dual ACE and NEP inhibition should be considered in the prevention of atherosclerosis after endoluminal angioplasty.

DOPPLER ECHOCARDIOGRAPHY

P3519 Comparison between parameters of diastolic function derived from conventional Doppler echocardiography and from Doppler tissue imaging

C. Selton-Suty, L. Mock, R. Piquemal, M. Nippert, A.C. Vançon, Y. Juillière. *Chu Nancy-Brabois, Cardiology Dept., Nancy, France*

Background: Measurement of left ventricular flow propagation velocity (LV FPV) is a useful noninvasive estimate of Tau. Doppler tissue imaging (DTI) seems a promising new echocardiographic approach of diastolic function.
Methods: We studied 54 pts (50±17 yrs, 16 nl pts, 29 pts with idiopathic DCM, and 9 pts with primary pulmonary hypertension) and recorded from apical 4C view 1) LV FPV with color M-mode echocardiography, 2) mitral flow (mit) with conventional Doppler, 3) septal (sep) and lateral (lat) wall motion with pulsed Doppler tissue imaging (DTI). We tried to correlate color M-mode LV FPV (mean value: 46.1±16.7 cm/s), that is well correlated with Tau, with the following parameters: maximal velocity of mit, sep and lat E waves; mit, sep, and lat E/A ratio; LV, sep, and lat myocardial performance index (MPI). LV MPI is defined as the ratio of the sum of isovolumic contraction and relaxation times to ejection time, and is an index of global function. We applied the same formula to DTI derived sep and lat time intervals.
Results: see table.

Correlations with LV FPV

	mean±SD	r value	p value
age	50±17	-0.487	0.002
mit E (cm/s)	69.5±22.6	0.579	0.000
sep E (cm/s)	7.7±3.3	0.545	0.000
lat E (cm/s)	10.5±4.9	0.659	0.000
mit E/A	1.4±1.0	0.318	ns
sep E/A	1.1±0.6	0.609	0.000
lat E/A	1.5±1.1	0.505	0.004
LV MPI	0.59±0.24	-0.468	0.003
sep MPI	0.92±0.62	-0.500	0.002
lat MPI	1.5±1.1	-0.125	ns

Conclusion: Our study shows interesting correlations between pulsed DTI parameters of diastolic or global function and LV FPV, suggesting further correlations with Tau.

P3520 Detection of a pseudonormal mitral inflow pattern using Doppler myocardial imaging

T. Poerner, B. Goebel, C. Wolpert, T. Sueselbeck, S. Pfleger, M. Borggrefe, K.K. Haase. *Univ. Hospital Mannheim, 1st Dept. of Med., Mannheim, Germany*

Background: Impaired relaxation can be masked by elevated filling pressures, resulting in a pseudonormal mitral inflow pattern. Aim of the study was to assess the ability of Doppler myocardial imaging (DMI) - derived parameters to improve the noninvasive diagnosis of pseudonormalization.
Methods: 83 consecutive patients with a normal transmitral Doppler profile (E/A > 1) scheduled for coronary angiography underwent DMI and left heart catheterization. Peak transmitral velocities were determined at rest (E, A) and during the strain phase of a Valsalva maneuver (Ev, Av). Propagation velocity of the early mitral inflow (Vp) was measured by color M-mode. Early diastolic peak velocities of lateral mitral annulus (E') and the peak diastolic myocardial velocity gradient of the posterior basal wall (MVG) were obtained by DMI. Myocardial relaxation time (MyoRT) was calculated between aortic valve closure and the early diastolic myocardial velocity peak of the posterior basal wall by DMI. The left ventricular end-diastolic pressure (LVEDP) and ejection fraction (EF) were determined invasively.
Results: Pseudonormalization, defined as LVEDP > 14 mm Hg and E/A > 1, was found in 46 patients (LVEDP 21 ± 7 mm Hg, EF 62 ± 15%, E/A 1.4 ± 0.5), while 37 patients served as a control group (LVEDP 7 ± 2 mm Hg, EF 71 ± 8%, E/A 1.4 ± 0.4). Parameters presenting significant differences between these 2 groups are summarized in the table, together with the coefficients of linear correlation with LVEDP and the values of AUC (area under the receiver-operating characteristic curve for the prediction of LVEDP > 14 mm Hg).

Parameters	Pseudonormalization	Control group	AUC (ROC-Curve)	r
Valsalva response	0.28 ± 0.28 *	0.14 ± 0.22	0.667 *	0.43 **
E/E'	14.2 ± 6.1 **	9.9 ± 2.9	0.724 **	0.45 **
MyoRT (ms)	118 ± 31 **	82 ± 17	0.738 **	0.45 **
E/Vp	1.8 ± 0.8 **	1.2 ± 0.5	0.751 **	0.39 **
MVG (1/s)	-2.5 ± 1.5 **	-4 ±1.7	0.775 **	0.45 **

Valsalva response = 1-(Ev/Av)/(E/A); r = coefficient of linear correlation with LVEDP; * $p < 0.05$; ** $p < 0.01$

Conclusions: 1) MVG had the highest predictive accuracy to identify elevated filling pressures. 2) Combined indexes MyoRT, E/Vp and E/E' are faster reliable alternatives superior to Valsalva maneuver for detecting a pseudonormal Doppler profile.

P3521 Dependence on venous return of diastolic left ventricular flow propagation and mitral annular velocities

B.P. paelinck[1], M. van Eck[1], J. Walpot[1], S. De Hert[2], T. Gillebert[3].
[1]University Hospital Antwerp, Cardiology, Edegem, Belgium; [2]University Hospital Antwerp, Anesthesiology, Edegem, Belgium; [3]University Hospital Ghent, Cardiology, Ghent, Belgium

Background: The response of diastolic mitral flow to increased venous return due to leg lifting (LL) provides prognostic information in congestive heart failure patients. Recent studies in open chest coronary surgery patients explained these effects in terms of length dependent activation of cardiac muscle and contraction-relaxation coupling. Colour M-mode of mitral inflow and tissue Doppler imaging of mitral annular motion have been presented as relatively preload independent parameters. The present study analysed the response to LL of Doppler measurements in healthy subjects.
Methods and Results: Pulsed Doppler of left ventricular filling and outflow, colour M-mode of early left ventricular filling and mitral annular velocities were measured at baseline and during 45° LL (n=24).
LL resulted in increased stroke volume (69.1 ml ± 13.5 to 73.5 ml ± 13.5, P<0.01), left ventricular ejection time (286 ms ± 20 to 293 ms ± 18, P<0.01) and systolic annular velocity (6.8 cm/s ± 1.2 to 7.3 cm/s ± 1.1, P<0.01). LL induced an increase in peak early (E) mitral flow velocity (73.5 cm/s ± 12.9 to 80.3 cm/s ± 13.6, P<0.01), flow propagation (53.1 cm/s ± 10.2 to 59.2 cm/s ± 12.6, P<0.01) an E' diastolic annular velocity (10.8 cm/s ± 2.2 to 11.7 cm/s ± 2.0, P<0.01). There was a shortening of E wave deceleration time (178 ms ± 27 to 163 ms ± 27, P<0.01) and isovolumic relaxation time (76 ms ± 11 to 68 ms ± 10, P<0.01). Interobserver variability was low (mean of the difference for E was 0.3 cm/s ± 0.5).
Conclusions: LL enhanced systolic function according to Frank-Starling's law. The changes of diastolic function reflected the combination of elevated filling pressures and accelerated relaxation. Flow propagation and diastolic mitral annular velocities obviously were dependent on venous return.

P3522 Inadequacy of mitral flow propagation velocity assessed by color M-mode Doppler for differentiation of pseudonormal from normal left ventricular filling

K. Dennig, H.U. Haase, A. Schömig. *Klinikum rechts der Isar, 1. Medizinische Klinik, Munich, Germany*

Background: Impaired diastolic LV function may be associated with a normal E/A ratio of mitral inflow in the presence of combined relaxation and compliance abnormalities. We sought to assess whether flow propagation velocity (vp) of early LV filling determined by color M-Mode Doppler may enable differentiation between such pseudonormal from normal velocity profiles. Methods: We studied 43 patients with marked LV hypertrophy due to hypertension and a normal mitral inflow E/A ratio as well as no valvular lesion. Fourty healthy persons served as control group. From PW Doppler registered LV filling profiles E, A, E/A, E acceleration and deceleration slopes as well as time intervals were measured. Flow propagation velocity vp was determined as the slope of the aliasing velocity from color M-Mode Doppler recordings oriented from the LV apex towards the tips of the mitral leaflets. Results: In the entire patient group with a pseudonormal filling pattern, vp was not significantly different from the control group, 73 ± 37 vs. 74 ± 32 cm/s. Only 5/43 patients showed a vp < 45 cm/s and all of them had a reduced systoliv LV function. Except for acceleration slope, which measured 997 ± 367 in patients with pseudonormalisation vs. 755 ± 260 cm/s^2 in normals, no significant differences were present for all other PW Doppler parameters between both groups. Conclusion: 1) Flow propagation velocity of early LV filling is frequently normal in patients with a pseudonormal mitral inflow profile and, thus, does not enable differentiation from normal filling patterns. 2) Reduced flow propagation is found in patients with impaired systolic LV function suggesting that ventricular suction is a major determinant of vp.

P3523 Pulsed-wave tissue Doppler echocardiography of various corners of mitral annulus in assessment of left ventricular diastolic function

T. Paleèek, A. Linhart, M. Aschermann. *General teaching hospital, IInd department of internal medicine, Prague, Czech Republic*

Background: Early diastolic mitral annulus (Em) velocity measured by pulsed wave tissue Doppler echocardiography (PW-TDE) has been referred to be a relatively preload independent parameter of left ventricular (LV) diastolic function. However, there are substantial differences among Em velocities measured on various corners of mitral annulus. Therefore, uniform cut-off values distinguishing normal and abnormal LV diastolic function are difficult to apply.
Aim of the study: To compare the sensitivity and the specificity of Em velocities measured on septal, lateral, posterior and anterior corner of mitral annulus by using receiver operating characteristics (ROC) curves analysis and to determine cut-off values for selected limit of 90% sensitivity.
Methods: Pulsed wave Doppler analysis of mitral inflow and pulmonary venous flow was performed in 69 patients (65% men, mean age 49±19 years). Patients were then classified into two groups: group N with normal LV filling pattern (n=35) and group I with impaired LV filling pattern (n=34). The latter included 23 subjects with impaired relaxation and 11 patients with pseudonormalized filling pattern. PW-TDE was performed on the septal, lateral, inferior and anterior corner of mitral annulus and peak Em velocities were measured. ROC curves of Em velocities were compared by assessing the areas under the curve (AUC) and 95% confidence intervals.
Results: Em velocities were significantly (p<0,001) lower in the group I compared to the group N. AUC of ROC curves were comparable on all four corners of mitral annulus ranging from 0,92 on the septal corner to 0,96 on the lateral corner. Cut-off values and specificities (for 90% sensitivity) were -0,09 m.s-1 and 89% on the septal corner, -0,12 m.s-1 and 94% on the lateral corner, -0,10 m.s-1 and 94% on the inferior corner and -0,11 m.s-1 and 91% on the anterior corner.
Conclusions: Values of Em velocity differ substantially according to the site of measurement. On all mitral annular corners the assessment of Em velocity allows detection of LV diastolic dysfunction with high and comparable sensitivity and specificity. However, different cut-off values should be used with the lowest value for the septal corner of annulus (-0,09 m.s-1) and the highest for the lateral corner (-0,12 m.s-1).

P3524 Evaluation of diastolic function of the left ventricle in white coat hypertension patients using tissue Doppler imaging

G. Koutroulis[1], K. Liosis[2], D. Dawson[3], N. Giatrakos[3], M.R. Wilkins[2], P. Nihoyannopoulos[3]. [1]Hammersmith Hospital, Cardiology Dept., London, United Kingdom; [2]Imperial College, Hammersmith Hospital, Department of Clinical Pharmacology, London, United Kingdom; [3]Hammersmith Hospital, NHLI, ICSM, Department of Cardiology, London, United Kingdom

Background The clinical significance of white coat hypertension (WCH) has been a subject of much debate. In this study we hypothesise that patients with WCH will have impaired diastolic function, similar to hypertensive patients with a family history of hypertension (FHT).
Methods Sixteen patients with WCH (mean age 36.25±11.3 years, mean daytime blood pressure 135/84 mmHg), and 13 FHT patients (mean age 37.6 ± 8.7 years, mean daytime blood pressure 146/94 mmHg), were compared with 14 controls (mean age 31.8 ± 6.9 years, mean daytime blood pressure 113/74 mmHg). From apical four chamber projections, the E wave velocity, E/A ratio, isovolumic relaxation time (IVRT), and deceleration time (DT), were measured from transmitral Doppler velocities. From apical long axis projections, (posterior mitral annulus), the peak systolic velocity (Sa), early (Ea) and late (Aa) diastolic velocities, the Ea/Aa ratio were measured with pulsed TDI. The E wave velocity corrected for the influence of relaxation as a less load dependent index (i.e., the E/Ea ratio) was also measured.
Results E, A, E/A transmitral velocities, were similar between WCH, FHT and controls. Similarly, there were no differences between Ea, Aa and Sa of WCH, FHT and controls. Only DT (WCH 176 ± 41 vs controls 142 ± 24 msec, P<.012, FHT 183 ± 36 vs controls 142 ± 24 msec, P<.002), and E/Ea (FHT 5.7 ± 1.3 vs WCH 4.7±.95 P<0.031) were higher in FHT compared with both, WCH and controls respectively.
Conclusion This study suggest that patients with WCH have normal diastolic function which distinguishes this group from patients with FHT. This distinction could have significant prognostic implications.

P3525 Adamantiades-Behcet's disease is associated with impaired aortic distensiblity and left ventricular diastolic function

I. Ikonomidis[1], J. Lekakis[1], K. Stamatelopoulos[1], K. Aznaouridis[1], A. Protogerou[1], N. Markomihelakis[2], P.H. Kaklamanis[2], M. Mavrikakis[1]. [1]*Alexandra Hospital, University of Athens, Department of Clinical Therapeutics, Athens, Greece;* [2]*Athens Medical Center, Rheumatology, Athens, Greece*

Adamantiades-Behcet's disease (ABD) is multisystem disorder characterized by vasculitis leading to vascular complications (VC) such as aneurysm formation, stroke, arterial or venous occlusive disease. Endomyocarial fibrosis has also been described in ABD. We investigated whether ABD is related with impaired aortic distensibility (AoD) and left ventricular (LV) function.

Methods: We studied 50 patients with ABD (age 38+11 years) and 20 normal controls by 2D, and Doppler Echocardiography. AoD was calculated using the formula 2 x (pulsatile change in aortic diameter)/[diastolic aortic diameter x (aortic pulse pressure)]. Thoracic aorta diameters (TAO-mm/m^2) were measured 3 cm above the aortic valve by 2D guided M-mode echocardiography and pulse pressure was obtained simultaneously by cuff sphygmomanometry. Isovolumic relaxation time (IVRT-ms), deceleration time (DT-ms) and flow propagation index (FPI-m/s) were measured to assess diastolic LV function. The duration of disease from diagnosis to time of examination and presence of VC were noted.

Results: All patients had normal systolic LV function. Patients and controls had similar age and atherosclerotic risk factor distribution. AoD and stiffness (cm^2 dyn(-1) 10^{-6}), IVRT and FPI were impaired in patients with ABD compared to controls (table). The duration of disease was related to low AoD and high TAO (r=- 0.48 and r=0.52, P<0.01) independently of age and risk factors. Patients with VC (n=19) had higher LV mass (g/m^2) left atrium (LA-mm/m^2)and DT than patients without (table). DT>190ms predicted VC with 83% sensitivity and 81% specificity (ROC curve area:81% (CI:65-97%)) independently of age and risk factors.

	Ao D	Ao stiffness	IVRT	FPI	Vascular complications	LV mass	LA	DT
Behcet (n=50)	0.79±0.5	53±38	85±13	0.42±0.1	Yes (n=18)	103±12	19±1	220±34
Controls (n=20)	2.0±0.9	15±6	70±15	0.69±0.3	No (n=32)	89±17	16±2	180±30
p	<0.01	<0.01	<0.01	<0.01	p	<0.01	<0.01	<0.01

Conclusion: ABD is related with impaired AoD possibly due to vasa vasorum vasulitis leading to increased Ao diameters as disease progresses in time. ABD is related with impaired diastolic LV function likely due to coronary vasculitis leading to endomyocardial fibrosis. Diastolic LV dysfunction is linked to presence of vascular complications implying the presence of a common pathophysiological pathway.

P3526 Do patients with heart failure and normal systolic function really have diastolic heart failure?

P.M. Mottram, T.H. Marwick. *Princess Alexandra Hospital, University Department of Medicine, Brisbane, Australia*

Background: Diastolic heart failure (DHF), conventionally defined by exclusion (clinical heart failure [CHF] with normal LV systolic function), is reported to account for 30-50% of CHF in the community. We sought to use new echo-Doppler parameters to make a specific (rather than exclusive) diagnosis of isolated DHF among pts referred to a large tertiary echo center for assessment of LV function.

Methods: Between April 2000 and June 2001, 938 consecutive pts were referred for echo assessment of LV function. Pts with clinical CHF and normal LV systolic function, no wall motion abnormalities or valve disease, and no history of coronary artery disease were assessed for evidence of diastolic dysfunction based on transmitral and pulmonary vein flow. Impaired LV relaxation (IR) was defined by E/A<1 and E wave deceleration time (DT) >240msec. Pulmonary vein systolic (S), diastolic (D) and atrial reversal (A rev) velocities were used to differentiate pseudonormal (PN) filling (S/D<1 or A rev>35cm/s) in pts with normal E/A and DT who had LV hypertrophy or left atrial dilatation.

Results: Normal LV systolic function was present in 331 of 938 pts (35%). Fifty-three (27 male, age 72±11yrs) pts from this group (6% of referrals) met the inclusion criteria for a clinical diagnosis of DHF. Hypertension, and diabetes were present in 34 (64%) and 16 (30%) pts respectively. Twenty pts (38%) presented with acute CHF (19 admitted to hospital); 42 pts (79%) had chronic CHF symptoms. Diastolic dysfunction was confirmed by echo in 38 pts (72% of clinical DHF pts), of whom 27 pts had IR (E/A 0.75±0.16, DT 291±40 msec), 10 pts had PN filling (E/A 1.37±0.74, DT 190±42 msec), and 1 pt had restrictive filling. Diastolic function was normal in 13 pts and indeterminate in 2 pts. Diastolic dysfunction pts had increased LV septal thickness compared with pts with normal diastology (1.3±0.2 vs 1.1±0.2 cm, p=0.01). In comparison with pts with normal diastolic function, pts with PN filling had increased E velocity and E/A ratio (p<0.05 for both), and pts with IR had reduced E/A ratio (p<0.05) and prolonged DT (p<0.0001).

Conclusion: Isolated, clinically defined DHF is uncommon (6%) among pts referred for echo assessment of LV function at a tertiary center. However, echo evidence of diastolic dysfunction is present in the majority (72%) of these pts with clinically defined DHF. Most of these pts have impaired LV relaxation, but pseudonormal filling also accounts for a significant proportion (26%) of diastolic dysfunction in this population.

P3527 Subtle left ventricular systolic dysfunction detected by tissue Doppler is a diagnostic tool in heart failure with "preserved" systolic function

E. Garcia[1], E.R. Perna[2], E.F. Farias[2], E.A. Tassano[1], R. Obregon[1], S.M. Macin[2], D.A. Moratorio[2], P.D. Liva[3]. [1]*Instituto de Cardiologia J. F. Cabral, Echocardiography, Corrientes, Argentina;* [2]*Instituto de Cardiologia J. F. Cabral, Heart Failure Clinic, Corrientes, Argentina;* [3]*Instituto de Cardiologia J. F. Cabral, Coronary Intensive Care Unit, Corrientes, Argentina*

Aims: To evaluate the diagnostic utility of tissue Doppler echocardiography to identify patients with heart failure in presence of preserved systolic function

Methods: We evaluated 80 patients with left ventricular ejection fraction (LVEF) >=50%, 29 of them with heart failure, defined as subject who meet Framingham diagnostic criteria (Group 1), and 51 normal subject (Group 2). LVEF was measured by cross sectional Simpson's method and myocardial velocities were obtained by pulsed tissue doppler (pTD) at the basal septum wall in 4-chamber view. Sensitivity (S), specificity (E) and predictive value, positive and negative (PPV and NPV), were determined and ROC curves were used to select the best values.

Results: Mean age of group 1 and 2 was 67.3±13 vs 51.1±20 years (p<0.001) and LVEF was 65.3±8.2 vs 59.7±6.7 (p=0.002), respectively. pDT values in group 1 and 2 were the followings: peak E 5.9±2.4 vs 10.5±4 cm/s; peak S 5.6±1.7 vs 8.2±1.5 cm/s; peak A 7.2±3.4 vs 9.5±2.5 cm/s; isovolumic myocardial relaxation time (IVRT) 162.4±39 vs 89.3±23.3 ms; and isovolumic myocardial contraction time (IVCT) 106.8±34 vs 69.1±17 ms (all p<0.001). The area under the ROC curve and the S, E, PPV and NPV are displayed in the table:

Variable	Area	Cut point	S (%)	E (%)	PPV (%)	NPV (%)
Peak E	0.85	7.15 cm/s	78.4	76.9	66.7	85.1
Peak A	0.70	7.25 cm/s	82.4	49.3	60.9	73.7
E/A ratio	0.65	0.75	68.6	55.6	50.0	72.9
Peak S	0.89	6.75 cm/s	88.2	80.0	79.3	88.2
IVRT	0.95	117.5 ms	86.3	93.1	79.4	95.7
IVCT	0.86	87.5 ms	84.3	72.4	72.4	84.3

Conclusion: pDT was a usefulness tool to diagnose heart failure in patients with preserved systolic function, and the most important parameters were IVRT (diastolic function) and peak S (systolic function). Thus, despite normal ejection fraction, subtle impairment of left ventricular systolic function is present in patients with diastolic heart failure and our findings suggest that these abnormalities may have an important role to identify that subjects.

P3528 Early detection by pulsed Doppler tissue imaging of diastolic but also systolic myocardial dysfunction after anthracycline chemotherapy

S. tassan-mangina[1], C. brasselet[1], P. nazeyrollas[1], M. collot-bigot[1], B. costa[2], A.M. blaise[2], D. metz[1], J. elaerts[1]. [1]CHU Robert Debré, Cardiologie, Reims, France; [2]CHU, Service hématologie, Reims, France

Background: Anthracycline chemotherapy is the treatment for numerous malignant tumors despite a risk of cumulative chronic cardiotoxicity. We prospectively assessed the interest of pulsed Doppler Tissue Imaging (DTI) measurements for early detection of this cardiotoxicity.
Methods: We included 20 patients aged 38±10, without heart disease, who will undergo anthracycline treatment for breast cancer (n=11), lymphoma (n=5) or leukaemia (n=4). We performed two complete echocardiograms: one before the beginning of treatment and another one 6±4 months later. We recorded pulsed DTI spectrum of the basal segments of the posterior (Radial myocardial function (R)) and lateral (Longitudinal myocardial function (L)) left ventricular walls.
Results: For a doxorubicin cumulative dose of 227±91 mg/m^2, the left ventricular ejection fraction remained normal (71±8%). On mitral flow Doppler, there was an alteration of the relaxation: decrease of E wave velocity (65±12 cm/s vs 74±13 cm/s; p=0.04) and E/A ratio (1.34±0.28 vs 1.57±0.38; p=0.01). DTI study showed an alteration of the systolic (S) and early diastolic (Em) myocardial wave velocities, predominant for L. The decrease of S was significant for the lateral wall (table). The late diastolic myocardial velocity was unchanged.

	SL (cm/s)	SR (cm/s)	EmL (cm/s)	EmR (cm/s)

DTI measurements before and after anthracycline chemotherapy

Conclusion: Pulsed DTI rather than usual Doppler echography detects early diastolic, but also systolic myocardial dysfunction, despite the absence of LVEF change in patients who undergo anthracycline chemotherapy.

P3529 Mitral color Doppler M-mode during dobutamine stress echocardiography: a marker of ischaemic myocardium

R. Rambaldi[1], D. Castini[1], N. Colombo[1], D. Torta[1], A. Mantero[1], C. Fiorentini[2]. [1]"S. Paolo" Hospital, Division of Cardiology, Milano, Italy; [2]University of Milan, Department of Biomedical Sciences, Milan, Italy

Aim: The flow propagation velocity of early transmitral flow (Vp) determined by color Doppler M-mode was reported as a non-invasive index of global left ventricular relaxation, independent of loading or chronotropic ventricular changes. Vp determination could help dobutamine stress echocardiography (DSE) to recognize more objectively ischemic myocardium.
Methods: Forty-six consecutive patients (pts), mean age 63 ± 6 years, with known or suspected coronary artery disease underwent DSE. Vp was determined as the slope of the isovelocity line from mitral plane to 4 cm apically into the left ventricle. Vp was recorded at a sweep rate of 100 mm/s and calculated off-line at each step of DSE. Pts with significant arrhythmias, mitral or aortic valve disease and diastolic restrictive pattern were excluded. Coronary angiography (CAG) was performed within 3 months of DSE. A coronary stenosis was defined significant if >70% of lumen diameter of epicardial coronaries (>50% of left main coronary artery).
Results: Mean Vp at rest, low, peak dose of dobutamine and recovery of pts with ischemic and non-ischemic DSE are shown on the table. Peak dose Vp (cut-off <31 cm/s) predicted coronary artery disease: agreement 78%, kappa 0.35. During DSE Vp changes correlated to ischemic wall motion patterns and biphasic Vp correlated to biphasic wall motion changes (r = 0.85). In some cases of myocardial ischemia the dobutamine-induced reduction of Vp at peak test was on-line eye-recognizable.

(cm/s)	Rest	Low dose	Peak dose	Recovery
(a) Non-ischemic pts	60±16	73±20	73±15	63±18
(b) Ischemic pts	57±14	71±19	32±11*	51±17

* p <0.01 between (a) and (b).

Conclusions: In pts with known or suspected coronary artery disease, dobutamine-induced Vp reduction appears an accurate marker of coronary artery stenosis. Vp reduction reflects the slowed ventricular relaxation induced by ischemia. Vp change allows quantitation of myocardial ischemia and in same cases also on-line eye-recognition of myocardial ischemia. Vp patterns during DSE partially parallel wall motion patterns.

P3530 Assessment of regional diastolic left atrial function by pulsed-wave tissue Doppler imaging

M. Pérez-Paredes, A. Carnero, J.A. Ruiz Ros, D.M. Gimenez, M. Gonzálvez, F.R. Martínez-Corbalán, T. Cubero. *Hospital Univ. "Morales Meseguer", Cardiology, Murcia, Spain*

Background: Tissue Doppler imaging (TDI) allows to study the regional diastolic function in several clinical settings. Nevertheless, quantitative TDI of the LA has been poor studied. The aim of this study was to assess the regional diastolic function of the LA by TDI in a cohort of healthy subjects. Furthermore, we studied the relationship between the LA TDI patterns and the transmitral and pulmonary vein flows.
Methods: Ninety subjects (50 women) mean age 48±22 years (range 9-75 years)were studied. All subjects were examined using the four- chamber apical view. The lateral wall of the LA was divided in three erial segments (basal, medium and distal). The sample volume was placed in the center of these consecutives segments to be analized. In each atrial segment, the following measurements were acquired: Vs, Ve, Va and e/a ratio. TDI measurements were expresed as average values of 3 consecutive beats in each segment. To avoid the possible effect of the age on the actual measures, the study population was divided in two groups: group I (age<45 years) and group II (age>45 years). Transmitral and pulmonary venous flow velocities were obtained.
Results: TDI velocities in each group of age are shown in the table. The youngest subjects (group I) exhibit a pattern with high e wave and e/a ratio>1. With the age (group II), the relationship e/a it is made smaller than 1. It was not observed differences in the Vs between both age groups (13.5 ± 3.9 group I vs 13.1 ± 5.4 cm/sec group II; p=0.59). There were no relationship between the pulmonary venous flow velocities and those of LA TDI. On the contrary, a significant correlation was observed among the transmitral flow pattern and the LA TDI tracing (Kappa=0.584; p>0.0001). This relationship stays constant in all the age groups.

TDI velocities

Left Atrial TDI	s wave (cm/s)	e wave (cm/s)	a wave (cm/s)	e/a ratio
Group I	13.5 ± 3.9	22.6 ± 6.4	15.2 ± 6.1	> 1 (88%)
Group II	13.1 ± 5.4	10.5 ± 6.1	19.6 ± 7.9	< 1 (86.5%)
p value	0.59	P < 0.0001	P <0.03	P < 0.0001

TDI velocities in each group of age.

Conclusions: LA shows a similar TDI pattern to that of the left ventricle with a systolic wave and two diastolic waves. A narrow correlation of the diastolic patterns exists between the transmitral flow obtained by conventional pulsed Doppler, and those of the LA obtained by TDI.

P3531 The TEI index as a predictor of in-hospital cardiac events in patients with myocardial infarction

L. Ascione[1], L. Damiano[1], M. De Michele[2], M. Accadia[1], S. Rumolo[1], C. Sacra[1], P. Guarini[3], B. Tuccillo[1]. [1]Ospedale Santa Mare di Loreto, Cardiologia, Napoli; [2]Federico II University, Clinical and Exp. Medicine, Napoli; [3]Casa di Cura Villa dei Fiori, Division of Cardiology, Acerra, Italy

Objective: Recently, an easily measured Doppler index of global myocardial performance (TEI index), defined as the sum of isovolumetric contraction time and isovolumetric relaxation time divided by ejection time, has been proposed as a sensitive marker of cardiac dysfunction in patients with myocardial infarction (AMI). However, data regarding the ability of the TEI index to predict in-hospital cardiac events in AMI are lacking.
Methods: A complete two-dimensional and Doppler echocardiographic examination was performed within 24 h of arrival at the coronary care unit in 96 patients (81 men and 15 women; mean age 58 ± 9 years) with first AMI (42 anterior, 47 inferior and 7 lateral). Patients were divided a posteriori into 2 groups according to their in-hospital course: group 1 comprised 21 patients with a complicated in-hospital course (death, heart failure, arrhythmias or post-AMI angina) and group 2 comprised 75 patients with an uneventful course.
Results: Cardiovascular risk factors and conventional parameters of diastolic function were similar between the 2 groups. In complicated patients, the Killip class was higher (p = 0.0001), the wall motion score index and the left ventricular systolic volume were significantly increased compared with patients without events (1.84 ± 0.27 vs 1.52 ± 0.30, p = 0.0001; and 66 ± 29 ml vs 47 ± 21 ml, p = 0.001), whereas the ejection fraction was reduced (40 ± 10% vs 52 ± 10%, p = 0.0001). The mean value of the TEI index was significantly higher in patients with cardiac events than in those wihout events (0.65 ± 0.20 vs 0.43 ± 0.16, p = 0.0001), due to a prolonged isovolumetric contraction time (72 ± 37 msec vs 44 ± 27 msec, p = 0.001) and shortened ejection time (245 ± 35 msec vs 265 ± 26 msec, p = 0.007). A Tei index > 0.47 showed a sensitivity of 90%, specificity of 71% and a negative predictive value of 96% for identifying subjects with events. By multivariate logistic regression analysis, the TEI index (OR 13.5, 95% CI 2.5-71.3, p = 0.002) remained independently predictive of in-hospital cardiac events.
Conclusion: The present data suggest that in the acute phase of AMI, the TEI index is a strong predictor of in-hospital cardiac events.

P3532 The TEI index as a predictor of short term outcome in ischaemic cardiomyopathy

M.I. Burgess[1], A. McNab[1], P. Atkinson[1], G.D. Murray[2], S.G. Ray[1] on behalf of The CHRISTMAS Investigators. [1]*Wythenshawe Hospital, Department of Cardiology, Manchester, United Kingdom;* [2]*University of Edinburgh, Department of Community Health Science, Edinburgh, United Kingdom*

The Carvedilol Hibernation Reversible Ischaemia Trial; Marker of Success (CHRISTMAS) Study randomised patients with ischaemic cardiomyopathy to carvedilol or placebo. Randomisation was stratified according to the presence or absence of hibernating myocardium at baseline. 2-dimensional and Doppler echo was performed at baseline by the randomising centres and analysed at a core laboratory. The Tei index is a Doppler derived index of myocardial performance that reflects both systolic and diastolic dysfunction and may therefore improve on standard echocardiographic predictors of outcome.

Methods: We analysed baseline echocardiographic data on the 387 patients to determine predictors of death or worsening heart failure over a 3 month follow up period. Variables included were the Tei index, LV wall motion index, mitral E and A wave velocities, E:A ratio, E wave deceleration time, isovolumic relaxation time (IVRT), aortic ejection time, baseline hibernation status, age, sex and treatment allocation.

Results: Stepwise logistic regression identified age, IVRT and the Tei index as independent predictors. Odds ratios were age (per year) 1.08 (95% CI 1.02-1.15), IVRT (per ms) 0.96 (0.94-0.98), Tei (per unit) 8.09 (1.54-42.41). The area under the ROC curve for this model was 0.776 (0.684-0.867). However both the Tei index and IVRT could be analysed by the core lab in only 149 (aged 63±8 years, 87% male, LV ejection fraction 29±10%) of the 387 patients.

Conclusion: In multicentre studies variables that are strongest predictors of outcome may be not be applicable to all patients. A balance has to be reached between variables that are recordable in all patients and those providing the strongest prognostic information.

P3533 How flow contraction, pressure recovery, and viscous resistance affect Doppler measurements across tunnel obstructions – An in-vitro study

R. Rosenhek[1], J. Mascherbauer[1], L. Huber[2], H. Schima[2], G. Maurer[1], H. Baumgartner[1]. [1]*University of Vienna, Cardiology Dept., Vienna, Austria;* [2]*University of Vienna, LBI for Cardiosurgical Research, Vienna, Austria*

Background: We have previously shown that Doppler (D) measurements may not only underestimate pressure gradients across tunnel obstructions as reported by others but may also markedly overestimate them. This phenomenon was observed in tunnels as short as 5 mm and in settings where relevant pressure recovery distal to the obstruction was excluded. We suspected that the Doppler-catheter gradient relation in tunnel obstructions is determined by the combination of flow contraction, pressure recovery and viscous losses, which varies with diameter, length, inlet and outlet geometry of the tunnel.

Methods: To test this hypothesis, tunnels with a length of 20 mm, diameter of 5.5 mm and with gradually tapering inlet and/or outlet (20°) or with abrupt narrowing and/or expansion were studied in a pulsatile flow model. D and catheter (C) measurements were simultaneously performed. C gradients were estimated with the distal pressure port either at the tunnel entrance (dp C1), at the tunnel exit (dp C2) or 10 cm downstream (dp C3). Flow was visualized with a Laser system and recorded with a high-speed video camera.

Results: dp Do showed excellent agreement with dp C1 in all settings (mean difference 0.8±2.4 mmHg). In tunnels with abrupt narrowing, dp Do overestimated dp C2 by 54±19%. Flow visualization demonstrated that this dramatic change in lateral pressure within the tunnel was caused by marked flow contraction at the tunnel entrance resulting in a high velocity and low pressure field followed by readaption of the flow to the full cross-section with only little turbulence resulting in significant pressure recovery within the tunnel itself.

In contrast, in tunnels with gradually tapering inlet, dp Do underestimated dp C2 by 8±2%. In this setting, flow contraction was totally avoided and the neglection of viscous resistance in the simplified Bernoulli equation caused this D - C gradient discrepancy. Due to various extent of distal pressure recovery, dp C3 was 30±7% lower than dp C2 in tunnels with gradually tapering outlet but only 9 ±1% lower in abruptly expanding tunnels. This added various degrees of overestimation of dp C3 by dp Do.

Conclusion: Thus, the D - C gradient relation in tunnel obstructions is determined by the individual extent of (1) flow contraction with pressure recovery within the tunnel, (2) viscous resistance, and (3) pressure recovery distal to the tunnel. The predominance of one of these phenomena depends on inlet and outlet geometry, length and diameter of the obstruction. Overestimation and underestimation by Doppler as well as "pseudoagreement" can occur.

P3534 Transcutaneous continuous wave Doppler cardiac output monitoring of transpulmonary and transaortic flow is feasible

R.A. Phillips[1], M.J. Dadd[2], R.W. Gill[2], M.J. West[1], D.J. Burstow[3]. [1]*University of Queensland, Department of Medicine, Brisbane, Australia;* [2]*CSIRO, Sydney, Australia;* [3]*The Prince Charles Hospital, Echocardiography Department, Brisbane, Australia*

Introduction: Monitoring cardiac output (CO) is important, particularly during anaesthesia, and in the acute care and coronary care for both adults and children, where early detection of changes in cardiac function allows planned therapeutic intervention. Continuous wave Doppler (CW) interrogation of intracardiac haemodynamics is an accurate, reproducible and noninvasive method of quantitating CO. Transcutaneous CW CO monitoring would be a useful application of quantitative echo.

Objectives: Determine the feasibility and reliability of transpulmonary (PV) and transaortic (AV) CW Doppler signal acquisition in supine free breathing subjects, and determine intra and inter observer variability of digital CO signal measurement.

Method: Digital PV and AV flow data were acquired using non-image guided CW Doppler (uscom) from 40 supine free breathing subjects (normal adults (n=10, age =20.3±2.5yrs, BSA=1.81±0.17m^2), normal children (n=10, age =9.9±1.8yrs, BSA=1.21±0.19 m^2), and 20 consecutive patients with cardiopulmonary disease) and compared with signals acquired in the left lateral decubitus position (con). 688 stroke cycles were analysed and haemodynamic parameters measured for each subject, each method and each valve. Reliability was tested by comparison of methods, and reproducibility tested by comparison of repeated and independent observations by a second inexpert observer.

Results: Signal acquisition from supine free breathing subjects was feasible in all cases with excellent correlation between all uscom and con heamodynamic parameters from both PV and AV flow, and repeated observations by the same and independent observers ($p<0.001$) with excellent regression and Bland-Altman statistics. Results from the inexpert and expert readers were not significantly different.

Normal uscom haemodynamic values

	Vpk (m/s)	Pmn (mmHg)	vti (cm)	vti x HR (m/min)
AV adults	1.27±0.14	3.51±0.79	25.1±3.1	18.1±2.9
PV adults	1.07±0.16	2.61±0.64	22.9±3.1	17.1±3.3
AV child	1.13±0.10	2.83±1.55	21.6±2.7	18.7±2.1
PV child	0.91±0.08	1.88±0.32	18.7±2.1	15.3±1.9

Conclusion: A transcutaneous CW ultrasound device that can deliver an accurate beat to beat CO signal may have multiple applications in the delivery of safe, improved and cost effective medical care.

P3535 Doppler echocardiographic assessment of pulmonary hypertension in mild-to-moderate chronic heart failure: prevalence and prognostic implications

F.L. Dini[1], R. Nuti[2], S. Isidori[2], L. Barsotti[2], G. Micheli[2], S.M. De Tommasi[1].
[1]Santa Chiara Hospital, Cardiovascular Diseases Unit 2, Pisa, Italy;
[2]Villamarina Hospital, Cardiology Unit, Piombino, Italy

Pulmonary artery hypertension (PAH) is a frequent finding in patients with mild-to-moderate chronic heart failure, but it is not always easy to assess by Doppler echocardiography because of trivial flow velocity signals of tricuspid regurgitation.
This Doppler-echocardiographic study was carried out to evaluate prevalence and prognostic implications of PAH in patients with mild-to-moderate chronic heart failure and left ventricular (LV) dysfunction.
Two-hundred and fourteen patients with LV dysfunction (ejection fraction <45%) in NYHA class I-IV and sinus rhythm consecutively underwent a complete Doppler echocardiographic study. In case of weak or poor Doppler signals, PASP was measured after intravenous administration of a transpulmonary contrast agent (2.5 grams of Levovist at 400 mg/ml) or physiological saline. Patients were classified into three groups according to the degree of pulmonary artery systolic pressure (PASP): PASP <35 mmHg (absence of PAH), PASP between 35 and 50 mmHg (mild-to-moderate PAH) and PASP >50 mmHg (severe PAH). All patients were subsequently followed-up for a mean period of 22±14 months.
Overall, PASP was 45±14 mmHg and LV ejection fraction was 32±8%. Sixty-four percent of patients were in NYHA class I and II. In 27% of patients, PASP was estimated by the use of contrast. Prevalence of PAH was 67% (65 mild-to-moderate, 78 severe). During follow-up, 45 patients died from cardiac causes (17 sudden death, 28 progressive heart failure) and 38 were hospitalized for worsening heart failure. In the total study population, age >70 years, heart rate >80 beats per minute, PASP >35 mmHg were all independently associated with the combined end-point at multivariate Cox model. Probabilities of survival free from cardiac events were 74% in patients without PAH, 58% in those with mild-to-moderate PAH and 39% in those with severe PAH (p=0.001 by Log-rank). In patients with severe PAH, multivariate Cox analysis showed that only age (hazard ratio [HR]: 3.0, p=0.0037), restrictive mitral flow (HR: 2.7, p=0.0015) and more than mild mitral regurgitation (HR: 2.0, p=0.0033) were independent predictors of event-free survival.
By the use of echo-contrast agents, it was possible to determine noninvasively either prevalence or the prognostic impact of PAH in patients with mild-to-moderate chronic heart failure and LV dysfunction. Older age, restrictive filling and the degree of mitral regurgitation were all independently associated with the outcome of those with severe PAH.

P3536 Accurate measurement of the right atrial pressure using a simple direct noninvasive echocardiographic method: preliminary findings

M. Bertella, F. Scalise, L. Melchiorre, P. Valentini, F. Bassani, A. Colombo, F. Bruni, T. Bertoni. *Vimercate Hospital, Dept. of Cardiology, Vimercate, Italy*

In last decade several attempts have been made to noninvasively estimate right atrial pressure (RAP) by two dimensional (2-D) and doppler echocardiography (echo); however, a noninvasive direct measurement of the RAP has been never proposed. Using a right supraclavicular approach in most of adult patients (pts),examined in the right lateral decubitus, it is possible to record a nearly 12-14 cm longitudinal straight conduit, formed by the right internal jugular vein, right innominate vein and superior vena cava, that, at the bottom, is intersected by the right pulmonary veins. Color flow imaging allows real time visualization of flows, i.e. blue coloured descending laminar flows, alternated with red-painted upward flows, coincident with the v and a waves of the jugular venous pulse. The distance between a zero reference point (zero reference pressure) and the apex of the ascending red flow, could be a direct measure of the RAP. The aim of this study was to assess feasibility, accuracy and limitations of this novel method of RAP estimation, comparing noninvasive (echo) vs hemodynamic (hemo) measurements blindly performed by two distinct operators. Methods 10 consecutive pts (6 men, age 61± 11), in which invasive RAP monitoring was carry out for acute ischemic syndromes, underwent 2-D and M-mode color doppler echo. Zero reference pressure was estimated at the midaxillary line for hemoRAP estimation. EchoRAP was measured, using 2-D and M-mode color doppler echo, from the inferior wall of the superior right pulmonary vein (zero reference pressure) to the apex of the red coloured upward flows caused by the systolic "v" or pre-systolic "a" waves of the jugular venous pulse. EchoRAP and hemoRAP measurements were converted from "cm of blood" and "cm of water" (H2O) into "mmHg", multiplying the values respectively by 0.78 and 0.74. Results: in all pts except for one, who presented an enlarged ascending aorta, superior vena cava was easily imaged. In 7 pts, who presented hemoRAP between 3.5 and 15 cm H2O (i.e. 2.5 and 11 mmHg), a good correlation was observed between non-invasive vs hemodynamic measurements of the RAP (4,69 ±2.66 vs 5.07± 2.64 mmHg, R=0.98). In one subject in which the hemoRAP was more than 20 cm H2O and in one with a negative hemoRAP (mean RAP= -2 cm H2O), no reliable value of the RAP was measured. Conclusion: within a RAP range between 2.5 and 11 mmHg, it appears possible to obtain an accurate noninvasive direct measurement of the RAP using 2-D and M-mode color doppler echo.

CARDIAC METABOLISM

P3537 Improvement in myocardial glucose uptake after five months of exercise training in patients with dilated cardiomyopathy

K. Stolen[1], J. Kemppainen[1], K. Kalliokoski[1], M. Luotolahti[2], T. Salo[3], J. Airaksinen[3], P. Nuutila[1], J. Knuuti[1]. [1]*University of Turku, Turku PET Centre, Turku;* [2]*Dept. of Clinical Physiology,* [3]*Dept. of Internal Medicine, Turku University Central Hospital, Turku, Finland*

The effect of exercise training on myocardial glucose uptake was studied in 15 clinically stable patients with dilated cardiomyopathy (NYHA class I-II) using positron emission tomography (PET) techniques. Eight of these patients (ejection fraction = 33±9%) participated in a 5 month endurance and strength training program at an intensity of 70% of peak oxygen consumption (VO2), while 7 patients (ejection fraction = 35±7%) served as non-trained control subjects. All patients remained on the same standard medical therapy including ACE inhibitors and β-blockers for the duration of the study. Measurements of left ventricular function were assessed using two-dimensional echocardiography. Myocardial glucose uptake was measured under euglycemic hyperinsulinemic clamp conditions using [18F]FDG and positron emission tomography (PET). The patients that participated in the training program exhibited a 16% increase in ejection fraction (33±9 to 38±9%; p=0.004) while no change was observed in the control group (35±7 to 37±6%; p=NS). Exercise training was also associated with a 27% increase in peak VO2 in the training group (19.9±4.2 to 25.2±5.2 ml/kg/min; p<0.001) while no change was noted in the control group (20.6±4.2 to 21.2±2.9 ml/kg/min; p=NS). There was no statistical difference in serum free fatty acid, serum insulin, and plasma glucose levels between either patient group. Baseline myocardial glucose uptake rates were improved in the training group from 39.6±18.7 to 48.1±18.5 μmol/100g/min (P=0.01) while no change was observed in the control group (from 49.9±18.4 to 48.0±19.0 μmol/100g/min). Myocardial glucose uptake calculated for the whole left ventricle also was significantly improved in the training group (162.6±92.9 to 194.6±99.9 μmol/min; p=0.04) compared to the control group (161.9±65.1 to 159.8±57.0 μmol/min; p=0.90). These results indicate that exercise training in this patient population improves myocardial glucose uptake. This improvement in glucose uptake may be indicative of a switch in myocardial preference to a more energy-efficient substrate.

P3538 Myocardial fatty acid oxidation is increased in patients with insulin dependent diabetes mellitus

R. Gropler, D. Cassady, Z. Kisrieva-Ware, M. Srinivasan, J. McGill, P. Herrero. *Washington University School of Medicine, Radiology, St. Louis, USA*

Objectives: In patients with insulin-dependent diabetes (IDDM) there is a decline in myocardial glucose utilization (MGU) that is paralleled by an increase in myocardial fatty acid utilization (MFAU) and oxidation (MFAO). It is unknown if the increase in MFAO simply reflects the increase in fatty acid uptake by the heart or an increase in the percent of extracted fatty acids that are oxidized. **Methods:** In 11 IDDM (3M; 36±11 yrs; HgbA1C 8.4±1.9%) and 5 normal volunteers (NV; 5M; 25±5 yrs) measurements of myocardial blood flow (MBF in mL/g/min), myocardial oxygen consumption (MVO2), MGU, MFAU and MFAO (all in umol/g/min) were measured by PET using O-15 water, C-11 acetate, C-11 glucose and C-11 palmitate respectively under resting conditions. The IDDM were studied during a low dose glucose-insulin infusion and NV were studied after a standard carbohydrate meal. All subjects were nonsmokers and were without hypertension and hyperlipidemia and had a normal rest/stress echocardiogram. **Results:** Plasma glucose, insulin, and lactate levels were comparable between the two groups (p=NS). However, plasma fatty acid levels were significantly higher in IDDM (0.59±0.25 umol/mL) compared to NV (0.15±0.06 umol/mL, P<.03). The rate pressure product was higher in IDDM compared with NV (p<.05). As a consequence, MBF and MVO2 tended to be higher when compared with NV (p=0.11 and 0.08, respectively). As expected, MGU was significantly lower in IDDM (0.21±0.11) compared with NV (0.46±0.21, p<.01). Both MFAU and MFAO were significantly higher in IDDM (0.21±0.14 and 0.21±0.13) compared with NV (0.03±0.02 and 0.02±0.02, p<.03 for both measurements). In addition, MFAO/MFAU in IDDM was increased when compared with NV (0.94±0.07 vs 0.83±0.14,p<.05). There was a negative correlation between MFAO/MFAU and plasma fatty acid levels in NV (r=-.93, p<.03) where there was no correlation in IDDM.
Conclusion: In IDDM, the percent of extracted fatty acid that is oxidized is increased. This increase cannot be explained solely by an elevation in plasma fatty acid levels. The increase in MFAO may help partially explain the increase in cardiac complications associated with IDDM.

P3539 Cardiac phantom measurement validating the methodology for a cardiac multi-center trial with positron emission tomography

J. Nuyts[1], P. Mertens[2], F. Van de Werf[2], J. Djian[3], L. Mortelmans[1], M. Schwaiger[4], P. Touboul[5], A. Maes[1] on behalf of PSALM study group. [1]*UZ Gasthuisberg, Nuclear Medicine, Leuven, Belgium;* [2]*KULeuven, Cardiology, Leuven, Belgium;* [3]*Weyth Research, Paris, France;* [4]*TU Muenchen, Nuclear Medicine, Muenchen, Germany;* [5]*Hopital CardioVasculaire Pneumologique, Lyon, France*

In an ongoing international multi-center trial, positron emission tomography (PET) is used to evaluate the effect of a new P-selectin antagonist on the infarct size in patients with acute myocardial infarction treated with thrombolysis. Although it is possible to correct for site-dependent factors, it is desirable to reduce these factors to a minimum. Therefore, an acquisition and reconstruction protocol have been defined that could be closely followed by all participating centers. The resulting reconstructed images are transferred to the core center for central processing with semi-automatic software. This paper reports on the multi-center phantom experiment that was carried out to assess the inter-center reproducibility of infarct size determination with this protocol. Also the spatial resolution of the short axis slices was examined. In addition, the analysis procedure was applied to normal PET-studies to evaluate the specificity of perfusion defect detection.

The transmural infarction in the phantom occupied 14.8% of the left ventricular area. The automated analysis was applied to the phantom measurements from the fourteen participating PET cameras. It yielded an accurate estimate of 15.1% with a standard deviation of 0.6%, indicating excellent reproducibility. The spatial resolution in the short axis slices was similar for all PET systems: 9.6 mm ± 0.8 mm. The same procedure produced an infarct size of zero in the studies of the normal volunteers.

The same phantom experiment was repeated on 14 scanners in 13 PET centers. Excellent inter-center reproducibility of defect size and global spatial resolution was observed, indicating that myocardial images from different PET-centers can be pooled for statistical analysis.

P3540 Myocardial perfusion and metabolic changes induced by biventricular pacing in patients with dilated myocardiopathy and conventional pacing

E. bertaglia[1], P. Zanco[2], P. Sarto[1], F. Zerbo[1], F. Zoppo[1], N. Frigato[1], G.F. Neri[3], P. Pascotto[1]. [1]*Ospedale Civile, Cardiologia Dipt., Mirano, Italy;* [2]*Ospedale Civile, Nuclear Medicine, Castelfranco, Italy;* [3]*Ospedale Civile, Cardiologia, Montebelluna, Italy*

Background: Biventricular pacing recently demonstrated to be useful in improving symptoms of medical refractory heart failure in patients (pts) with dilated myocardiopathy (DMC) and left bundle branch block (BBB) with a prolonged QRS duration. Preliminary experience with cardiac Positron Emission Tomography (PET) suggested that biventricular pacing could eliminate the interference on the myocardial metabolism of the septum induced by left BBB. Pts with chronic right ventricular apical pacing show enlarged QRS with a left BBB-like activation. Aim of this preliminary study was to verify if upgrading to biventricular pacing could ameliorate the metabolism of the septum in patients with DMC and chronic right ventricular pacing too.

Methods: We performed an upgrading to biventricular pacing in 3 male pts (mean age 73.7±4.7 years) with DMC and end stage heart failure (NYHA class III-IV) despite optimal medical therapy in whom a conventional right ventricular pacing system (DDD in 2 and VVIR in 1) had been implanted 74±71 months before. A third degree AV block without spontaneous rhythm faster than 40 bpm was present in 2 pts, while a second degree AV block with a right BBB morphology (QRS duration < 120 ms) was present in 1 pt. Permanent atrial fibrillation was present in 1 pt.

PET and echocardiogram were performed few days before and 3 months after the upgrading. Metabolism was evaluated using F18-fluorodeoxyglucose, by the glucose load-insulin technique, and perfusion by N13-ammonia, injected at rest. A visual and a semi quantitative analysis were performed. Left ventricular ejection fraction was determined by calculating the end-diastolic and end-systolic volumes according to Folland.

Results: During conventional right apical pacing all pts presented at the visual analysis of the PET a relatively reduced FDG uptake in the septum when compared to the NH3 uptake (0.670±0,130 vs 0.983±0.040, p=0.01). This reverse mismatch disappeared after upgrading to biventricular pacing (1.116±0.300 FDG uptake vs 0,997±0,244 NH3 uptake, p=0.08). Left ventricular ejection fraction remained unchanged after upgrading to biventricular pacing (19.3±6.0 vs 26.0±6.1, p=0.15)

Conclusion: These preliminary results suggest that: 1) in pts affected by DMC conventional right ventricular pacing induces an alteration in the metabolism of the septum similar to that observed in pts with left BBB and DCM; 2) upgrading to biventricular stimulation eliminates this reverse mismatch.

P3541 Early determination of oxidative metabolism and development of perfusion and myocardial damage in acute ST-segment elevation myocardial infarction

G. Frostfeldt[1], J. Sorensen[2], B. Lindahl[1], L. Wallentin[1]. [1]*Uppsala University Hospital, Cardiology, Uppsala, Sweden;* [2]*Uppsala University Hospital, Clinical Physiology, Uppsala, Sweden*

Patients with acute ST-elevation myocardial infarction who obtain early reperfusion with TIMI grade 3 flow in the infarct related artery will have the best prognosis. It has been reported that oxidative metabolism after successful reperfusion was a stronger predictor than perfusion regarding left ventricular recovery.

Methods: In eight patients PET was performed as early as 3 h after start of fibrinolysis. The myocardium was divided into four regions, remote, border remote, border infarct and infarct region. The oxidative metabolism was determined with 1-11C-acetate, MBF (myocardial blood flow) and PTF (fraction (g/ml) of myocardial tissue capable of rapidly exchanging 15O-water) with 15O-water. PET investigations were also performed after 24 h and after 3 weeks (MBF and PTF).

Results: The myocardial perfusion and oxidative metabolism decreased closer to the infarct region. PTF (related to remote) was low at 3 h in the infarct and in the border infarct region and was significantly increasing over time (p=0.02 and p=0.01). Relative myocardial perfusion did not show any significant changes over time and there was no consistent correlation to PTF. However, oxidative metabolism at 3 h was correlated to PTF in the infarct area at 3 and 24 h and after 3 weeks (p= <0.01, r=0.96; p=0.04, r=0.79 and p=0.052, r=0.75.

Conclusions: Oxidative metabolism, determined as soon as 3 hours after start of fibrinolysis, correlated to PTF over time in the infarct area which myocardial perfusion did not. Further, PTF increased significantly over time. This suggests that further development of reperfusion treatment is needed, to achieve earlier and more complete restoration of myocardial perfusion and oxidative metabolism and PET might be useful in assessing treatment efficacy.

P3542 Influence of myocardial energetics on exercise capacity in patients with dilated cardilmyopathy

K. Stolen[1], J. Kemppainen[1], K. Kalliokoski[1], K. Hällsten[1], T. Salo[2], J. Airaksinen[2], P. Nuutila[1], J. Knuuti[1]. [1]*University of Turku, Turku PET Centre, Turku, Finland;* [2]*Turku University Central Hospital, Department of Internal Medicine, Turku, Finland*

Twenty clinically stable patients with dilated cardiomyopathy (DCM) and 13 apparently healthy age-matched controls were studied in order to determine the extent that myocardial perfusion and energetics effect peak exercise capacity (VO2). All study subjects underwent a symptom limited, incremental cycle ergometer test with respiratory gas analysis to volitional fatigue. Myocardial perfusion and biventricular oxidative metabolism were measured using positron emission tomography (PET) techniques along with [15O]H2O and the monoexponential clearance rate of [11C]acetate (kmono), respectively. Hyperemic perfusion was measured after dipyridamole (0.56 mg/kg per min) administration. Perfusion reserve was calculated as the ratio of hyperemic to resting perfusion. The ratio between right and left ventricular oxidative metabolism (Kratio) was also calculated. Basal myocardial perfusion (0.86 ± 0.17 vs. 1.00 ± 0.21 ml/min/g; p = 0.04), hyperemic perfusion (1.73±0.83 vs. 3.01±1.20 ml/min/g; p<0.001), and perfusion reserve (2.01±0.91 vs. 3.08 ±1.35 ml/min/g; p=0.01) were all lower in the DCM patients compared to the healthy subjects, respectively. There was no difference in left ventricular oxidative metabolism (LVkmono) between the two groups (0.066 ± 0.015 vs. 0.070 ± 0.012 per min; p = 0.40), however, the DCM patients had a significantly higher right ventricle kmono level (0.051 ± 0.007 per min) compared to the healthy subjects (0.043 ± 0.009 per min; p=0.007). Consequently, the Kratio was also higher in the DCM patients (0.81±0.17) compared to the healthy subjects (0.62±0.09; P=0.001). When assessing the relationship between exercise capacity and various myocardial parameters in the DCM patients, the strongest correlation was found between Kratio and exercise capacity (r=-.68, P=0.001). A positive correlation was also found between exercise capacity and myocardial perfusion reserve (r=0.62, p=0.004). Regression analysis showed that the combination of these two parameters explained 47% of the variability in peak exercise capacity. When further analyzing the relationship between exercise capacity and myocardial energetics, patients with a Kratio greater than the lowest value obtained from the healthy subjects (0.8) had a significantly lower exercise capacity (16.2±2.8 ml/kg/min) compared to patients with a Kratio less than 0.8 (21.0±4.0 ml/kg/min; P<0.001). These findings indicate that exercise capacity is associated with myocardial energetics in patients with DCM and mild heart failure.

P3543 Myocardial blood flow and viability in patients with left ventricular dysfunction secondary to coronary disease

K. Morita[1], M. Pitt[2], R.S. Bonser[2], P.G. Camici[1], D.P. Dutka[3]. [1]*MRC Clinical Sciences Centre, NHLI, London, United Kingdom;* [2]*Queen Elizabeth Hospital, Cardiac Surgery Dept., Birmingham, United Kingdom;* [3]*University of Cambridge, Medicine, Cambridge, United Kingdom*

The identification of viable myocardium in patients with chronic left ventricular (LV) dysfunction and coronary artery disease (CAD) is important to select patients who may benefit from revascularisation. The extent of hibernating myocardium may be predicted by myocardial glucose uptake (MGU) measured by positron emission tomography (PET) using 18F-fluorodeoxyglucose (FDG). The relationship between myocardial hibernation and myocardial blood flow (MBF) is the subject of continuing debate. Similarly, the prevalence of dysfunctional but viable myocardium in this increasingly common group of patients remains unclear. We therefore measured MBF and myocardial viability in patients with impaired LV function and CAD referred for bypass surgery (CABG).

Patients and Methods: 114 patients (aged 60.2 ± 8.8 yrs) with significant LV dysfunction (LV ejection fraction <35%, mean 26 ± 10%) and multivessel CAD were studied. MBF was measured using oxygen-15 labelled water at rest and during adenosine infusion (140 μg/kg/min). MGU determined by quantitative PET during hyperinsulinaemic clamp. A 16-segment LV model was used for PET data analysis.

Results: Global resting MBF in patients was similar to normal volunteers (0.84 ± 0.28 vs 0.90 ± 0.14 ml/min/g, P=NS) but markedly blunted during adenosine (1.27 ± 0.63 vs 3.57 ± 0.84 ml/min/g, P<0.001). In patients, overall MGU was 0.41 ± 0.21μmol/min/g and in 83% of LV segments MGU was >0.25 μmol/min/g (previously found to optimally predict viability). A stepwise decline in hyperaemic MBF, MGU and an increase in prevalence of non-viable segments was noted as MBF decreased (table).

Quartile MBF(ml/min/g)	>1.02	0.81 - 1.01	0.65 - 0.80	<0.64
No segments	371	374	374	370
MGU (micromol/min/g)	0.51 ± 0.22	0.43 ± 0.21	0.39 ± 0.18	0.35 ± 0.15
MBF (Adenosine)	1.50 ± 0.71	1.28 ± 0.56	1.25 ± 0.61	1.05 ± 0.56
% non viable	9	16	20	23

ANOVA: P<0.001 for each column vs Q1

Conclusions: Viable dysfunctional myocardium is common in patients with impaired LV function and CAD. The reduction in segmental MGU in association with lower resting and peak MBF suggests that the ability of the heart to withstand ischaemia and number of viable myocytes that will benefit from revascularisation also declines.

P3544 Cardiac power output and myocardial blood flow during dobutamine stress in patients with coronary artery disease

K. Morita[1], E. Barnes[1], P.G. Camici[1], D.P. Dutka[2]. [1]*MRC Clinical Sciences Centre, NHLI, London, United Kingdom;* [2]*University of Cambridge, Medicine, Cambridge, United Kingdom*

Patients with coronary artery disease (CAD) treated medically are frequently limited by breathlessness rather than angina that is thought to be secondary to the limited ability of the heart to increase cardiac output in response to demand. To probe this further we used positron emission tomography to simultaneously assess cardiac power and myocardial blood flow in response to dobutamine stress in patients with CAD whose exercise tolerance was limited by breathlessness.

Subjects and Methods: Comparison was made between 9 male healthy volunteers (age 57±7 (mean±SD) yrs) and 11 patients (age 63±8 yrs) with CAD who were limited on exercise by breathlessness rather than angina pectoris. All subjects had normal resting left ventricular (LV) function at echocardiography and the patients had >50% stenosis in 2 or more major coronary arteries. Myocardial blood flow (MBF) and cardiac output (CO) were measured using the flow tracer oxygen 15-labelled water (10 MBq/Kg) at baseline and at peak dobutamine stress. Beta-blockers and calcium antagonists were withdrawn 72 hours prior to the study and other anti-anginal medication withdrawn on the day of the study. A single tissue compartment tracer kinetic model was used to calculate global MBF (ml/min/g) and CO. Cardiac power output was calculated as CO x MAP x K watts (where MAP is mean arterial pressure and K conversion factor 0.00222).

Results: Resting CO was 4.13 ± 1.27 l/min in volunteers and 4.21 ± 0.76 l/min in patients and MBF 0.81 ± 0.16 ml/min/g and 0.89 ± 0.22 ml/min/g respectively. The mean increase in cardiac output after dobutamine was 3.05 ± 1.1l/min in the volunteers and 2.3 ± 0.8 l/min in the patients (P<0.05). The corresponding changes in cardiac power output were 0.81 ± 0.31W and 0.66 ± 0.35W respectively (P<0.01). In the volunteers, the increase in MBF was 1.89 ± 0.72 ml/min/g but only 0.79 ± 0.37 ml/min/g in the patients (P<0.01). The relationship between rate-pressure product and MBF was maintained in both patients and volunteers, although peak cardiac power occurred at lower MBF in the patients consistent with demand ischaemia.

Conclusion: In patients with stable CAD and normal resting LV function, the increase in cardiac output and power in response to dobutamine is limited by the failure of MBF to rise appropriately although the relationship between MBF and RPP is maintained.

P3545 Impact of estrogen on myocardial fatty acid utilization and oxidation in postmenopausal women

R. Gropler, M. Srinivasan, D. Delano, Z. Kisrieva-Ware, P. Herrero. *Washington University School of Medici, Radiology, St. Louis, United States of America*

Objectives: Results of studies in experimental animals have demonstrated that estrogen enhances myocardial fatty acid utilization (MFAU) and oxidation (MFAO) primarily through its modulation of the perioxsome proliferator receptor alpha system. Whether estrogen plays a similar role in myocardial lipid homeostasis in humans is unknown.

Methods: Measurements of myocardial blood flow (MBF in mL/g/min) oxygen consumption (MVO2), glucose utilization (MGU), MFAU and MFAO (all in nmol/g/min)were measured by PET using O-15 water, C-11 acetate, C-11 glucose, and C-11 palmitate, respectively. Under resting conditions and in the fasted state, measurements were obtained in 10 older males (OM, 67 ± 6 yrs), 6 older females not taking estrogen (OF, 68 ± 5 yrs) and in 5 females on long-term estrogen therapy (OFE, 64 ± 2 yrs). All subjects were nonsmokers and were without hypertension and hyperlipidemia and had a normal rest-stress echocardiogram.

Results: Plasma glucose, insulin, and fatty acid levels were comparable between the three groups (p=NS). Plasma lactate levels tended to be higher in OM compared with OF or OFE (p < 0.07). The rate pressure product tended to be higher in the OM compared with the OFE (p=.16). As we have shown previously, MBF/RPP was higher in both OF (2.21±0.26 x 10,000 mmHg x BPM) and OFE (2.31±0.86 x 10,000 mmHg x BPM) compared with OM (1.65±0.38x10,000 mmHg x BPM, p<.001). MVO2/RPP was significantly higher in OFE (1.35±0.48 mmHgxBPM) compared with OM (0.81±0.25 mmHgxBPM, p<.03) or OF (1.03±0.33 mmHgxBPM, p<.03). MGU/RPP did not differ among the three groups. However, MFAU/RPP was highest in OFE (0.049±0.019 mmHgxBPM) than either OF (0.033±0.005 mmHgxBPM, p<.02) or OM (0.029±0.01 mmHgxBPM, p<.02). Similarly, MFAO/RPP was highest in OFE (0.047±0.018 mmHgxBPM) compared with either OF (0.029±0.005 mmHgxBPM, p<.007) or OM (0.025±0.001 mmHgxBPM, p<.007).

Conclusion: In healthy postmenopausal women, estrogen replacement therapy stimulates MFAU and MFAO which may also result in an increase in MVO2. Whether similar effects occur in men are unknown. The effect of estrogen on myocardial lipid homeostasis may help explain some of the conflicting observations regarding estrogen replacement therapy and cardiovascular risk in postmenopausal women.

P3546 Intramitochondrial beta-oxidative fatty acid metabolism accelerating in spite of preferably a little energy fuels in chronic heart failure

H. Tachikawa[1], K. Watanabe[2], T. Takahashi[3], M. Kodama[1], M. Nakazawa[4], Y. Aizawa[1]. [1]Niigata University, First Department of medicine, Niigata, Japan; [2]Niigata College of Pharmacy, Department of Clinical Pharmacology, Niigata, Japan; [3]Niigata University, Radioisotope Center, Niigata, Japan; [4]Niigata University, Department of Medical Technology, Niigata, Japan

Background: Fatty acid are used as a major fuel in the fed state of heart, and 123I-beta-methyl-iodophenylpentadecanoic acid (BMIPP) is available for assessing mitochondrial metabolic function, but the metabolism in heart failure remained to be not clarified. 9-methyl-pentadecanoic acid (9MPA) is converted to 3-methyl-nonanoic acid (3MNA) by beta-oxidation in mitochondrium and then to p-iodophenylacetic acid (PIPA) as the next metabolite through additional beta-oxidation after alpha-oxidation. We investigated fatty acid metabolism in chronic heart failure using BMIPP and 9-MPA.
Methods: Autoimmune myocarditis was induced in Lewis rats by injection of porcine cardiac myosin. Three groups were designed as normal control(NC group), chronic heart failure(CHF group; 60th day after injection), and therapy group(Tx group; chinapril, angiotensin converting enzyme inhibitor, 2mg/kg/day in chronic phase). Rats were injected BMIPP(0.7MBq) or 9-MPA(1.0MBq), and then sacrifised after 3 min., 10 min., 30 min. and 60 min. We examined hemodynamic parameters, pathological findings, and fatty acid metabolism. The myocardial uptakes of BMIPP and 9-MPA were examined as %dose/g tissue and differential absorption ratio (DAR) corrected with body weight. The metabolism were analyzed by NIH image quantitatively substrate pattern of 9-MPA, 3-MNA, and PIPA fraction on thin layer chromatography(TLC).
Results: Left ventricular weight/body weight ratio was increased in CHF group(0.440%) compared with NC group(0.260%)($p<0.0001$), and it was reduced in Tx group(0.328%)($p<0.0001$). Histological changes such as fibrosis were prominent in CHF compared with control and Tx group. The myocardial uptakes of BMIPP and 9MPA were reduced in CHF compared with NC(1.617% vs 2.097%, $p<0.05$). According to quantitative analysis of metabolite fraction, in CHF 3MNA ratio(11.4% vs 6.6%) at 3 min., PIPA ratio(8.7% vs 6.3%) and 3MNA and PIPA ratio(15.7% vs 11.1%) at 10 min. were increased compared with NC(respectively $p<0.05$), and then also this ratio tendency remained until 60 min($p<0.01$), instead of TG pool amounts was not different among all. Therapy made intermittent metabolites(3MNA and PIPA) ratio at 10 min. and 60 min. decreased compared with CHF(respectively $p<0.05$ and $p<0.01$)
Conclusions: In chronic heart failure, the uptake of fatty acid were decreased and fatty acid metabolism was suppressed, but our deta suggested intramitochondrial beta oxidative metabolism were accelerated in spite of preferably a little energy fuels.

P3547 Myocardial fatty acid imaging and expression of peroxisome proliferator-activated receptor in volume-overloaded rabbit hearts

T. Miyamoto[1], Y. Takeishi[1], H. Takahashi[1], S. Tazawa[2], M. Inoue[2], I. Kubota[1]. [1]Yamagata University School of Medicine, The First Department of Internal Medic, Yamagata, Japan; [2]Daiichi Radioisotope Laboratories, Tokyo, Japan

The peroxisome proliferator-activated receptor (PPAR)-alpha is a member of the nuclear receptor superfamily and regulates gene expression of fatty acid utilization enzymes. In cardiac hypertrophy and heart failure by pressure-overload, myocardial energy utilization reverts to the fetal pattern, and metabolic substrate switches from fatty acid to glucose. However, myocardial metabolism in volume-overloaded hearts has not been rigorously studied. The aim of the present study was to examine fatty acid metabolism and PPAR-alpha expression in volume-overloaded rabbit hearts. Volume-overload was induced by carotid-jugular shunt formation. Sham operated rabbits were used as control. Chronic volume-overload increased left ventricular weight (4.1 ± 0.2 g vs. 6.1 ± 0.5 g, $P < 0.01$) and ventricular cavity size (12.8 ± 0.5 mm vs. 17.5 ± 0.5 mm, $P < 0.01$), and relative wall thickness was decreased (0.40 ± 0.02 vs. 0.28 ± 0.01, $P < 0.01$), indicating eccentric cardiac hypertrophy. Iodine-125-iodophenyl 9-methylpentadecanoic acid (9MPA) was intravenously administered, and animals were sacrificed at 5 min after tracer injection. The 9MPA was rapidly metabolized to iodophenyl-3-methylnonanoic acid (3MNA) by beta-oxidation. Lipid extraction from the myocardium was performed by the Folch method, and the radioactivity distribution of metabolites was assayed by thin-layer chromatography. Total RNA was extracted from the myocardium, and levels of PPAR-alpha mRNA were examined by semi-quantitative reverse transcriptase polymerase chain reaction (RT-PCR). Myocardial distribution of 9MPA was more heterogeneous in shunt than in sham rabbits ($P < 0.05$). In volume-overloaded hearts by shunt, the conversion from 9MPA to 3MNA was faster than in sham control hearts (56 ± 18 vs. 39 ± 3%dose/mg tissue, $P < 0.05$). However, mRNA expression of PPAR-alpha was downregulated in shunt rabbits compared to sham rabbits ($P < 0.05$). These data suggest that myocardial fatty acid metabolism was altered in eccentric cardiac hypertrophy by volume-overload.

CORONARY ANGIOGRAPHY

P3548 Coronary artery stenosis can be predicted by the presence of typical angina symptoms

P. Guzik[1], J. Tarchalski[2], H. Wysocki[1], A. Hoffman[3]. [1]University School of Medical Sciences, Div. of Cardiology - Intens. Therapy, Poznan, Poland; [2]Kalisz Hospital, Coronary Catheter Lab, Kalisz, Poland; [3]Bydgoszcz Academy of Medicine, Echocardiography Lab, Bydgoszcz, Poland

An appropriately taken history is the richest source of information concerning ischaemic heart disease. The study goal was to determine the predictive value of angina-like symptoms in the diagnosis of stenotic changes within coronary arteries. A prospective study was performed in 250 patients (26 - 75 years old, 187 male, 64 female) who had coronary angiography due to their angina symptoms. No patient had known previous myocardial infarction. According to their symptoms all patients were divided into typical or atypical angina group. The typical angina was defined as the presence of a pain in typical (retrosternal) location, triggered by exercise or stress and relieved by sublingual nitrates or rest. Any kind of angina that could not fulfil these criteria was characterised as an atypical one. We evaluated specificity, sensitivity, and positive and negative predictive value of angina-like symptoms according to the results of coronary angiography (narrowing of artery lumen $\geq$ 50% in at least 1 vessel). Additionally, an unadjusted and adjusted for age, sex, history of smoking, hypertension and diabetes mellitus logistic regression analysis was performed for prediction of the presence of any significant stenotic change in coronary arteries. Logistic regression results are presented as an odds ratio with 95% confidence interval (CI). The presence of typical angina was associated with specificity of 79.55%, sensitivity of 84.66%, positive predictive value of 88.46% and negative predictive value of 73.68%. Odds ratio for typical angina symptoms and the presence of coronary stenosis in the unadjusted logistic regression was 21.47 (95% CI: 10.98 - 41.98; $p < 0.0001$) whereas in the adjusted analysis it was 23.13 (95% CI: 10.59 - 50.53; $p < 0.0001$). The obtained results indicate that typical angina symptoms have a high predictive value for the presence of significant stenosis within coronary arteries. It confirms also that a carefully taken patient history is still a powerful diagnostic tool in coronary artery disease.

P3549 Comparison of TIMI frame counts of patients with and without coronary artery ectasia

E. Yetkin[1], R. Atak[2], H. Turhan[2], N. Sivri[1], M. Ileri[2], F. Kosar[1], R. Ozdemir[1], S. Cehreli[1]. [1]Inonu University Faculty of Medicine, Department of Cardiology, Malatya, Turkey; [2]Turkiye Yuksek Yhtisas Hospital, Dept. of Cardiology, Ankara, Turkey

Background: Thromblysis In Myocardial Infarction (TIMI) frame count is a simple clinical tool for assessing quantitative indexes of coronary blood flow. Coronary artery ectasia,(CAE) is characterized by segmental or diffuse dilatation of the coronary arteries to >1.5 the diameter of the adjacent segments of the same artery or of different artery. In this study we aimed to evaluate the coronary flow in patients with CAE by the means of TIMI frame count (TFC) and to compare with subjects who have angiographycally normal coronary arteries.
Materials and Methods: Study population consisted of 37 patients with coronary artery ectasia only in the right coronary artery (RCA). To be included in the study, patients also needed to have no significant stenostic lesion (>50%) in the coronary three, no valvular heart disease, previous myocardial infarction, and no wall motion abnormalities with echocardiography. Control group consisted of 31 patients with angiographically proven normal coronary arteries.
Results: There are no statistically significant differences between two groups in respect to age, gender, presence of hypertension, smoking ($p>0.05$ for all). TIMI frame count of RCA in the study group was significantly higher than in that of control group(51 ± 17 vs 25 ± 8 $p<0.001$ respectively). TIMI frame counts of the study group for left anterior descending (LAD) and left circumfle(LCx) coronary artery were also significantly higher than those of control group (Corrected TFC for LAD=42 ± 11 vs 24 ± 7 respectively $p<0.001$, TFC for LCx; 44 ± 15 vs 25 ± 9 respectively $p<0.001$). In patients with CAE, TFC of the RCA was higher than that of LAD and LCx coronary artery(51 ± 17 vs 42 ± 11 and 44 ± 15 respectively $p<0.05$). TIMI frame count of the RCA showed significant correlation with the TFC of the LAD($r=0.422$ $p<0.01$) and LCx coronary arteries($r=0.530$, $p<0.01$).
Conclusion: Patients with CAE have significantly increased TFC when compared to patients with normal coronary arteries. In one vessel ectasic patients, TFC of non-ectasic vessels is also significantly higher than that of patients with normal coronary arteries. Significant correlation between the TFCs of ectasic and non-ectasic vessels in the same patients has also suggested that the mechanism underlying CAE, affects the coronary flow even in non-ectasic vessels.

P3550 Comparison of clinical state and quality of life of patients with and without angiographic follow-up after coronary angioplasty

P. Sick[1], J. Krutzsch[1], K. Krieger[1], G. Gelbrich[2], G. Schuler[1]. [1]Heart Center, Clinic for Int. Medicine/Cardiology, [2]Coordination Center for Clinical Trial, University of Leipzig, Leipzig, Germany

Background: Angiographic follow-up is normally scheduled 6 months after percutaneous transluminal coronary angioplasty (PTCA) and stent implantation (SI). The common experience is, that 10-20% of the patients do not appear for follow-up. It would be important to know whether the drop-out might be informative to take this into account when planning clinical trials, and interpreting their results.
Methods: We included 49 patients with single-vessel coronary artery disease treated by PTCA and SI who did never appear for follow-up. The examination was done 2-18 months after the scheduled follow-up date and consisted of recording the CCS class, answering a questionnaire regarding satisfaction with health (SH), physical functioning (PF), heart-related discomfort (HD) and physical exhaustion (PE), and performing a structured interview on physical activity, comorbidity and use of medication. This cohort was compared to a sample of 104 patients who visited the hospital for angiographic follow-up, and underwent the same examination besides the routine clinical procedures.
Results: Patients without follow-up were more likely to be free of symptoms of angina (OR=3.1 to have CCS-0, 95% C.I.: [1.5,6.5]) and reported less HD (4.1 vs 5.4 points on a 24 point scale, 95% C.I. for difference of means [0.0,2.8]). The two groups were not distinguishable in SH, PF and PE. A non-significant but remarkable difference was noticed among patients with CCS-0: Nitrate was more often used by patients without follow-up (21% vs 8%, P=0.17). Nonetheless, the clinical difference between the cohorts is still significant when adjusting for nitrate (OR=2.0 for CCS-0 and no use of nitrate, 95% C.I. [1.0,4.0]). Among patients without follow-up who were classified as CCS-0, those ones using nitrate reported more HD (P=0.06) and PE (P<0.001), and less PF (P=0.004) and SH (P=0.1) in comparison to patients not using nitrate.
Conclusions: Drop-outs by missing the angiographic follow-up should be considered to be informative. When evaluating only patients seen at the follow-up examination, the mean clinical success of the treatment is underestimated. In randomized clinical trials, differences between treatments measured by endpoints related to symptoms of angina may be underestimated. In addition, patients who prefer to avoid follow-up angiography should be encouraged to undergo the non-invasive clinical examinations. Physicians should consider the possibility that apparently angina-free patients might suppress serious symptoms by the use of nitrate.

P3551 High incidence of microcirculation abnormality produced by percutaneus transluminal coronary rotational athrectomy (PTCRA)

S. Yasuda, H. Matsuo, M. Tomita, T. Yamaki, T. Kadosaki, T. Hirose, S. Tanaka, S. Watanabe. Gifu Prefectural Hospital, The Department of Cardiology, Gifu City, Japan

Background: Potential risk of microcirculation abnormality produced by embolization of abraded non-compliant plaque, platelet aggregation, and vasospasm is an important issue. However, the incidence of perfusion and functional abnormality caused by PTCRA is not fully known yet.
Methods: Serial 99mTc-tetrofosmin QGS SPECT were performed before and just after coronary intervention in 39 patients (21: Rotablator, 18: POBA and Stenting) to assess the acute effect to myocardial perfusion and function.
Results: Procedural success with TIMI 3 flow was aschieved in all patients. Patients with PTCRA experienced significantly high incidence of ST segment elevation(4 out of 21 patients) and scintigraphical deterioration in perfusion (14 of 21 patients) compared with POBA and stenting, although no significant difference of functional deterioration was observed.

Change of QGS parameter after PCI

	PTCRA	Other devices	p value
prolonged ST elevation	4/21	0/18	n.s
perfusion abnormality	14/21	3/18	0.005
change of extent score	14.8 (SD 16.2)	-3.0 (21.7)	0.005
change of severity score	30.4 (SD 32.9)	-7.6 (SD 39.6)	0.002
change of EDV	-6.0 (SD 15.8)	-4.8 (SD 12.4)	n.s
change of ESV	0.1 (SD 8.1)	1.4 (SD 8.9)	n.s
change of LVEF	-1.0 (SD 24.2)	-3.4 (SD 5.0)	n.s

Conclusion: Patients treated with PTCRA were more likely to experience microcirculation abnormality compared with POBA and stenting. And alteration of perfusion is more sensitive to detect the microcirculation abnormality than ECG and functional parameters.

P3552 Relation between coronary and renal atherosclerosis in hypertensive patients referred for coronary angiography

T. Sayin[1], O.A. Omer Akyurek[1], D.K. Deniz Kumbasar[1], B.B. Berkten Berkalp[1], C.K. Celal Kervancioglu[1], M.O. Metin Ozenci[1], D.O. Dervis Oral[2]. [1]Ankara University Heart Center, Cardiology, Ankara; [2]Ankara University, Cardiology, Ankara, Turkey

Aim: To search for prevalence of renal atherosclerotic involvement in hypertensive patients referred for coronary angiography and investigate the relation between the coronary and renal atherosclerotic involvement. **Method:** We performed selective renal angiography after coronary angiography in hypertensive patients who were referred for a coronary angiogram. Demographic variables, coronary artery disease (CAD) risk factor profile and lipid profiles of the patients were collected. So as to score the severity of coronary atherosclerosis we used the "Gensini" scoring system. In order to score the severity of the atherosclerotic involvement in renal arteries, we first visually graded per cent stenosis in each renal artery into quartiles and gave a score from 0 to 4, the cumulative for both renal arteries equaled to renal artery score for each patient. Patients who had a myocardial infarction in the preceding month were not included. **Results:** We performed selective renal angiograms to 148 hypertensive patients at the end of the coronary angiography. They were aged 37-78 (60.2 ± 9.5), and 92 of them (62.2%) were men. Thirty-eight patients (25.6%) of the study cohort had either completely normal coronary arteries or atheorsclerotic plaque of < 50%. We found varying degrees of renal atherosclerotic involvement in 27 patients (18.2%). We considered renal atherosclerotic involvement of equal to or more than 50% as significant. Excluding only one patient with a 40% renal artery stenosis, all out of the 27 had significant CAD. Eight out of 27 had lesions more than 50% (5.4%) and 3 of the 8 had renal interventions (2 renal stent implantation, 1 operation). In correlation analysis we found a mild degree of correlation between the Gensini and renal score and age and renal score ($r = 0.45$, $p<0.001$) and ($r = 0.32$, $p<0.001$) respectively. Multivariate logistic regression analysis revealed 2-3 vessel disease as an independent risk factor for significant renal atherosclerotic involvement (p=0.04, relative risk =6.4) **Conclusion:** Renal atherosclerotic involvement is quite common among hypertensive patients referred for coronary angiography (18.2%). Diffuse CAD might be a risk factor for renal atherosclerotic involvement. So as to exclude renovascular hypertension and detect and follow-up low grade renal atherosclerotic involvement, it seems prudent to perform renal angiography routinely to hypertensive patients referred for coronary angiography.

P3553 Increased WBC count independently predicts presence of multiple complex plaques in patients with history of unstable angina

M. Kruk[1], J. Przyluski[2], Z. Chmielak[2], L. Kalinczuk[3], J. Pregowski[3], A. Debski[2], A. Witkowski[2], W. Ruzyllo[2]. [1]General Cardiology Department, [2]II Independent Haemodynamic Department, National Institute of Cardiology, Warsaw, Poland; [3]Medical Academy, Warsaw, Poland

Background: Complex appearance of atherosclerotic lesion on angiography may reflect its instability. Subsequently, presence of multiple complex (MC) lesions has been shown to predict worse prognosis in patients with coronary artery disease (CAD). Inflammation has been demonstrated to be an important contributor for the development of vulnerable atherosclerotic plaque. A level of inflammation may be assessed by white blood cell (WBC) count. Therefore we sought to assess whether presence of multiple complex plaques seen in coronary arteries of patients with history of unstable angina may be related independently of classical risk factors to intensity of systemic inflammatory activation as measured by WBC count. **Methods:** We prospectively assessed 212 consecutive patients (148 males, age 60,2±10,3) with history of unstable angina within preceding 6 months, who underwent coronary angiography. Baseline characteristics and WBC count ($10^3/\mu l$) was assessed within 48hrs prior to cardiac catheterization. Coronary angiograms were analyzed and all plaques ≥30% stenosis were classified into complex or smooth groups. Complex plaque was defined if irregularities, ulcerations, total occlusion or thrombus were present and the remaining accounted smooth lesions. Multiple lesions were defined as ≥2 plaques. To reveal independent predictors of presence of MC plaques history of DM, hypertension, hyperlipidemia, family history, smoking, age, sex, BMI, WBC count and number of all identified coronary plaques were analysed using multivariate logistic regression. **Results:** Angiographically complex plaques number was 305 out of all 706 plaques identified on angiography. 83 patients who had MC plaques had higher WBC count than remaining patients (student's T-test; 8,0±2,4 vs 7,1±2,2 respectively, p=0,009.). Multivariate analysis revealed that the only independent predictors of presence of multiple complex (MC) plaques were WBC count (OR 1,19; 95%CI (1,02-1,39); p=0,023) and number of all plaques (OR 2,45; 95%CI (1,88-3,21); p<0,0001). **Conclusion:** Intensity of systemic inflammatory activation expressed by WBC count is linked independently to increased incidence of multiple complex lesions. Our findings suggest that enhanced inflammation may adversely influence prognosis not only by modification of plaque structure but also by increasing number of vulnerable atherosclerotic lesions.

P3554 Long-term clinical outcome of IVUS-guided versus angio-guided stenting. A meta-analysis of published studies

G. Casella[1], F. Ottani[2], V. Klauss[3], F. Prati[4], A. Capecchi[5], P. Sangiorgio[5], D. Bracchetti[5]. [1]*Cardiology Ospedale Maggiore, Bologna, Italy;* [2]*Ospedale San Bortolo, Cardiology, Vicenza, Italy;* [3]*Ludwig-Maximilians University, Cardiology, Klinikum Innenstadt, Munich, Germany;* [4]*Ospedale San Giovanni, Cardiology, Rome, Italy;* [5]*Ospedale Maggiore, Cardiology, Bologna, Italy*

Background: Intracoronary ultrasound (IVUS) has provided insights into the mechanism of percutaneous coronary interventions (PCI) as well as the pattern and mechanism of restenosis. Prior studies have demonstrated that the use of IVUS measurements of vascular dimensions improves angiographic results of PCI, mostly when a stent is deployed. To date only few underpowered studies (a mixture of small, randomized or observational trials) comparing the clinical efficacy of IVUS-guided versus Angio-guided stenting have been performed and odds ratios (OR) vary substantially between them. Thus, the present investigation refines these values by means of a formal meta-analysis.
Methods: Nine studies were considered suitable for analysis. Odd Ratios (OR) were calculated for 6-month clinical follow-up. Primary end points were a composite of death and non-fatal MI as well as binary restenosis, as considered in every single study. Secondary end points were a composite of death, reinfarction and target vessel revascularisation (MACE), according to single study definition, and individual cardiac events as well.
RISULTS. A total of 2972 patients were included. At 6 month, the OR for death and non-fatal MI was 1,13 (95% Confidence Interval [IC], 0,79-1,61, p=0,5) for patients with IVUS-guided vs. Angio-guided stenting. Patients treated with IVUS-guided stenting had significantly less restenosis (OR 0,75, 95% CI 0,60-0,94, p=0,01). In addition, patients treated with IVUS-guided stenting had less TVR (OR 0,62, 95% CI 0,49-0,78, p=0,00003) and MACE (OR 0,79, 95% CI 0,64-0,98, p=0,03) compared to Angio-guided stenting. Death (OR 1,0, 95% CI 0,42-2,38, p=NS) and non-fatal MI (OR 1,14, 95% CI 0,78-1,64, p=0,5) were similar between the two groups.
Conclusions: IVUS-guided stenting implantation does not confer any substantial advantage on long-term clinical outcomes compared to an angiographic-guided optimisation. However, IVUS-guided stenting significantly reduces 6-month angiographic restenosis and TVR. This additional benefit could be very helpful when treating lesions with high risk of restenosis like small vessel, long lesion or vein grafts.

P3555 Do spatial wall shear stress gradients affect left coronary atherosclerosis location?

T.M. Farmakis[1], J.V. Soulis[2], G.D. Giannoglou[1], G.A. Giannakoulas[1], G.J. Zioupos[2], G.E. Louridas[1]. [1]*AHEPA Hospital-Aristotle University, 1st Department of Cardiology, Thessaloniki, Greece;* [2]*Democrition University of Thrace, Fluid Mechanics/Hydraulics division, Xanthi, Greece*

Introduction: Spatial Wall Shear Stress Gradient (SWSSG) in vitro has shown its importance in atherogenesis, probably as local modulator of endothelial gene expression. The purpose of our study is to numerically analyze the SWSSG distribution over the normal human Left Coronary Artery (LCA) tree.
Methods: A three-dimensional computer generated model of the LCA tree, based on averaged human data set extracted from angiographies and reported previously, was adopted for subsequent analysis. The LCA tree includes Left Anterior Descending (LAD), Left Circumflex Artery (LCxA) and their major branches. A steady, plug flow corresponding to resting conditions (0.17 m/s) was applied, whereas the blood was treated as non-Newtonian fluid. Discharges from distal branches were set proportional to the third power of the corresponding branch diameter. The governing Navier-Stokes flow equations were solved using a previously validated finite-element solver. The SWSSG is calculated using 40,843 grid nodes throughout the tree extension.
Results: Computational results indicate that on the left main coronary artery bifurcation the SWSSG ranges between 0.2 and 1.7 dyn/cm^3. In the LAD, minimum values of SWSSG are in the order of 0.3 dyn/cm^3, occurring around the origin of first diagonal branch, whereas maximum values are of the order 12.5 dyn/cm^3, occurring on the distal segment of the LAD at the apex, where high shear stress values, also, coexist. In the LCxA there is a predilection of low SWSSG (0.4 dyn/cm^3), occurring around the origin of the first marginal branch, whereas the highest values are of the order 5.2 dyn/cm^3 occurring at the distal segment of the second obtuse marginal. Again, high shear stress values coexist with high SWSSG. Spatial gradients of wall shear stress attain large values at small caliber branches. Furthermore, the general pattern of SWSSG distribution is in accordance to the wall shear stress distribution.
Conclusions: Low SWSSG occurs nearby to and at bifurcations, particularly at regions opposite to the flow divider, which are anatomic sites predisposed for atherosclerotic development. In general, low SWSSG appear in the proximal regions of the LCA tree, where atherosclerosis frequently occurs. At distal segments the SWSSG increases substantially due, perhaps, to increased velocity resulted from increased vessel tapering. Probably, wall shear stress gradients can be established as a reliable predictor for atherosclerosis location.

P3556 Wall shear stress differences between proximal and distal left coronary artery bifurcations

G.D. Giannoglou[1], J.V. Soulis[2], T.M. Farmakis[1], G.J. Zioupos[2], G.A. Giannakoulas[1], G.E. Louridas[1]. [1]*AHEPA Hospital-Aristotle University, 1st Department of Cardiology, Thessaloniki, Greece;* [2]*Democrition University of Thrace, Fluid Mechanics/Hydraulics division, Xanthi, Greece*

Introduction: The coronary left artery, generally, demonstrates the most intense atherosclerosis involvement within its first few centimeters, exhibiting particular predilection to proximal bifurcation regions. The purpose of our study was to quantitatively analyze the three-dimensional (3D) wall shear stress differences between proximal and distal bifurcations of the human Left Coronary Artery (LCA) tree.
Methods: A 3D computer model of the normal LCA tree, reported previously, was adopted for numerical analysis. Uniform flow corresponding to resting conditions was applied at the LCA tree inlet. The governing mass, momentum and energy flow equations were solved using a previously validated numerical code. Wall shear stress was calculated at the following bifurcation regions: 1) left main coronary artery (LMCA), 2) first obtuse marginal (OM1), 3) second obtuse marginal branch (OM2), 4) first (D1S1), 5) second (D2S2), and 6) third (D3S3) diagonal and septal branches. The number of utilized grid nodes of the bifurcation regions was ranged between 6000-13000, depending upon the physical size of the lumen as well as the wall shear gradient.
Results: The computed average wall shear stress at the LMCA was found to be 3.93±0.01 N/m^2, at OM1 6.45±0.05 N/m^2, at OM2 7.24±0.03 N/m^2, at D1S1 6.30±0.01 N/m^2, at D2S2 7.21±0.01 N/m^2 and finally at D3S3 10.72±0.07 N/m^2, ($p<0.001$ for all above cases). Results indicate that wall shear stress increases gradually from proximal to distal bifurcations.
Conclusions: Low wall shear stress values occur at the proximal bifurcations of the LCA tree. Shear stress increases gradually from proximal to distal bifurcation regions. At the very distal segments this increment becomes substantial. Low wall shear stress bifurcation regions agree well with preferred sites of atherosclerotic coronary lesions in humans.

P3557 Sustained clinical benefit of IVUS guided stenting for long coronary artery stenoses: long-term follow-up of a randomized study

P.V. Oemrawsingh, M.J. Schalij, J.W. Jukema, E.E. van der Wall. *Leiden University Medical Center, Dept of Cardiology, Leiden, Netherlands*

Background: Long coronary lesions treated with stent implantation (SI) have a poor outcome. This study compares the 6 month angiographic and long term clinical outcome of long SI in patients (pts) with stable angina, randomized to SI with intravascular ultrasound (IVUS) guidance (group U) or angiographic guidance (group A). Methods: stenoses >20 mm in length and a reference diameter (D) >2.75 mm were eligible. IVUS criteria for optimal SI were: complete apposition, minimal lumen D (MLD)>80% of (proximal + distal reference D)/2 and minimal residual lumen area > distal reference area. Results: In 150 pts (group U, n=74, group A, n=76) a total of 187 stents were implanted. Baseline data were comparable in both groups. All IVUS criteria were achieved in 65 (89%) of group U. Quantitative angiography showed no differences between the groups with respect to baseline (2.9±0.3 vs. 3.0±0.5 mm) post-stent (3.0±0.3 vs. 3.2±0.4 mm) or follow up (2.7±0.4 vs. 2.8±0.3 mm) reference D. The MLD as well as D stenosis before (0.9±0.2 vs. 0.9±0.3 mm/66±14 vs. 69±10%) and after stenting (2.9±0.2 vs. 2.9±0.2 mm/10±6 vs. 11±9%) were also comparable. At 6 months the MLD and D stenosis in group U (1.8±0.4 mm/ 34%) were more favorable than in group A (1.4±0.3 mm/48%; both $p<0.05$). Restenosis (>50%) was found in 9 pts of group U (18%) and in 18 pts of group A (36%; $p<0.05$). The target lesion revascularization rate at 6-months was 4% (n=2) in group U and 21% (n=11) in group A ($p<0.05$), whereas 5 pts (10%) had an intervention for a non-target lesion in both groups (NS). No pts of group U died or had a myocardial infarction within 6 months, but of group A, 1 pt (2%) died and 2 pts suffered an acute myocardial infarction during the 6-month follow up period. Major cardiac events occurred in 8 pts (15%) of group U and in 18 pts (37%) of group A ($p<0.05$) within 6 months. Long term follow up (mean 310±30 days) revealed a target lesion revascularization rate of 8% (n=6) in group U vs. 25% (n=19) in group A ($p<0.05$). Non-target lesion revascularizations were done in 8% (n=6) of group U and in 1% (1 pt) of group A >6 months after the intervention (NS). The long term major adverse cardiac event rate was 18% in both groups (NS). Conclusion: This prospective randomized study shows that 6-month angiographic and clinical outcome after IVUS guided long SI is significantly better compared to angiography guided SI and that this clinical benefit is sustained up to 10 months after the intervention.

P3558 L-arginine and the shear stress response mechanism in diseased epicardial coronary arteries

D. Tousoulis[1], C. Tentolouris[1], G. Goumas[1], C. Pitsavos[1], C. Toutouzas[1], G. Davies[2], C. Stefanadis[1], P. Toutouzas[1]. [1]*Athens University, Cardiology Dept. Hippokration Hospital, Athens, Greece;* [2]*Hammermith Hospital, Cardiology Dept, London, United Kingdom*

Backgroud: L-arginine is the substrate for nitric oxide synthesis and atrial pacing dilates normal epicardial coronary arteries. This study assessed the effects of L-arginine on basal coronary tone and flow-mediated dilation induced by atrial pacing in patients with coronary artery disease and stable angina.

Methods: The effects of an intracoronary infusion of L-arginine 150 μmol/min for 10 mins, was studied in 8 patients with coronary artery disease. In all patients atrial pacing was performed during normal saline and during L-arginine infusion. The luminal diameter of epicardial coronary arteries was assessed by quantitative angiography.

Results: During atrial pacing with saline infusion a significant increase ($p<0.01$ vs. saline) occurred in luminal diameter of the proximal (3.4±0.8%), distal (8.5±1.6%) and stenosis reference segment (5.0±1.2%), but stenosis diameter did not change (0.5±1.5%). L-arginine administration significantly ($p<0.01$ vs. normal saline) increased the diameter of proximal (4.7±1.1%) and distal (6.4±1.4%) segments, coronary stenoses (8.7±2.0%) and their reference segment (6.3±1.6%). However, L-arginine administration did not change (p=NS) the magnitude in mm of atrial pacing induced dilatation from saline or L-arginine respectively in proximal (0.09±0.02 vs. 0.06±0.02 mm) and distal segments (0.12±0.02 vs. 0.09±0.02 mm) and in coronary stenoses (0.01±0.02 vs. 0.02±0.02 mm). A significant correlation ($p<0.001$) was found between % response to nitroglycerin and % L-arginine during atrial pacing.

Conclusions: Non stenotic segments of diseased coronary arteries dilate in response to atrial pacing, but stenoses do not. L-arginine dilates these segments and stenoses but does not increase the magnitude of the response to atrial pacing. These findings provide evidence that the shear stress responsive mechanism is absent at stenoses but present in non-stenotic segments of diseased coronary arteries. They also indicate a relative deficiency of L-arginine, except in the shear response mechanism.

P3559 Coronary artery stenosis assessment – Diagnostic value of contrast enhanced MSCT in comparison with coronary angiography – Pilot study

M. Pasowicz[1], P. Klimeczek[1], T. Przewlocki[2], P. Pieniazek[2], A. Kozanecki[2], M. Konieczynska[2], K. Zmudka[3], W. Tracz[2]. [1]*The John Paul II Hospital, Cardiac and Vascular Diseases, Krakow, Poland;* [2]*The John Paul II Hospital, Institute of Cardiology, CM UJ, Krakow, Poland;* [3]*Institute of Cardiology, Hemodynamics, Krakow, Poland*

Purpose: The present study aimed to compare the diagnostic value of contrast-enhanced Multislice Spiral Computed Tomography (MSCT) for detection of different types of stenoses (>50%, occlusion) in patients with coronary artery disease in comparison with coronary angiography.

Materials and methods: Forty seven patients (28 men and 19 women) with a mean age of 61 SD 12 years underwent MSCT and CA throughout 2000. Patients were included in a retrospective case series study. The examinations were assessed in a blinded fashion, by two separate teams comprised of cardiologists and radiologists. One hundred twenty three out of 186 (66%) proximal and middle segments of left main (segment 5), circumflex artery (segments 11,12), left anterior descending artery (segment 6,7), right coronary artery (segment 1,2) had no significant stenosis, 14 segments (7.5 %) were occluded, and 49 (26%) had significant stenosis > 50%, as determined by CA.

Results: Twenty three (12.3%) segments were unevaluable by MSCT due to poor quality of visualization. Sensitivity and specificity in the evaluable segments were 79% (95% confidence interval, 71% to 89%) and 83% (95% confidence interval 76% to 87%) for > 50% stenosis, and 100% (95% confidence interval, 96% to 100%) for occlusion. There were no differences between MSCT and CA in the detection of occlusion.

Conclusions: MSCT is a promising instrument in non-invasive screening of coronary stenosis and detection of occlusion in proximal part of the arteries. Spatial and time resolution of the method should be enhanced.

P3560 Clinical and angiographic correlates of coronary calcium scoring in multi-slice computed tomography (MSCT)

R. Ryczek[1], M. Zagrodzka[2], M. Dziuk[1], P. Twarkowski[2], M. Cholewa[1], B. Jaron[2]. [1]*Central Hospital WAM, Internal Medicine and Cardiology, Warsaw, Poland;* [2]*Central Hospital MMA, Radiology, Warsaw, Poland*

The MSCT calcium scoring allows to identify patients with increased coronary event risk or at early stages of coronary artery disease (CAD).

The aim of the study was to find the correlation of calcium score with various clinical features and degree of coronary stenosis.

Methods: 40 consecutive patients (10 women) with angiographically proven coronary artery disease were assessed for coronary calcium score by means of MSCT not later than 48 hours after the angiography. The acquisition parameters were as follows: 3.2 mm slice thickness, 1.6 mm increment, pitch 1.25, 120 kV, 200 mAs, rotation time of 500 ms, supine patients during single breathhold. The calcium score was semiautomatically calculated taking into account the size and density higher than 130 Hounsfield units. The clinical features such as the presence of hypertension, diabetes, dyslipidaemia, obesity (body mass index), smoking, CCS angina score, previous myocardial infarction, CAD duration, degree of stenosis and diffused disease were also analysed by means of Spearman's test.

Results: The calcium score in the left anterior descending artery (LAD) 271±598 showed good correlation with the degree of stenosis in the LAD 69±37 (R=0.591, $P<0.0001$) and angina score (median 2, $P<0.001$). It was also correlated as well as calcium score in the LMS 55±147 with the CAD duration of 9±9 years and diabetes ($P<0.01$). The CS in the RCA 102±362 was associated with the diabetes, dyslipidaemia and obesity with the $P<0.03$. The score in the LCX 282±797 was correlated with the degree of stenosis in every artery ($P<0.001$ for the LCX=56±39). The total calcium score 675±1462 was associated with the angina score, CAD duration ($P<0.001$), diffused disease and the stenosis in the LAD and LCX ($P<0.0001$).

Conclusion: The total and the LAD coronary calcium score may be associated with the severity of symptoms, degree of stenosis in the LAD and disease extent. The calcium deposits in the RCA may be more frequent in patients with metabolic disorders.

P3561 Gadolinium based coronary angiography in patients with chronic renal insufficiency

E. Garbarz[1], V. ludman[1], F. boudghene[1], P. goube[1], M. tassart[1], B. iung[2], P.L. michel[1]. [1]*tenon, paris, paris, France;* [2]*bichat hospital, cardiology, paris, France*

Background: Coronary artery disease is one of the leading cause of death in patients with chronic renal insufficiency(CRI). Coronary angiography with injection of iodinated contrast material remains to date the only recognised means to assess coronary anatomy. However iodine, particularly in patients(pts) with CRI, can cause an acute reduction in renal function leading to substantial morbidity and mortality. Gadolinium is a contrast agent believed to be less nephrotoxic than iodine. The aim of our study was to evaluate the safety and accuracy of gadolinium used as an alternative contrast agent in coronary angiography

Methods: We studied 12 pts (mean age 63±9 years- male 8 - 4 with diabetes) with CRI(including 4 pts with a renal graft) referred for coronary angiography because of: angina pectoris n=5, acute coronary syndrom n=4, left ventricular dysfunction n=3. Angiography was performed using the standard judkins technique with 5 or 6 french catheter. A total volume of 45 mL of gadolinium was allowed. Quality of the angiograms obtained was assess by two experienced physicians. After the procedure pts were monitored 48 hours for: cardiac rhytmn abnormality, cardiac troponin I release and, serum creatinine concentration.

Results: No intraprocedural adverse event occurred.Quality of the angiograms was judged sufficient in 10 pts avoiding any significant amount of iodine. In two cases the operator had to switch to iodinated contrast agent. Mean serum creatinine value was 311±110 μmol/L at baseline and 328±149 at H48(p=NS). Only one patient(who received iodine)had an acute renal failure leading to dialysis. No arrhythmias or cardiac troponin I elevation was observed

Conclusions: gadolinium based coronary angiography is feasible and safe in a majority of pts with CRI

P3562 Diagnostic value of electrocardiogram-gated reconstruction by MSCT in assessing patency of arterial and venous coronary artery bypass grafts

M. Pasowicz[1], P.K. Klimeczek[1], T. Przewlocki[1], A. Krochin[1], M. Konieczyńska[1], J. Sadowski[2], K. Zmudka[2], W. Tracz[1]. [1]*The John Paul II Hospital, Cardiac and Vascular Diseases, Krakow, Poland;* [2]*Cardiovascular Surgery, Krakow, Poland*

The present study aimed to analyse the diagnostic value of contrast enhanced MSCT for non-invasive assessment of venous and arterial bypass graft patency.

Material and Methods: Study group consisted of 84 patients (27 women) age 42-75 years; mean age 62±10 years who had received venous or arterial bypass grafts. Overall, 235 bypass grafts (26 arterial, 209 venous) were implanted: 65 venous to right coronary artery (RCA), 71 venous and 26 arterial to left anterior descending artery (LAD), and 73 venous grafts to circumflex artery (Cx). MSCT scans (Somatom Plus Volume Zoom, Siemens, Erlangen, Germany) were obtained using Heart View software. Images were acquired throughout the entire cardiac cycle and then reconstructed at diastole with retrospective ECG gating. MSCT scanning and coronary angiography were performed by two separate teams and evaluated in a blinded fashion.

Results: By MSCT 165 grafts, including 147 venous and 18 arterial, were identified as patent and 70 grafts (62 venous and 8 arterial) were diagnosed as occluded, or had significant stenosis (>50%). Bypassography revealed 169 patent (149 venous and 20 arterial) and 66 occluded, or significantly stenosed grafts (60 venous and 6 arterial).Eight bypass grafts (2 arterial and 6 venous: 4 to LAD and 2 to Cx), considered as occluded by MSCT, were patent by conventional bypassography. Four bypass grafts considered as patent by MSCT were occluded in bypassography (1 to LAD, 2 to Cx, 1 to RCA). The specificity and sensitivity of MSCT in detection of graft occlusion was 94.7% and 96.4%, respectively.

CABG to LAD and Mg

Conclusion: MSCT is a valuable instrument in evaluation of bypass patency in patients after surgical treatment of coronary artery disease. MSCT may also be effective in screening patients after CABG procedure.

BRACHYTHERAPY, COATED STENTS

P3563 IVUS dosimetry for intracoronary beta brachytherapy after stenting – What should be the target?

A. Witkowski[1], M. Kawczynska[2], Z. Chmielak[3], P. Szmaus[4], J. Lyczek[5], W. Bulski[2], S. Pszona[6], W. Ruzyllo[3]. [1]*Institute of Cardiology, Haemodynamics, Warsaw, Poland;* [2]*Oncology Center, Medical Physics, Warsaw, Poland;* [3]*Institute of Cardiology, Haemodynamics, Warsaw, Poland;* [4]*National Institute of Cardiology, Dept.of General Cardiology, Warsaw, Poland;* [5]*Oncology Center, Brachytherapy, Warsaw, Poland;* [6]*Institute of Nuclear Research, Radiation Physics, Warsaw, Poland*

Background: It seems not to be clear whether the cells responsible for neointimal growth after stent deployment are recruited from media or adventitia. In this latter case the recommended prescription dose for P-32 beta centered source used in Guidant Galileo Brachytherapy System (20 Gy 1 mm beyond the lumen surface, based on angiographically measured artery mean reference diameter) may not have expected effect on reduction of restenosis rate (RR).

Methods: To test the hypothesis whether dosimetry based on IVUS could influence the clinically driven target vessel revascularization (TVR) rate at 6 months we compared two groups of pts, in whom reference diameter (RD) was measured at two different points of reference: 1) 1mm beyond lumen surface (LARD-IVUS)/20 Gy-aimed at media, 17 pts and 2)1 mm beyond the external elastic lamina (EEL) surface (EELRD-IVUS)/20 Gy-aimed at adventitia, 16 pts. In the LARD-IVUS group were 10 pts with in-stent restenosis (ISR), 1 pt with restenosis after balloon angioplasty and 6 pts after elective stenting of de novo (DN) lesions. In the EELRD-IVUS group were 7 pts with ISR and 9 pts after elective stenting od DN lesions. Both groups were well matched in regard to demographic, clinical and angiographic parameters. In each individual pt doses at luminal surface (LS) and 1mm beyond the EEL surface (EEL+1) were calculated.

Results: LS dose for LARD-IVUS group was 60.01±2.44 Gy vs 115.68±33.02 Gy in EELRD-IVUS group, p<0.0001. EEL+1 dose for LARD-IVUS group was 11.46±4.64 Gy vs 20.0±0 Gy in EELRD-IVUS group, p<0.0001. Despite the escalation of the radiation dose in EELRD-IVUS group (93% increase of LS dose and 75% increase of EEL+1 dose) both pt groups have comparable numbers of MACE at 6-month follow-up. There were no death, 1 subacute stent thrombosis followed by QMI and 3 clinically driven TVR in each pt groups. 16 pts (6-LARD-IVUS, 10-EELRD-IVUS) had IVUS follow-up study with volumetric analysis at 6-month. The only difference found was lack of neointimal hyperplasia in LARD-IVUS in comparison to EELRD-IVUS group (delta% change: -0.73% vs 3.64%, p=0.042)

Conclusions: There were no difference in clinically driven TVR rate at 6-month between two pt groups with dose prescription aimed at two different targets within the vessel wall. However, lack of neointimal hyperplasia at 6-month in vessels irradiated with dose of 20 Gy/1 mm beyond the luminal surface is promising and may result in lower TVR rate at 6-month – this should be verified in a large sample study.

P3564 Repeat coronary brachytherapy for recurrent in-stent-restenosis

H. Roguelov[1], E. De Benedetti[1], P.H. Coucke[2], G. Pasche[2], H. Do[2], E. Eeckhout[3]. [1]*CHUV, Cardiology, Lausanne, Switzerland;* [2]*CHUV, Radio Oncology, Lausanne, Switzerland;* [3]*CHUV, cardiology, lausanne, Switzerland*

Background: Vascular brachytherapy (VBT) is an effective treatment option for in-stent-restenosis (ISR). Nevetheless, the reported target vessel revascularization rate (TVR) after VBT varies between 17 and 33%.

Methods: From 1999 on, repeat VBT is proposed to patients with recurrent ISR after initial successful beta irradiation. Procedures all concern beta irradiation, intervention and dosimetry are guided by intravascular ultrasound and systematic 6 months angiographic follow-up is performed.

Results: From July 1998 on, VBT has been performed in 224 patients at our institution (189 cases of ISR). 11 patients with recurrent ISR have been treated by re-VBT between 25.11.1999 and 16.10.2001. Mean age was 60±6.8 years and 9 patients were male. Vessel type was: LAD (3 pts), RCA (5 pts) and Lcx (3 pts). The pattern of ISR (first, recurrent presentation,respectively) was: focal (4, 4 pts), diffuse (7, 5 pts) and total occlusion (0, 2 pts) with a probably geographical miss in 2 cases at the second restenosis. Clinical recurrence occurred on average at 7±1.9 months the second time. All pts had been treated by beta irradiation with an initial dose of 23.3±3.7Gy and were treated a second time by beta irradiation with a second dose of 25.3±2.2Gy. During the second intervention, no patients received additional stents and evident geographical miss was not noted. All second procedures were performed with the betacath 5F system (Novoste, Brussels, Belgium). The actual follow-up time is 12 ±8 months. At present, a major adverse event occurred in one patient only (CABG for significant non target vessel disease with absence of restenosis at radiation site at 4 months). 6 months repeat angiography has been performed in 7 patients showing absence of restenosis with an average diameter stenosis of 19 ±12%. Currently, all patients are symptoms free on a combined clopidogrel-aspirin therapy to be maintained for at least one year.

Conclusions: These preliminary data show the feasibility of re-beta VBT for recurrent ISR but await further confirmation of its efficacy during a longer follow-up period and by larger patients series.

P3565 External beam irradiation to prevent recurrent coronary in-stent restenosis after balloon angioplasty – A CT based, 3D rendered approach

J.M. Strotmann[1], P. Schanzenbaecher[1], K. Bratengeier[2], G. Ertl[1], W. Voelker[1], M. Flentje[2], L. Pfreundner[2]. [1]*Medizinische Universitätsklinik, Würzburg, Germany;* [2]*University Clinic of Radiation Oncolog, Wuerzburg, Germany*

Background: Diffuse proliferative in-stent restenosis (ISR) is still a therapeutic challenge. Endovascular brachytherapy can reduce the recurrence of ISR. We hypothesized that selective external beam irradiation may also reduce the reccurrence rate of ISR.

Methods and Results: Twelve symptomatic patients with diffuse, proliferative ISR underwent quantitative coronary angiography (QCA) with subsequent percutaneous transluminal coronary angioplasty (PTCA). Following PTCA, intravascular ultrasound was performed to assess the neointima and media area of the stenotic segment. All patients underwent selective external beam irradiation (total dose: 15 Gy, 5 Gy/fraction, day 1-3, first fraction within 24 hours from PTCA). Irradiation treatment was planned by a true 3D conformal treatment planning system (TMS, Helax). Three or four wedged 5-18 MV photon or cobalt beams with individual absorbers or multi-leaf collimators were used for irradiation. Dose calculations were performed according to the ICRU-Report 50. After six months a control QCA including intravascular ultrasound was performed. The diameter of ISR was 81 ± 1.3% of the reference diameter, decreased significantly after PTCA to 24 ± 0.8% and remained constant 6 months after PTCA (27 ± 1.5% ($p < 0.005$)). Neointima area within the stent was 3.0 ± 0.2 mm^2 immediately after PTCA and remained unchanged after 6 months (2.9 ± 0.2 mm^2). Media area was 7.9 ± 0.5 mm^2 directly after PTCA and was also unchanged at the six month follow up with 7.6 ± 0.4 mm^2. Only one patient showed a significant ISR of 68% accompanied by recurrent angina needing further revascularisation. All other patients were free of clinical symptoms.

Conclusion: Selective external beam irradiation is feasible to prevent restenosis after PTCA of ISR. It can be done on a computed tomography guided, 3D rendered basis and provides a selective noninvasive approach for the irradiation of coronary arteries.

P3566 Stent implantation prior to intracoronary irradiation in instent lesions does not affect the incidence of restenosis

B. Syeda, P. Wexberg, G. Beran, S. Denk, R. Schmid, C. Kirisits, P. Siostrzonek, D. Glogar. *AKH-Wien, Cardiology Dept., Wien, Austria*

Background: Stent deployment prior to intacoronary irradiation is recently being debated since publication of trials with poor results in the stent group. In this analysis we aimed to determine if pre-irradiational stent implantation in instent lesions has negative effects on the incidence of restenosis at follow up.
Methods: Interventional data of 93 vessels in 92 patients undergoing revascularization of instent lesions with adjunct intracoronary irradiation and succeeding six-months Clopidogrel treatment were prospectively selected and analyzed. Follow-up percent diameter stenosis was measured with a quantitative coronary angiography edge-detection algorithm (ACOMPC, Siemens). Binary restenosis was defined as %DS >50% within the target vessel.
Results: 48 lesions were localized in the left anterior descending coronary artery, 18 lesions in the left circumflex coronary artery, 25 lesions in the right coronary artery and 2 lesions in bypass grafts. Sr/Y-90 treatment was performed in 46 vessels, P-32 treatment in 31 vessels, and Ir-192 treatment in further 16 vessels. Stents of 3.2±0.5mm diameter and 16.7±7.8mm length were implanted in a total of 32 (34.4%) vessels during the revascularizaion of the instent lesion prior to intracoronary irradiation. Binary restenosis occurred in 27 (31.9%) vessels within a follow-up period of 6.9±2.2 months. Thrombus associated total occlusions were found in 2 patients who have had stent implantations, and in further 2 patients who have had balloon treatment only (6.25% vs. 3.51% respectively; p=0.54). Stent implantation during the revascularizaion of the instent lesion did not lead to higher incidence of binary restenosis than balloon treatment alone without stent deployment (25.0% vs. 35.7% respectively; p=0.29).
Conclusion: Stent implantation prior to intracoronary irradiation in instent lesions with adjacent six-months Clopidogrel treatment is not associated with higher restenosis rates at follow up.

P3567 The degree of residual stenosis does not impact the long-term outcome of patients treated for in-stent restenosis with brachytherapy

E. cheneau, L. Leborgne, A. Ajani, A. Pichard, L. Satler, K. Kent, J. Lindsay, R. Waksman. *Washington Hospita Center, Washington, United States of America*

Background: Vascular brachytherapy (VBT) demonstrated efficacy in the reduction of recurrence of in-stent restenosis (ISR). However, the importance of minimal residual stenosis of the angioplasty preceding VBT has not been established in patients with ISR.
Methods and Results: 368 patients were treated for ISR in native coronary arteries with gamma-radiation in the WRIST (Washington Radiation for In-Stent Restenosis) series. Patients had conventional angioplasty followed by 192Ir radiation. Quantitative coronary angiography was performed at the index procedure with subsequent 6-month angiographic and clinical follow-up. Patients were classified in three groups according to the residual stenosis (RS) after the index procedure: optimal angiographic result (RS<20%, n=45), sub-optimal angiographic result (RS=20-30%, n=85), and incomplete angiographic result (RS>30%, n=211). The late loss was higher in the optimal and sub-optimal angiographic result groups than in the incomplete angiographic result group (respectively 0.65 ± 0.65 mm, 0.56 ± 0.73 mm and 0.32 ± 0.65 mm, p=0.003). The 6-month clinical outcome was similar in the three groups. Major cardiac event rates were 30% in the optimal angiographic result group, 32% in the sub-optimal angiographic result group, and 26% in the incomplete angiographic result group (p=0.47). Multivariate regression analysis shows that the residual stenosis and the post-procedure MLD were not predictors of TVR at 6 months, when RS was considered a continuous variable.
Conclusions: An optimal result of the angioplasty procedure does not influence the angiographic and clinical outcome of patients undergoing VBT for the treatment of ISR.

P3568 Angiogenesis and intraparietal haemorrhages are the major long-term effects of intravascular gamma-radiation after stenting in rabbit arteries

D. Busseuil[1], M. Zeller[2], Y. Cottin[2], P. Maingon[3], P. Allouch[2], F. Briot[4], J-E. Wolf[2], L. Rochette[1]. *[1]Medecine Faculty, LPPCE, Dijon, France; [2]CHU-Dijon, Cardiology Dept., Dijon, France; [3]CGFL, Radiotherapy, Dijon, France; [4]CEA, Valduc, France*

Background: Experimental data on the long term effects of Intravascular Brachytherapy (IVB) associated with stenting are limited. Recent clinical trials showed adverse events after IVB, in particular thrombosis occurring at long term follow-up. In the present study, we examined the late outcome of rabbit stented arteries after IVB, in particular neovessels formation. Methods: Stents (Bestent, Medtronic) were implanted in arteries of 32 male N-Z rabbits and immediately followed by gamma IVB using an afterloading device (Nucletron) or sham radiation procedure. High dose rate 192 I source delivered 18 Gy at 2 mm from the source centre. The animals received ticlopidine for 30 days. At 1 and 6 month follow-up, arteries were harvested for histomorphological and immunohistochemical analysis. Results: No significant difference in intimal area was observed between the control and the irradiated group at 1 and 6 months (respectively 1.26 ± 0.09 vs 1.02 ± 0.2 mm^2, ns and 1.07 ± 0.17 vs 1.32 ± 0.47 mm^2, ns). In contrast, intramedial haemorrhages (free hemosiderin deposition) and inflammation (presence of macrophages) were only observed in radiated arteries. In IVB group, Von Willebrand labelling showed adventitial and intra-medial neovascularization at 6 month follow-up confirmed by neovessels count in radiated vs control arteries (respectively 5.05 ± 1.04 vs 1.51 ± 0.27/mm^2, p<0.001). Conclusion: Our study strongly supports the hypothesis that IVB associated to stenting induced late arterial wall neovessels formation and intraparietal haemorrhages. Whether the rupture of these fragile neovascular structures could lead to late occlusions described at long term follow-up in clinical trials remains to be elucidated.

P3569 Failure of prevention of vein graft disease by prophylactic gamma radiation in a chronic hypercholesterolemic porcine model

C. Bartels[1], A. Erasmi[1], F. Sayk[2], R. Eggers[2], A. Dendorfer[3], E. Ihnen[4], T. Feyerabend[4], H.H. Sievers[1]. *[1]University of Luebeck, Cardiac Surgery, Luebeck, Germany; [2]Institute for Anatomy, University of Luebeck, Luebeck, Germany; [3]University of Luebeck, Institute for Pharmacology, Luebeck, Germany; [4]Institute for Radiation Therapy, University of Luebeck, Luebeck, Germany*

Background: The value of brachytherapy in preventing neointima formation and vessel occlusion in proliferating healthy vessels, such as vein grafts, is unknown. We studied the effect of gamma radiation on vein graft patency, vessel wall diameters, platelet-derived growth factor (PDGF) expression, and smooth muscle cell (SMC) proliferation/cell death in a chronic hypercholesterolemic porcine model.
Methods and Results: Carotid artery jugular vein bypass grafts were anastomozed end-to-side in 23 pigs after ex-vivo irradiation of the vein grafts (10, 20 and 40 Gy). 16 native vein grafts served as controls. Quantitative expression of PDGF-AA and -BB was assessed using ELISA, quantitative SMC proliferation/cell death with double-stain immunohistochemistry (Mib-1/TUNEL/SMC a-actin). Computer-aided planimetry was used for morphometric analysis. The in-vitro response of endothelial vasodilatation in veins irradiated with 40 Gy was examined.
Planimetric data on vessel wall dimensions revealed no positive effect of gamma radiation on neointima formation and inner lumen diameter. On the contrary, vein grafts subjected to 40 Gy were significantly more likely to be occluded and to have reduced inner lumen and increased neointima formation. Radiation therapy had no effect on PDGF expression and SMC proliferation/cell death. The mean inner lumen diameter decreased as PDGF-AA expression increased. Vasodilation induced by acetylcholine was unaffected.
Conclusions: Prophylactic gamma radiation of unaffected vein grafts failed to prevent vein graft disease in a hypercholesterolemic porcine model. High-dose radiation (40 Gy) resulted in more frequent graft occlusion and vein sclerosis. PDGF values and SMC proliferation/cell death were unaffected by radiation.

P3570 Sirolimus inhibits restenosis irrespective of the vessel size. A subanalysis of the multi-center RAVEL trial

E. Regar[1], P.W. Serruys[2], C. Bode[3], C. Holubarsch[3], J.L. Guermonprez[4], W. Wijns[5], C. Disco[6], M.C. Morice[7] on behalf of RAVEL investigators.
[1]Thoraxcenter, Z 120, Cardiology, Rotterdam, Netherlands; [2]Thoraxcentre, Erasmus Medical Centre, Cardiology H552, Rotterdam, Netherlands; [3]Med. Universitaetsklinik, Cardiology, Freiburg, Germany; [4]Hopital Broussais, Cardiology, Paris, France; [5]Onze Lieve Vrouw Ziekenhuis, Aalst, Belgium; [6]Cardialysis, BV, Rotterdam, Netherlands; [7]L Institut Cardiovasculaire Paris Sud, Massy, France

Vessel size is an established predictor of angiographic outcome after catheter-based intervention. Neointimal growth is a uniform vascular reaction to vessel injury. Higher relative neointima growth (with respect to vessel caliber) is considered responsible for the unfavorable outcome in small vessels.
We investigated the relationship between vessel size and late lumen loss after implantation of sirolimus eluting stents.
Pts with single de-novo lesions were randomized to receive a 18mm sirolimus eluting (SES) BX velocity™ stent (Cordis, Waterloo, Belgium) or a bare 18mm BX velocity™ (BS) stent (Cordis, Waterloo, Belgium). QCA was performed at baseline and at 6 month follow-up (fup). Vessels were stratified according to their diameter (RD) terciles. Late lumen loss (LL) was calculated as "MLD post procedure (post) - MLD fup".
Results:

Stratum	Parameter	SES	BS
I	n	37	38
	RD (mm)	2.05 ±0.20	2.08± 0.21
	MLD post (mm)	2.03 ±025	2.07± 0.29
	MLD fup (mm)	2.05 ±0.32	1.22± 0.46
	LL (mm)	-0.01± 0.25	0.85 ±0.52
II	n	40	38
	RD (mm)	2.53 ±0.14	2.61± 0.14
	MLD post (mm)	2.38 ±0.28	2.39± 0.26
	MLD fup (mm)	2.35 ±0.39	1.68 ±0.45
	LL (mm)	0.03± 0.34	0.79 ±0.51
III	n	39	38
	RD (mm)	3.21± 0.39	3.22 ±0.29
	MLD post (mm)	2.80± 0.28	2.72 ±0.29
	MLD fups (mm)	2.83 ±0.36	1.97± 0.55
	LL(mm)	-0.04 ±0.25	0.76 ±0.58

The classical negative relation between vessel size and late lumen loss was seen in the bare stent group, but not in the sirolimus eluting stent group. Sirolimus eluting stents prevent neointimal growth and late lumen loss irrespective of the vessel size.

P3571 Local delivery of paclitaxel to prevent recurring, diffuse in-stent restenosis

P. Buszman, A. Zurakowski, A. Gruszka, M. Tendera. *Silesian Medical School, 3 rd Department of Cardiology, Katowice, Poland*

It has been proved in animal model that paclitaxol has cytotoxic influence on intimal cells. Therefore, the aim of this study is to test weather locally delivered paclitaxol can prevent recurrence of diffuse in-stent restenosis.
Methods: Five patients with at least two episodes of in-stent restenosis within the same coronary segments were included to the study. Eleven restenotic segments underwent pre-dilatation with Remedy balloon catheter. At the end of the first dilatation 100ìg of paclitaxol diluted in 2 cc of 0.9% NaCl was delivered into the artery wall under the pressure of 2-3 atm during 60 s in each place. Post-dilatations with larger balloon was performed to gain optimal result. No additional stenting was required in any case. There was no major acute coronary events during hospitalization and 6 month observation. Blood tests performed one and four weeks after the procedure did not reveal any abnormalities which could be connected to cytostatic treatment.
Follow-up angiographic evaluation showed late loss of 0.4±0.5 mm and restenosis in 3 segments (27.2%). Repeat angioplasty with delivery of increased dose of paclitaxol (200 ìg in 2 cc) was performed in three patients with restenosis. The late results will be known after next six months.
Conclusions: Locally delivered paclitaxol might be valuable treatment of in stent restenosis, however further evaluation of a proper dose of delivered drug is warranted.

P3572 Evaluation of incomplete stent apposition at six month follow-up in the multi-center RAVEL trial

M. Degertekin[1], K. Tanabe[1], E. Sousa[2], A. Colombo[3], G. Guagliumi[4], W. Wijns[5], M C. Morice[6], P.W. Serruys[1] on behalf of RAVEL investigators.
[1]Erasmus University-Thoraxcenter, Interventional Cardiology, Rotterdam, Netherlands; [2]Dante Pazzanese de Cardiologia, Cardiology, Sao Paulo, Brazil; [3]Centro Cuore Colombus, Cardiology, Milan, Italy; [4]Opsediali Riuniti di Bergamo, Cardiology, Bergamo, Italy; [5]Ziekenhuis, Cardiology, Aalst, Belgium; [6]Institut Cardiovasculaire Massy, Cardiology, Paris, France

The incidence of incomplete stent apposition(ISA) has been recently reported between 12 and 17% immediately after stent implantation.Most of the ISA resolve at 6m FU. The objective of this study was to quantify and investigate the incidence of ISA as well as its clinical implication in the RAVEL trial.
Methods: A subset of pts included in the RAVEL trial whom IVUS was performed (n=95)at 6m FU were investigated. Pts with single de-novo lesions were randomized to receive 18mm Sirolimus eluting stent(SES) and uncoated BX-Velocity stents(UCS).ISA was defined as >1 strut clearly separated from vessel wall with evidence of blood speckles behind the strut.The incidence of ISA was established based on the consensus of three independent analysts.
In pts who had ISA, the number of areas of ISA per stent were determined from cross sectional IVUS images.The total length of ISA were calculated by number of frames involved.The maximal number of struts separated from the vessel wall,the maximal depth (distance between the most separated strut and the vessel wall)and the maximal circumferential extent of ISA(angle)are reported.Finally,the volume of the ISA was quantified.
Results: Two groups revealed similar ISA characteristics in quantitative analysis (table). The event free survival rates at 1 yr was 98% in the SES grp vs 72% in the UCS grp. The 10 pts with ISA in SES grp were event free at 1yr while 1 pt in the UCS grp underwent re-PTCA.

Characteristics of ISA

	SES	UCS
Frequency (%)	(21) 10/48	(4) 2/47*
Number of ISA per stent	1.9± 0.6	2
Max. number of struts	3.6 ±0.97	4.0 ±1.41
Total length(mm)	6.7± 3.7	6.9 ±2.2
Max.Depth(mm)	0.75 ±0.33	0.62 ±0.08
Max.Angle	154 ±68	131± 38
Volume of ISA	20 ±24	27± 16
Stent Volume	131±35	132±36

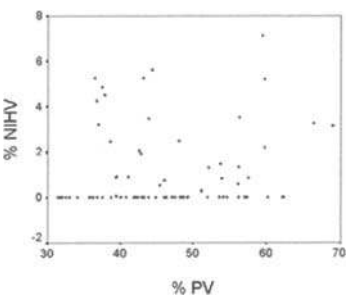
*p<0.001

Conclusion: The incidence of ISA in pts with SES is higher than with UCS at 6M FU. In the SES grp no sub-acute or late (1yr) adverse event was associated with ISA detected at 6M. Long-term follow-up migt be necessary to establish the significance of this phenomenon.

P3573 Sirolimus-eluting stents suppress neointimal proliferation irrespective of the amount of residual plaque burden

K. Tanabe, M. Degertekin, E. Regar, C.H. Lee, S.A. de Winter, N. Bruining, J. Ligthart, P.W. Serruys. *Rotterdam, Netherlands*

Background: The correlation between residual plaque burden after conventional stenting and neointimal formation has been previously reported. However, it has not been established whether this phenomenon is seen as well in drug-eluting stents. In addition, the pharmacological kinetics (elution, diffusion, ...) might be affected by the amount of plaque burden (cell contents).
Methods: 15 patients who received an 18 mm sirolimus-eluting Bx VELOCITY stent (Cordis, Waterloo, Belgium) and intravascular ultrasound (IVUS) examination with a motorized pullback after stenting and at 6-month follow-up were included in this 3D IVUS analysis. The stented segments were divided into six subsegments. The following IVUS measurements were obtained in each subsegment: external elastic membrane volume (EEMV), stent volume (SV), lumen volume (LV), % plaque volume behind stent (PV) calculated as 100*(EEMV-SV)/EEMV, % neointimal hyperpasia volume (NIHV) calculated as 100*(SV-LV)/SV.
Results: Complete analysis was possible in 76/90 subsegments (14 subsegments were excluded because of calcification which precluded the quantification of EEMV). No significant correlation between %PV after stenting and %NIHV was found (figure). %NIHV in the subsegments (n = 24) with %PV > 50 was similar to that in the subsegments (n = 52) with %PV < 50 (1.3 ± 1.9%, 0.9 ± 1.7%, respectively; p = 0.41).



Conclusion: The plaque burden behind a sirolimus-eluting stent does not correlate with neointimal formation, supporting the fact that sirolimus elution from stent suppresses NIH irrespective of the amount of residual plaque burden.

P3574 Cost-effectiveness of the sirolimus eluting Bx-VELOCITY stent: 1-year results

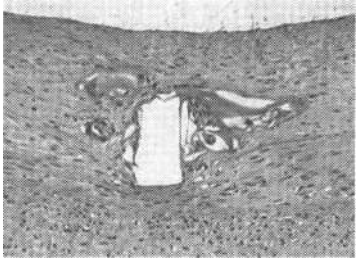
B.A. van Hout[1], W.K. Lindeboom[2], M.C. Morice[3], P. de Jong[4], F. Molnar[5], W. Wijns[6], C. Holubarsch[7], A. Bartorelli[8] on behalf of the RAVEL investigators. *[1]Universitair Medisch Centrum, Julius Centrum, Utrecht, Netherlands; [2]Cardialysis, Statistical Department, Rotterdam, Netherlands; [3]L'Institut Cardiovasculaire Paris Sud, Cardiology Department, Massy, France; [4]Cordis, a Johnson & Johnson Company, Health Economics Department, Waterloo, Belgium; [5]Semmelweis University, Cardiology Department, Budapest, Hungary; [6]Onze Lieve Vrouw Ziekenhuis, Cardiology Department, Aalst, Belgium; [7]Medizinische Universitatsklinik, Cardiology Department, Freiburg, Germany; [8]Centro Cardiologico Ford. Monzino, Cardiology Department, Milano, Italy*

Background: The RAVEL study showed excellent efficacy results in favor of the Sirolimus eluting Bx-VELOCITY stent(CYPHER) when compared to non-eluting stents. However, when using these stents, costs may increase and questions may arise about the balance between the additional costs and effects.
Methods: In the RAVEL trial, an international randomized clinical trial in patients with single vessel disease, 120 patients were randomized to CYPHER and 118 patients were included in the control arm. Data about resource utilization was collected alongside the trial and costs are calculated by multiplying resource utilization with unit costs from The Netherlands. The cost of CYPHER was set at EUR 2,000. Effectiveness was defined as freedom from composite death, myocardial infarction and target lesion revascularization (MACE free).
Results: Except for the cost of stents, the procedure cost in both treatment arms were similar leading to a net difference in procedure cost of EUR 1,274 (EUR 4,451 vs. EUR 5,725). Due to the decreased need for repeat-revascularizations (1 vs. 28) the percentage patients MACE-free differed in favor of the Sirolimus eluting stent with 23.0% (71.2% vs 94.2%). As a consequence, follow up cost differed significantly (EUR 3,568 vs. EUR 2,072) and after 12 months the higher procedure cost in the Sirolimus eluting stent group were more than compensated by the savings in follow-up costs (p=0.01).
The cost-effectiveness analysis showed dominance of CYPHER over the bare stent (better effectiveness in combination with cost savings). The upper limit of the 95% confidence interval considering the costs per additional MACE-free survivor was estimated at EUR 5,237.
Conclusions: This study shows that, after 12-month follow-up, CYPHER is both more effective (94.2% vs. 71.2% MACE free) as well as less costly (EUR 7,796 vs. EUR 8,019). This, together with the upper 95% limit concerning cost effectiveness suggest that using CYPHER is a cost-effective treatment option in the type of patients as selected for this study.
Please note that these data are preliminary. Final data will be presented during the congress.

P3575 Quinaprilat coated PC stents do not attenuate intimal thickening in a porcine coronary model

H.M.M. Van Beusekom[1], V. Ferrero[2], M.S. Harteveld[1], M.G. Punt[1], S. Rodjan[1], M. van Dullemen[1], W.J. van der Giessen[1]. *[1]Erasmus Medical Centre Rotterdam, Cardiology Dept., Rotterdam, Netherlands; [2]Ospedale S. Croce, Cardiology, Cuneo, Italy*

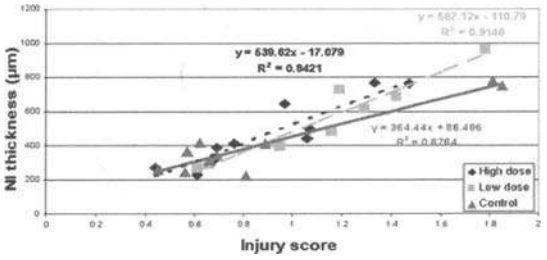
Introduction: ACE inhibitors such as quinapril are known to inhibit smooth muscle cell proliferation. In addition, quinapril has matrix metalloproteinase inhibitor activity which is also postulated to attenuate intimal thickening. Our objectives were therefore to evaluate the performance characteristics of PC coated stents loaded with 800 μg quinaprilat (Q) and it's solvent dimethylacetamide (S) in comparison to coated but not loaded control stents (C) in normal porcine coronary arteries.
Methods: Ten animals received both a Q, S and C under guidance of QCA. They received 300 mg ASA and 75 mg Clopidogrel daily until sacrifice at 4 weeks. Arteries were harvested for histology and morphometry with stents in situ.
Results: QCA revealed a balloon-artery ratio of 1.0±0.1, 1.1±0.1 and 1.1±0.1. Late loss was 0.23±0.26, 0.25±0.3 and 0.05±0.3 for Q, S and C (p=NS). Morphometry revealed neointimal areas of 2.6±1.1, 2.1±0.6 and 1.9±0.5 mm^2 and intimal thicknesses of 0.4±0.1, 0.3±0.05 and 0.3 ±0.1 mm for Q, S and C. While late loss and intimal area are smaller for the control group, statistical analysis showed no significant differences, even when taking balloon-artery ratio or histological injury scores into account. Microscopy showed no qualitative differences between the three groups, all containing a minimal to moderate but asymmetrical neointima. Endothelialization was complete but leucocyte adhesion was observed in all groups, as were macrophage giant cells surrounding stent struts and coating remnants (figure).
Conclusion: Quinapril given locally in a concentration of 800 μg per stent has no significant influence on intimal thickening at four weeks following stent placement in normal porcine coronary arteries.



P3576 Simvastatin coated PC stents do not attenuate intimal thickening in a porcine coronary model

H.M.M. Van Beusekom, E. Regar, S. Visser-van der Veer, M. van Dullemen, S. Rodjan, M.G. Punt, M. Harteveld, W.J. van der Giessen. *Erasmus Medical Centre Rotterdam, Cardiology Dept., Rotterdam, Netherlands*

Introduction: Intermediates of cholesterol biosynthesis are essential for cell growth and drugs affecting this metabolic pathway are potential anti-restenotic agents. Inhibitors of HMG-CoA reductase such as statins fall into this category and have shown antiproliferative properties in vitro. Statins can also improve endothelial function. Our objectives were therefore to evaluate the performance characteristics of PC coated stents loaded with a high (H, 100 μg) and a low dose (L, 30 μg) of Simvastatin in normal porcine coronary arteries in comparison to not loaded control stents (C).
Methods: Animals (n=10) received both a H, L and C under guidance of QCA. They received 300 mg ASA and 75 mg Clopidogrel daily until sacrifice at 4 weeks. Arteries were harvested for histology and morphometry with stents in situ.
Results: QCA revealed a balloon-artery ratio of 1.05±0.1, 1.18±0.1 and 1.15±0.1 for H, L and C (p<0.05 H vs. L). Morphometry showed no statistically significant difference in neointimal area in the three groups (3.4±1.7, 4.0±1.6 and 2.8±1.6 mm^2 for H, L and C). Regression analysis for injury vs neointimal thickness showed no difference in the slope (Figure I).
Microscopy revealed a marked asymmetrical but endothelialized neointima. The degree of cellularity of the intima was similar between the groups and only in instances of extensive NI thickening was the relative proportion of extracellular matrix increased. All arteries contained macrophage giant cells surrounding stent struts and coating remnants.



Conclusion: Simvastatin given locally using the drug delivery BiodivYsio PC stent at 30 and 100 μg per stent does not have a significant influence on intimal thickening at four weeks following stent placement in normal porcine coronary arteries.

P3577 Synergistic effects of a novel nanoporous stent coating and tacrolimus on intima proliferation in rabbits

H. Wieneke[1], O. Dirsch[2], T. Sawitowski[3], S. Wnendt[4], H. Brauer[5], J.L. Gu[6], U. Dahmen[6], R. Erbel[1]. [1]University Essen, Department of Cardiology, Essen, Germany; [2]University Essen, Department of Pathology, Essen, Germany; [3]University Essen, Department of Inorganic Chemistry, Essen, Germany; [4]Department of Biology, University Aachen, Aachen, Germany; [5]University Essen, Department of Material Science, Essen, Germany; [6]Department of Surgery, University Essen, Essen, Germany

Background: To overcome the problem of in-stent-restenosis the concept of local delivery of antiproliferative or immunosuppressive drugs has been introduced into interventional cardiology. Local drug delivery can be achieved by drug-eluting-stents coated with polymer surfaces used for controlled drug release. However, several polymer coatings have shown an induction of inflammatory response and increased neointima formation. In contrast, inorganic coatings have been shown to reduce intima proliferation, but are normally not suitable for sustained drug release. In the present study the effect of a new ceramic nanoporous aluminum-oxide (Al2O3) coating on neointima proliferation and its suitability as a carrier for the immunosuppressive drug tacrolimus (FK506, Fujisawa Pharmaceuticals Co., LTD., Japan) has been investigated.
Methods: 316L stainless steel coronary stents were coated with a 500 nm thin nanoporous aluminum-oxide layer. This ceramic nanolayer was used as a carrier for the anti-proliferative and anti-inflammatory drug tacrolimus. Bare stents (n=6), ceramic coated stents (n=5), ceramic coated stents with 60 mg (n=6) and 120 mg (n=6) tacrolimus loading were implanted in the common carotid artery of New Zealand rabbits.
Results: The ceramic coating caused a 42% reduction in neointimal thickness (p=0.16). Loading the ceramic stents with tacrolimus led to a significant reduction of neointima thickness by 52% for 60 mg (p=0.047) and 60% for 120 mg (p=0.036). The ceramic coating alone as well as in combination with tacrolimus showed a reduced infiltration of lymphocytes and macrophages in response to stent implantation than the bare stents.
Conclusion: Ceramic coating of coronary stents with a nanoporous layer of aluminium oxide results in a significant reduction in neointima formation and inflammatory response. The synergistic effects of the ceramic coating and tacrolimus suggest that this new approach may have a high potential to translate into clinical benefit.

P3578 Stent coating alone with n-butyl methacrylate induces apoptosis of smooth muscle cells

A. Curcio[1], M.C. Faniello[2], C. Coppola[1], E. Campopiano[1], D. Torella[1], G. Cuda[2], F.S. Costanzo[2], C. Indolfi[1]. [1]Università "Magna Graecia", Division of Cardiology, Catanzaro, Italy; [2]Università "Magna Graecia", Department of Biochemistry, Catanzaro, Italy

Background: Coated stents can deliver locally drugs in adequate concentrations to inhibit cell proliferation and migration. Several stent coatings have been tested either experimentally or clinically, including heparin, silicon carbide, gold, polymers with and without drug elution, and radioactive coatings. Synthetic polymers, like methacrylate compounds, have been proposed as a solution to improve the quality of stents, to serve as a vehicle for local (high-dose and site-specific) drug delivery, or both. However, the effects of coating alone has non been studied extensively.
Methods: The aim of this study was to evaluate the potential effects of coating alone with n-butyl methacrylate (BMA) on VSMC proliferation in vitro. SMC (A10, thoracic aorta, rat) were grown to ~ 80% confluence in monolayers at 37°C in a humidified atmosphere at 95% air CO2 in 10% FCS-DMEM (fetal calf serum-Dulbecco's modified Eagle's medium) with 4 mmol/liter l-glutamine, 4.5 g/liter glucose, and 1.0 mmol/liter sodium pyruvate. Coating was prepared releasing BMA on the stents, under sterile conditions, at the following concentrations: 0.003μg, 0.03μg, 0.3μg. For growth inhibition experiments, 1 x 10^5 cells were plated into a six-well plate and grown in DMEM 10% FCS in the presence of BMA-coated stents gently added in each well, or in the absence of them (controls).
Results: Cell number in both conditions was assessed at baseline and at 3h, 12 h and 24 h. After 24 hours treatment, apoptosis was detected by fluorescence microscopy using propidium iodide (PI) and annexin V. A significant increase in % of apoptosis was detected after release of coated stents (BMA-coated stent 0.003μg= 68.4% p<0.01, versus controls; BMA-coated stent 0.03μg = 96.1%, p< 0.001 Vs controls; BMA-coated stent 0.3μg= 94.7% p<0.001 Vs CONTROL =7.6%).
Conclusions: Methacrylate coating induced apoptosis in a dose-dependent manner. Thus, methacrylate is biologically active per se, this effect should be taken in account in evaluating an association of this coating with an antiproliferative and antinflammatory agent.

P3579 Effect of autologous vein graft coated stents saturated with combined chemotherapy agents on porcine coronary arteries

E. Tsiamis, C. Stefanadis, S. Vaina, E. Stefanadi, D. Tsekoura, K. Toutouzas, K. Tentolouris, P. Toutouzas. Hippokration Hospital, Dept of Cardiology, Athens, Greece

Background: One of the main limitations of stenting is restenosis. The purpose of this study was to investigate the effect of implantation of autologous vein graft coated stents (AVGCS), saturated with a combination of two cytotoxic agents, on intimal hyperplasia in the coronary arteries of 15 pigs (20-25Kg).
Methods: An autologous vein graft was removed from the right front leg of the animal. The boundary tissues of the graft were removed and it was stabilised on the external surface of a new stent which was designed in our Institution. The new stent consists of waveform rings connected by small bridges. Three connecting arms are attached at each edge of the stent and can be rotated by 180° after the placement of the graft, in order to stabilize the graft on the stent. Thereafter, a solution of cis-platinum (0.1mg/0.05ml) and mitoxandrone (0.465mg/0.95ml) was evenly infused into the wall of the vein. Eight AVGCS saturated with cis-platinum and mitoxandrone were implanted to LAD and 7 to LCx. Fifteen unsaturated AVGCS were placed in the other branch of the left coronary artery serving as control group. Balloon to artery ratio was 1.17 ± 0.1. Maximum balloon pressure was 15 atm. At 5 weeks, the animals were sacrificed after completion of coronary angiography and morphometric studies were performed.
Results: All vessels were patent after the implantation and at 5 weeks. No acute or late thrombosis was observed. Histologically, endothelialization was similar between the two groups. The arterial middle layer was thinner in the AVGCS saturated with cis-platinum and mitoxandrone compared to the control group.
Conclusion: The implantation of AVGCS saturated with a combination of cis-platinum and mitoxandrone in porcine arteries is easy and uncomplicated. This is the first study demonstrating that combined cytotoxic drug delivery autologous vein graft coated stents may reduce intimal thickening in this animal model.

PAEDIATRIC CATHETER INTERVENTION

P3580 Four year follow-up of ASD catheter closure with the Amplatzer septal occluder in adults: single center experience in 223 patients

U. Krumsdorf, T. Trepels, K. Billinger, E. Zadan, K. Horvath, S. Ostermayer, H. Sievert. Cardiovascular Center Bethanien, Cardiology, Frankfurt, Germany

Purpose: Atrial septal defect (ASD) transcatheter closure has been reported as a suitable alternative to surgery in children and adults. This is a report of the results in one of the world largest series of adult patients.
Methods: Between November 1997 and January 2002, catheter closure of an ASD was attempted with the Amplatzer ASD occluder in 223 consecutive adult patients (mean age 45 ± 17 years; range 13 to 90). These patients had an atrial septal defect with a diameter between 11 and 34.5 mm (21 ± 5 mm). Qp:Qs ranged from 0.8 to 4.2 (2.0 ± 0.7). 15 patients had multiple defects. The systolic pulmonary artery pressure was > 30 mm Hg in 70 patients (31%) and > 50 mm Hg in 20 patients (9%).
Results: The implantation of the device was primarily successful in 222/223 patients. 200/223 procedures could be performed under local anesthesia. The device diameter varied from 12 mm to 40 mm (median 22). The mean procedure time was 46 ± 21 min., the X-ray time 7.8 ± 5.5 min. and the length of hospital stay 0.9 ± 1.1 days. Device embolization occurred in 1 patient (surgery uneventful), pericardial effusion in 1 (asymtomatic) and air embolism in 1 (without clinical consequences). Transesophageal echocardiography showed complete closure after 6 months of the defect without any residual shunt in 218 of 223 patients. 5 small residual shunts disappeared 1 year after closure. During follow-up up to 48 months, another patient developed pericardial effusion (pericardiocentesis successful, no sequelae). One patient suffered from hemopericardium 7 months after device implantation (surgical uneventful). 9 patients developed atrial fibrillation (cardioversion successful in all of them). No thrombus formation could be detected.
Conclusion: After transcatheter closure of an atrial septal defects late complications may occur. However, compared with some older devices this is a reliable and safe procedure with excellent short and mid term results. High closure rates of up to 98% can be achieved. According to the literature these results are superior to surgery.

P3581 Improved interventional closure of patent foramen ovale with the Cardia ASD-Star occluder

M. Höher[1], J. Spieß[1], O. Grebe[1], M. Kochs[1], M. Giesler[2]. [1]*University of Ulm, Cardiology Dept., Ulm, Germany;* [2]*Clinic Deggendorf, Internal Medicine, Deggendorf, Germany*

Despite angiographically successful sealing of a patent foramen ovale (PFO) with an implantable occluder, transesophageal echocardiography reveals residual leakage in up to 30%. This applies particularly to small, low metal, double umbrella devices (e.g. Cardia PfoStar®). With the PfoStar® the thin center pin connecting the two umbrellas tends to position itself asymmetrically at the border of the PFO increasing the risk that the foramen is not covered by the umbrella. Possibly one or more wires even cross the foramen, resulting in a considerable leakage.

To overcome this limitation, we implanted a new occluder type, the Cardia ASD-Star® in 20 patients (12 male, 8 female; age 48±14 years) with cerebral ischemia and PFO. Unlike the PfoStar® consisting from 2 polyvinyl-alcohol umbrellas attached to 2 crossed wires connected by a thin metal pin, the ASD-Star® has 3 crossed Nitinol-wires and a tube-like, elastic connection between the umbrellas. In 19 patients cardiac magnetic resonance imaging (MRI) was performed before and after device delivery. MRI included shunt quantification and first-pass perfusion in the atria during valsalva's manoeuvre and anatomical evaluation of the atrial septum and the position of the occluder by cine-MRI in short and long axes.

The mean PFO length (TEE at 150 degrees) was 16.7±3.6 mm (9-24 mm). Before device implantation TEE revealed an inducible atrial right-to-left passage of echo-contrast medium in all patients. MRI before PFO sealing showed in 10 (53%) patients contrast leakage in the septum, and in 4 (21%) patients a quantifiable atrial shunt. Correct placement of ASD-Star device was achieved in all 20 patients. The mean outer diameter of the ASD occluders was 33±3 mm (28-36 mm) with a mean inner diameter of 13±3 mm of (8-20 mm). All patients received ASA and Clopidogrel for 6 months. Following sealing the atrial septum was perfectly closed in 19 patients, without residual shunt detectable by TEE or MRI. Only 1 patient showed in TEE a minor right-to-left leakage at Valsalva's manoeuvre. One patient who had also a non-critical 60% stenosis of the carotid arteria, suffered from a transient ischemic episode during 6-months follow-up.

We conclude, that despite the same outer diameter, centering the umbrella provides an improved covering of the PFO. It prevents dislocation of wires through the PFO, and reduces residual shunts after interventional PFO sealing.

P3582 Catheter closure of patent foramen ovale (PFO) with the Helex occluder: the European experience

K. Billinger[1], H. Sievert[1], N. Wilson[2], A. Salmon[3], M. Schneider[4], J. Hess[5], W. Sebening[5], P. Ewert[6]. [1]*Cardiovascular Center Bethanien, Frankfurt, Germany;* [2]*Royal Hospital for Sick Children, Glasgow, United Kingdom;* [3]*Southampton General Hospital, Southampton, United Kingdom;* [4]*Pediatric Cardiology Charite, Berlin, Germany;* [5]*German Heart Center, München, Germany;* [6]*German Heart Center, Berlin, Germany*

Background: Patients with cryptogenic embolic events and a PFO are at risk to suffer from recurrent cerebral events. We conducted a prospective multicenter trial to evaluate the feasibility of PFO closure with the new Helex occluder (W.L. Gore).

Methods: The Helex Septal Occluder consists of two discs. A nitinol wire frame is covered by expanded polytetrafluoroethylene (ePTEE). The device is introduced, and if necessary retrieved also after complete deployment, via a 9 F delivery catheter. There is no need for using a long trans-septal sheath. The flexible device has a very low profile once deployed. We attempted transcatheter PFO closure in 127 patients in Europe. The age ranged from 15 to 80 years (mean 50 "b 13). These patients suffered from 158 embolic events prior to PFO closure. The streched diameter of the PFO ranged from 3 to 23 mm (mean 10 mm).

Results: The implantation of the Helex Septal Occluder was successfully performed in all patients. Two devices embolized and could easily be retrieved with a snare. The PFO was closed with a second occluder. The device diameter was 15 mm in 34, 20 mm in 53, 25 mm in 27, 30 mm in 10 and 35 mm in 2 patients. The procedure was performed in local anesthesia in 107/127 patients. Mean X-ray time was 10 min., including balloon sizing of the defect. 44 patients showed a residual shunt immediately after implantation by transesophageal echocardiogram (TEE).

Follow-up: After 6 months 10/65 patients had a residual shunt. In one of them this was closed with a second occluder. During follow up (1 to 27 months) no further embolic event occurred. One wire fracture was detected. Atrial flutter could be observed in one patient. The cardioversion was successful.

Conclusion: Compared to other devices this device has soft atraumatic edges. There is no risk of air embolism during implantation. Catheter removal is possible at any stage during or after deployment. The thrombogenity of the device is very low. PFO closure with the Helex occluder is a very safe procedure and prevents further embolic events.

P3583 Advantages and limitations of ASD and PFO closure with the CardioSEAL-STARFlex-occluder: single center experience in 110 adult patients

U. Krumsdorf, K. Billinger, T. Trepels, S. Ostermayer, K. Horvath, E. Zadan, H. Sievert. *Cardiovascular Center Bethanien, Cardiology, Frankfurt, Germany*

Background: The STARFlex occluder is a modified CardioSEAL double umbrella device which provides a self-centering mechanism achieved by microsprings attached in alternating fashion between the opposing arms of the umbrella. The microsprings also lead to a better apposition of the device arms to the septum. **Methods:** Between June 1999 and January 2002 catheter ASD closure (n=32) or PFO closure (n=78) was attempted with the STARFlex occluder in 110 consecutive patients aged from 17 to 77 years (mean 50 ± 14). 17 of the ASD patients had multiple defects. In 11/17 patients two occuders were implanted.The ASD diameter varied between 5 and 20 mm (14 ± 4 mm), Qp:Qs from 0.8 to 4.2 (2.0 ± 0.7). In the PFO patients an atrial septal aneurysm was found in 24%, the PFO diameter ranged from 4 to 17 mm (10 ± 3 mm). 118 embolic events occurred in these patients before PFO closure. **Results:** The implantation of the occluder was successful in 107/110 patients. The device diameter varied from 23 mm to 40 mm (median 24). In 2 patients with 20 mm defects a stable position of the device could not be achieved, it had to be retrieved. In another patient with a 20 mm defect the occluder embolized into the aorta several hours after implantation without causing clinical symptoms. Catheter retrieval was successful. During follow up (0.03 to 32 months) routine 4 week transoesophageal echocardiogram (n=83) revealed a thrombus on the device in 6 patients (7%). Two minor strokes occurred. In two patients the thrombus was removed surgically. No further complications occurred. After 6 months transesophageal echocardiography showed complete closure of the defect in 107/110 patients (97%). No device arm fractures occurred. **Conclusion:** The STARFlex-occluder is suitable for both defects, ASD's and PFO's, even in complex defects like multiple perforations or with associated septal aneurysm. However, the success rate in defects larger than 20 mm is lower, device malposition or embolization may occur. Thrombus formation seems to be relatively high. This should be addressed in the development of future device generations. The advantage of this device is that despite the centering mechanism large devices can be implanted in small defects. Thereby occasionally additional defects can be covered with only one device providing an excellent closure rate.

P3584 Can transcatheter closure of patent foramen ovale be safely and effectively performed without transoesophageal echocardiography?

H. Baumgartner, R. Rosenhek, H. Gabriel, T. Binder, G. Mundigler, M. Zehetgruber, G. Maurer, P. Probst. *University of Vienna, Cardiology Department, Vienna, Austria*

Background: The use of transesophageal echocardiography (TEE) during transcatheter closure of patent foramen ovale (PFO) adds significantly to patient discomfort. TEE, particularly when performed with general anesthesia significantly increases procedure time and demands on personal and equipment resources, thus raising costs. Therefore, we studied safety and efficacy of PFO closure without routine use of TEE. **Methods:** After a learning period during which PFOs were closed under TEE surveillance, procedures were performed with fluoroscopy, only. Results were evaluated with right atrial angio and transthoracic echo (TTE) before device release. TEE was restricted to situations where appropriate implantation remained uncertain. Amplatzer PFO occluders were used and the choice between size 25 and 35mm was based on preinterventional TEE studies (PFO size, location, septal aneurysm). Patients received Aspirin 2 days prior to intervention and the following 6 months. TTE was performed 1 day, 1 week, 3, 6, 12 and 24 months after intervention. Echo contrast studies were repeated until complete closure was documented. **Results:** 100 patients (56 female, age 47.6±11.5 years) underwent PFO closure. In one pt. the procedure was terminated before implantation because of technical problems at the groin site, in one pt. no implantation was performed because the PFO presented with such a small fixed channel that predilation would have been necessary and in one pt. no PFO was found and repeat TEE showed that the preinterventional study had been false positive. In the remaining 97 pts, device implantation was successfully performed with a mean total procedure time of 32±11 minutes. Unplanned TEE during the procedure was necessary in only 2 pts (2%). Complications were: pseudoaneurysm requiring surgery (1), uncomplicated coronary air embolism (1), atrial fibrillation with spontaneous conversion (1), AVNR-tachycardia (2). Residual shunt as documented by echo contrast was frequent on the first day (23%) but only present in one pt. at 3 months and in no pt. after 6 months. During a mean follow-up of 291±221 days, one stroke and 4 TIAs occurred. A residual shunt at the time of the event was found in only one pt. One pt. developed multiple sclerosis, one pt. epilepsia. **Conclusion:** These results demonstrate that PFO closure can safely and effectively be performed without routine TEE and, thus, without general anesthesia. However, they also emphasize the dilemma of patient selection for the procedure and the necessity of ongoing randomized trials comparing PFO closure and medical treatment.

P3585 Cardiopulmonary excercise capacity increases in patients with atrial septal defect following transcatheter closure

T. Neumann, M. Weber, T. Dill, R. Brandt, M. Rau, V. Mitrovic, M. Bourian, C. Hamm. *Kerckhoff-Clinic, Department of Cardiology, Bad Nauheim, Germany*

Objectives: Hemodynamic abnormalities in adult patients with atrial septal defect (ASD) of the secundum type are associated with exercise limitation. The purpose of the prospective non-randomized study was to evaluate cardiopulmonary exercise capacity and ventilatory function in adults with ASD before and twelve months after transcatheter closure using the Amplatzer septal occluder. Background: There are only few data available on cardiopulmonary exercise tolerance after surgical closure, but nothing about patients after transcatheter closure of atrial septal defects in adults.
Methods: Twenty-three patients (14 women, 9 men, aged 43±13 years) underwent interventional closure of an ASD with an Amplatzer occluder (mean occluder size 24±3 mm, range 15 to 32). The pulmonary-to-systemic flow ratio was >1.5:1 in all patients. No life-threatening procedural complications occurred. Cardiopulmonary exercise testing was performed by supine bicycle ergometry. We determined peak oxygen uptake at anaerobic threshold, maximal performance, oxygen pulse, and the breath volume per minute before and twelve months after interventional closure of the defect.
Results: Peak oxygen consumption at baseline was reduced to 14.2±3.6 ml/min/kg and increased to 16.1±4.5 ml/min/kg after twelve months ($P<0.01$). The increasing in maximal performance from 75±32 watts to 125±30 watts ($P<0.05$) and the oxygen pulse 8.1± 2.2 ml to 10.1± 2.5 ml ($P<0.05$) were also significant. Breath volume per minute increased after twelve month from 27.1±6.2 l/min to 35.3±9.1 l/min ($P<0.05$).
Conclusions: Exercise capacity as assessed by oxygen consumption in patients with ASD is reduced. Significant improvement in exercise capacity occurred over the period of twelve months after transcatheter closure. These novel data emphazises the benefit of transcatheter closure as an alternative to surgery.

P3586 Transcatheter ASD closure with amplatzer device versus surgery in children-comparison of results and complications

J. Bialkowski, B. Karwot, J. Biakowski, M. Szkutnik, P. Banaszak, J. Kusa, M. Frycz. *Silesian Center for Heart Diseases, Department of Paedriatric Cardiology, Zabrze, Poland*

Objective: Comparisons of results, closure rates, morbidity and complications of transcatheter and surgical closure of ASDs in children performed at the same period and in the same institution.
Material & Methods: Our material comprised all children (2-18 y old) with ASDII and a pulmonary/systemic flow ratio of 1,5:1 or more admitted consecutively to Our Department between February 98 and November 00. All patients (pts) except those with defects unfeasible for interventional closure or children, whose parents prefered surgery were catheterized prior to planned transcatheter closure with Amplatzer Atrial Septal Occluder (ASO). Pts in whome catheter diagnosis proved that interventional closure was not possible underwent surgery. Complications after ASD closure were classified as mild, moderate and severe. Small pericardial effusion, headache and first degree av block were considered as mild - pneumonia, paroxysmal supraventricular tachycardia, nodal or atrial rhythm were described as moderate - bleeding requiring reoperation and transient neurological events were severe complications.
Results: 44 pts underwent surgery (S) at median age 8,1 (2,3-16,9) y and 47-ASO implantation at a median age 10 (2,3-17,7) y. No death occurred. Hospital stay in surgically treated pts was 10,5 (4-22)days versus 2,2 (1-15) days in ASO group ($p<0,001$). ASD size was larger in the surgical group ($p<0,001$). Closure rate was similar in both groups- S-95,5% vs ASO- 97,9%. Mild complications were observed in 17/44 (38,6%) of S group vs 2/47(4,3%) in ASO pts, moderate - 11/44 (25%) in S vs 1/47 (2,1%) in ASO pts and severe- in 2/44 (4,5%) of S group vs none in ASO group. Blood products were administered in 18 pts in S group and 1 in ASO group ($p<0,001$).
Conclusions: Trancatheter closure of ASDII with Amplatzer device has the advantage of fewer complications, shorter hospitalisation, reduced need of blood products and less patient discomfort. The surgeon's ability to close any ASD regardless of anatomy remains an important advantage of surgery. Complete closure rate is similar in both groups.

P3587 The application of interventional cardiac catheterization procedures as adjuncts to surgical management of single ventricle paediatric patients

A. Rudzinski, W. Krol-Jawien, Z. Kordon, P. Werynski, L. Szydlowski, E. Olczykowska-Siara. *Polish-American Children Hospital UJ, Pediartic Cardiology, Krakow, Poland*

The aim of the study was a retrospective analysis of the types of cardiologic interventions employed in children with complex congenital heart defects (CCHD) and single ventricle (SV) depending on age, type and stage of surgical management. Material consisted of 70 patients (pts) with CCHD+SV treated 1.01.90-31.12.01. In course of hemodynamic diagnostic management these children were subjected to 72 interventions, what accounted for 22.2% of the total number of hemodynamic studies performed in CCHD+SVA pts. The pts were divided into 3 groups: 1)before hemi-Fontan (HF), 2)after HF, 3)after a modified Fontan (F) palliation. Results are presented in the table:

Stage	BAS/BFOD	Colis	BAA	BPA	Procedures	No patients
Before HF	16	2	15	0	32	30
After HF	0	28	4	6	38	38
After F	0	2	0	0	2	2

BAS/BFOD – ballon atrial septostomy/balloon foramen ovale dilatation,BAA – balloon aortic angioplasty, BPA – balloon pulmonary angioplasty,

Group 1: Among 30 children - BAS/BFOD was performed in 16 (53.3%) aged 0.56-5.5 mo,(x =2.2, SD=1.8), in 13 (43.3%) pts - 15 BAA was done when 3-7 mo (x = 5.5, SD=1.4), including 12 pts with aortic arch obstruction after Norwood procedure, and in 2 pts abnormal systemic to pulmonary collaterals were closed employing coils.
Group 2: Among 38 pts, in 28 (73.7%) major systemic-to-pulmonary collaterals were closed with coils at the mean age 47.5 mo (SD=36.9), and 3-108 mo (x=23.3,SD=23.2) after HF procedure, in another 6 pts (15.8%) BPA of left pulmonary artery was done when 12-30 mo(x=22.5, SD=7.2), 5-20 mo (x=13.1, SD=5.8) after HF, subsequent 4 (10.5%) pts (2 with HLHS and 2 with CCHD+SV and CoAo) underwent BAA when 18-24 mo(x=21.5, SD=2.6), i.e. x=13.8 mo,SD=2.4 after HF.
Group 3: In 2 pts at the age 13 and 11 yrs respectively closure with coils of systemic to pulmonary collateral in first and right to left interatrial communication in second was done.
Conclusions: In children before HF procedures the types of cardiologic interventions were associated with forms of congenital heart defects and types of previous operation. After the HF operation the most common procedure of coils embolization was associated with the development of abnormal systemic to pulmonary collaterals and not with the type of a defect or as initial surgery.

P3588 Balloon valvoplasty as an initial palliation in newborns with severely symptomatic tetralogy of Fallot

M.H. Wu, E.-T. Wu, J.-K. Wang, W.-L. Lee, M.-T Lin, J.-Y Mar. *National Taiwan University Hospital, Pediatrics, Taipei, Taiwan, Province of China*

Background: In newborns with tetralogy of Fallot (TOF), the pulmonary flow is limited by the stenosis or hypoplasia of the right ventricular outflow, pulmonary valve or pulmonary arteries. Balloon dilation of the critical stenosis may increase the pulmonary flow and prompt the growth of pulmonary arteries.
Method: From 1994 to 2001, percutaneous transluminal balloon valvoplasty (PTPV) was performed in 20 newborns and young infants with TOF. The indication for PTPV included severe hypoxemia (SpO2 below 75% under room air) and repeated hypoxic spells requiring intravenous propranolol or ambu-bagging or intubation. The age at PTPV ranged from 8 to 114 days (mean 38 ± 34 days, median 27 days) and the body weight was 3.45 ± 1.15 kg (median 3 kg). After the delineation of the right ventricular outflow and pulmonary arteries, a balloon catheter (4 to 6 mm in diameter and 2 cm in length) was used to dilate the pulmonary valve.
Results: No procedure-related complications occurred. The SpO2 increased significantly after the procedure (14 ± 9%). Thereby, a palliative shunt operation could be avoided in 8 patients (40%). Twelve patients still needed a palliative shunt operation (mean, 54 days after the PTPV) due to significant cyanosis or hypoxic spells. The presence of recurrent hypoxic spells before the dilation was the most important indicator of PTPV failure ($p=0.02$). Follow-up catheterization was performed in 14 patients and adequate pulmonary arterial size was found in all. Fifteen patients underwent total correction with one death.
Conclusion: PTPV could be safely performed in newborns and young infants with TOF to ameliorate the severe cyanosis and to prompt the growth of the pulmonary arteries. However, PTPV may be less effective to prevent the recurrence of hypoxic spells. Nonetheless, a palliative shunt operation may be avoided in about half of the patients. The advantages of prompted growth of the pulmonary arteries and the avoidance of a shunt operation and shunt-related pulmonary arterial distortion are addressed.

CARDIAC SURGERY – MISCELLANEOUS

P3589 Factors associated with cardiac complications during waiting for elective coronary artery bypass graft surgery

F.H.Y. Cesena[1], D. Favarato[1], L.A.M. César[2], P.L. da Luz[1]. [1]Heart Institute (InCor)-HC-FMUSP, Atherosclerosis Unit, São Paulo, Brazil; [2]Heart Institute (InCor)-HC-FMUSP, São Paulo, Brazil

Background: waiting lists for coronary artery bypass graft surgery (CABG) are inevitable in countries which depend on public health insurance. Severe and lethal cardiac events can occur during waiting for surgery.
Purpose: to identify factors associated with cardiac complications during waiting for elective CABG.
Patients and methods: four hundred ninety-three patients referred to elective CABG were separated into two groups: without and with cardiac complications during waiting for surgery, considered as worsening of functional class (FC, NYHA) to III or IV, unstable angina (UA), acute myocardial infarction (AMI), hospitalization or death due to cardiac causes. The groups were compared in regard to previous cardiac events, presence of risk factors, angiographic findings and results of non-invasive tests. Univariate analysis with chi-square and Student's t tests and logistic regression were performed.
Results: one hundred and eighteen (23.9%) patients had cardiac complication. Univariate analysis showed the following variables related to the presence of complication: female sex (OR 1.71, 95% CI 1.08-2.73, p=0.02), FC III or IV (OR 2.39, 95% CI 1.52-3.76, p<0.0001), previous UA (OR 2.24, 95% CI 1.25-4.02, p=0.005) and arterial hypertension (AH, OR 2.40, 95% CI 1.10-5.38, p=0.02). Waiting times were 148±148 and 179±161 days in the groups with and without complication, respectively (p=0.06). After logistic regression, FC III or IV, previous UA and AH were independently related to the presence of complication. Risk factors other than AH, previous AMI, coronary anatomy, left ventricular systolic function and ischemia at non-invasive tests were not significantly different between the groups.
Conclusion: FC III or IV at the moment of referral to CABG, previous UA and AH were associated with higher risk of cardiac complications during waiting for elective CABG. The findings must be considered when establishing priorities for the surgery, in order to minimize morbi-mortality during the waiting.

P3590 Predictors of mortality in patients with valvular heart disease waiting for cardiac surgery

J.J. Alonso, E. Fulquet, J.M. Duran, B. Ramos, M. Acuña, J. Robles, J. Lopez, F. Fernández-Avilés. *University Hospital of Valladolid, Institute of Heart Science (ICICOR), Valladolid, Spain*

Background: A common feature of many Public Health Services is the existence of patients waiting for cardiac surgery. Previous studies have addressed this issue by establishing priority criteria for patients with coronary artery disease. However, there are scant data regarding patients with valvular heart disease.
Methods: The objective of the present study was to identify predictors of mortality in patients with valvular heart disease waiting for surgery. We have analysed 697 pts (age 65±11 years, 55% males) included consecutively in the waiting list, between January 1997 and May 2000, after an indication for isolated valvular surgery or combined valvular and coronary surgery.
Results: Mitral stenosis was present in 12% of patients, mitral insufficiency in 33%, aortic stenosis in 44% and aortic insufficiency in 20%. Significant coronary disease was detected in 20% of patients. The most frequent clinical presentation was heart failure (40%), followed by angina (19%) and syncope (5%). Only 7% of patients had a left ventricular ejection fraction <35%, and 32% showed pulmonary hypertension. Mitral surgery was performed in 33% of the patients, aortic surgery in 50% and combined mitral and aortic surgery in 13%. Associated coronary surgery was carried out in 20% of patients.
The delay before surgery lasted 132±129 days (range: 0-1.183 days). During this period 30 patients died (5%). Multivariate analysis (logistical regression) showed 4 independent predictors of mortality: 1) associated coronary disease (OR 1,77; CI 95% 1,14-2,76; p=0,01); 2) indication for mitral and aortic combined surgery (OR 2,15; CI 95% 1,37-3,37; p <0,01); 3) waiting time until surgery (OR 1,03; CI 95% 1,002-1,05; p= 0,02); and 4) severely depressed left ventricular ejection fraction (OR 4,15; CI 95% 1,30-13,1; p=0,01).
Conclusion: Thus, the reduction of waiting time until surgery and the prioritization of patients at high risk of death (associated coronary disease, mitral and aortic combined diseases, depressed ejection fraction) should decrease the mortality of patients with valvular heart disease while waiting for surgery.

P3591 Randomized study of the efficacy of oral diltiazem to prevent cardiac events after surgical revascularization with internal mammary artery

M. Marijan[1], A.N. Neskovic[2], M. Peric[2], D. Radojevic[2], M. Vukovic[2], A. Vlahovic[2], B. Brkic[2]. [1]Dedinje Cardiovascular Institute, Division of Clinical Pharmacology, Belgrade, Yugoslavia; [2]Dedinje Cardiovascular Institute, Cardiovascular Research Center, Belgrade, Yugoslavia

Background: Calcium antagonists are widely used to prevent coronary spasm after coronary artery bypass grafting (CABG) with internal mammary artery (IMA) despite the lack of evidence of the proposed benefit.
Purpose: To determine the efficacy of oral diltiazem to prevent cardiac events in the first week after CABG with at least one IMA graft.
Methods: We randomly assigned 324 consecutive patients who underwent CABG with IMA graft to receive diltiazem retard 90 mg orally two times daily for 7 days, starting from arrival in intensive care unit (group A, 160 patients), or not to receive diltiazem (group B, 164 patients). Patients with emergency CABG, acute coronary syndromes and current therapy with calcium antagonists were not included in the study. Patients received all standard medications according to clinical condition, including beta-blockers. The two groups were matched for all preoperative characteristics, including age, sex, risk factors and preoperative left ventricular ejection fraction (EF). Primary end-points were episodes of coronary spasm and myocardial ischemia during 7 postoperative days. Secondary endpoints were myocardial infarction, cardiac death, arrhythmias, heart failure, and composite of total cardiovascular events.
Results: In the intention-to-treat analysis, no significant differences were found between the groups A and B in any of outcomes measured: coronary spasm (5/160 vs 3/164), myocardial ischemia (2/160 vs 5/164), cardiac death (1/160 vs 2/164), myocardial infarction (5/160 vs 12/164), arrhythmias (24/160 vs 18/164), heart failure (3/160 vs 2/164), composite of total cardiac events (40/160 vs 42/164). EF improved significantly postoperatively in both groups (from 48 to 49%, p=0.001, and from 48 to 49%, p=0.038, for groups A and B, respectively), although it was similar between groups A and B (50 vs 49%), as well as maximal postoperative serum creatine-kinase MB level (52 vs 60 IU).
Conclusion: It appears that oral diltiazem does not reduce the occurrence of coronary spasm and other cardiac events in the first week after CABG with IMA graft. Therefore, routine use of oral diltiazem in this setting should be discouraged.

P3592 Pharmacological strategies for myocardial protection in patients undergoing non-cardiac surgery: a meta-analysis of randomized controlled trials

H. Burri[1], R. Stevens[2], M. Tramèr[2]. [1]University Hospital, Cardiology, Geneva, Switzerland; [2]University Hospital, Anesthesiology, Geneva, Switzerland

Introduction The impact of pharmacological interventions on the incidence of perioperative cardiac complications in non-cardiac surgery has not been systematically evaluated.
Methods A systematic search of full reports on randomized controlled trials on pharmacological myocardial protection in non-cardiac surgery was done. Dichotomous data was extracted on ischemia, non-fatal infarction, or cardiac mortality within 30 days after surgery. Meta-analyses were performed using a fixed effect model.
Results Beta-blockers (BB, six agents) were compared with placebo in 11 trials (877 patients), alpha2-agonists (AA, clonidine, mivazerol) in six (2,613 patients), calcium channel blockers (diltiazem, verapamil) in three (121 patients), and nitroglycerin in one (45 patients). There were no direct comparisons between different agents.
Ischemia: BB reduced ischemia intraoperatively (7.6% versus 20.2% with placebo, relative risk (RR) 0.40 {95%CI 0.24 to 0.67}) and postoperatively (15.2% vs 27.9%, RR 0.57 {0.37 to 0.87}). Patients on AA had less intraoperative ischaemia (19.4% vs 32.8%, RR 0.59 {0.46 to 0.76}).
Myocardial infarction: BB reduced the risk of infarction (0.9% vs 5.0%, RR 0.26 {0.11 to 0.63}) when two trials with high-risk patients were included. The effect of AA on infarction was not significant (6.1% vs 7.3%, RR 0.86 {0.65 to 1.14}). With both BB and AA there was a relationship between the pre-study prevalence of myocardial infarction, the incidence of infarction in controls, and the efficacy of these agents in preventing non-fatal infarction.
Mortality: Cardiac mortality was reduced with both BB (0.6% vs 3.1%, RR 0.39 {0.17 to 0.92} and AA (1.1% vs 2.3%, RR 0.53 {0.29 to 0.96}.
For calcium channel blockers and nitroglycerin, evidence of any benefit was lacking. With BB, the risk of bradycardia was significantly increased (24.5% vs 9.1%, RR 2.88 {1.96 to 4.23}).
Conclusions In patients at risk of cardiac complications undergoing non-cardiac surgery, beta-blockers and alpha2-agonists improve perioperative outcome

P3593 Endoventricular patch repair in postinfarction cardiomyopathy: comparison between early and late surgical experience

V. Dor[1], A. Toso[2], M. Sabatier[1], F. Montiglio[1], M. di donato[2]. [1]Centre Cardiothoracique de Monaco, Monaco Cedex, Monaco; [2]University of Florence, Critical Care Medicine, Florence, Italy

Background: we started to perform endoventricular patch repair associated with CABG in 1985. Since then 1050 patients have been submitted to the procedure at the Cardiothoracic Center of Monaco. **Objectives:** to analyze if differences in surgical strategy and in clinical outcome existed between an old series of patients operated during 1991-93 and a more recent series operated between 1998-2000. **Patients and methods:** the first series (A) included 222 patients (60 ± 9 yrs; 33 F) and the second series (B) included 165 patients (63 ± 10 yrs; 29 F). All pts had associate coronary grafting; patch was used in 90% of pts in both series.
Results: in B operative mortality decreased from 8% to 5%, re-do surgery increased (9% vs 3%), a higher proportion of patients with recent myocardial infarction (MI) (≤ 3 months)was present. The reduction of volumes and the increase in EF was significant in both series. Surgical technical differences were the introduction of a balloon of known volume, to size the ventricle during reconstruction, and a more accurate peri-op assessment of mitral regurgitation (MR) with a consequent increase in mitral procedures, in B.The strategy to repair mitral valve in almost all patients with any grade MR and also in few patients without pre-op MR, but with annular dilatation, lead to a significant reduction in late MR in B. Mean pulmonary pressure increased significantly in patients whose mitral valve was not repaired (21±9 to 28±15 mmHg. P.0007)

Comparison between series (n° pts)

	Delay MI ≤3 m.	Pre-op MR	Patch	Mitral procedure	Mitral replace	Mitral repair	1 yr MR ≥2+
A	36/222	49/222	192/222	26/222	9/26	17/26	10/102
B	49/165	49/165	148/165	52/165	6/52	46/49	0/40
p value	0.0015	ns	ns	0.001	0.01	0.0001	0.037

MI: myocardial infarction; MR: mitral regurgitation.

Conclusions: the 2 most striking differences between the two series are 1) the decision to treat MR of any grade and to repair instead of replacing the valve; 2) the balloon-sized residual diastolic volume. This lead to a decreased operative mortality, to a lack of increase in pulmonary pressure and to a significant reduction of late MR, which is a critical issue in this procedure.

ATHEROSCLEROSIS AND CORONARY HEART DISEASE

P3594 Correlation between coronary calcium score and intima-media thickness at carotid arteries in patients with coronary artery disease

M. Pasowicz[1], A. Kablak-Ziembicka[2], M. Konieczynska[2], P. Klimeczek[2], R. Banys[2], T. Przewlocki[2], P. Podolec[2], W. Tracz[2]. [1]Cardiac and Vascular Diseases, [2]Inst. of Cardiology, CM UJ, John Paul II Hospital, Krakow, Poland

There is scarce evidence on the relationship between coronary atherosclerosis and carotid thickening of intima-media, as well as between calcium score obtained in coronary arteries. The present study aimed to assess clinical application of coronary calcium score (CCS) and carotid intima-media thickness (IMT) measurement in patients with coronary artery disease (CAD).
Material and methods: One hundred patients, aged 59±9,4 years, admitted to the Department with suspected CAD were studied. Coronary Calcium Score (CCS), B-mode ultrasound quantification of carotid IMT and coronary angiography were obtained in all patients. CCS was measured using Multidetector Spiral CT (MSCT), Somatom Plus 4 Volume Zoom, software Calcium Scoring. CCS was calculated for left main, left anterior descending, circumflex and right coronary arteries. IMT was measured at left and right carotid arteries and expressed as the mean of the maximal value for the common carotid artery, bifurcation and the internal carotid artery. The statistical correlation between age and CCS, age and IMT, as well as between CCS and IMT were assessed by Pearson test. Furthermore, statistical analysis between advancing CAD and CCS, as well as advancing CAD and IMT were calculated using one-way variance analysis (ANOVA).
Results: Coronary angiography revealed 17 patients with no atherosclerotic lesions, 5 patients with non-significant atherosclerotic lesions, 30 patients with one-vessel CAD, 20 with two-vessel CAD, and 28 with three-vessel CAD. Statistically significant positive correlation between age and both CCS and mean IMT ($p<0,0000$ r= 0,486; $p<0,0001$ r= 0,385, respectively) was found. Greater mean IMT values were encountered in patients with two-and three-vessel CAD ($p=0,0530$ and $p=0,0009$), as compared to patients with normal coronary arteries. CCS values < 100 were detected in all patients with normal coronary arteries on angiograms. All patients with CS > 400 developed atherosclerotic lesions. Furthermore, 56% of patients with three–vessel coronary artery disease had CS > 400. Mean IMT correlated well with CCS ($p<0,0000$, r=0,506).
Conclusions: 1. The extent of calcification in coronary arteries and IMT of carotid arteries increases with age. 2. The increase of CCS and mean IMT are well correlated 3. CCS and mean IMT correlates significantly with advancing coronary artery disease.

P3595 Correlation of the severity of coronary atherosclerosis with extracoronary atherosclerosis

P. Guzik[1], J. Tarchalski[2], J. Michalowska[3], H. Wysocki[1]. [1]University School of Medical Sciences, Div. of Cardiology - Intens. Therapy, Poznan, Poland; [2]Kalisz Hospital, Coronary Catheter Lab, Kalisz, Poland; [3]Municipal Hospital, Radiology Dept., Kalisz, Poland

Atherosclerosis is responsible for most cases of cardiovascular disease in the general population. Intima-media thickness (IMT) of common carotid and femoral artery is used as a marker of atherosclerotic changes of extracoronary arteries. The severity of coronary atherosclerosis can be described by Gensini score (GS). This study aimed to examine the relation between the extent of coronary and generalized atherosclerosis measures. Ninety one (33 - 72 years old, 29 female) patients referred for elective coronary angiography underwent ultrasound imaging for IMT measurement of carotid and femoral arteries. For further analysis we used separately the maximal and the minimal value of IMT measured for the right- and left-sided extracoronary arteries. The associations between Gensini score and IMT values were analyzed with the use of Spearman test with presentation of r coefficient and p value in the table below. There are significant and positive associations between GS and IMT values measured at the level of carotid and femoral arteries. The associations between IMT and GS are higher for carotid than for femoral arteries. The observed relationships are higher for the maximal than for minimal IMT values measured at the carotid level. Moreover, the highest observed associations are between GS and IMT values measured on the right-sided extracoronary arteries.

Correlation of GS with IMT

Extracoronary artery	Left-sided arteries	Right-sided arteries
Carotid - the maximal IMT	r=0.38; p=0.0002	r=0.46; p< 0.0001
Femoral - the maximal IMT	r=0.24; p=0.0225	r=0.34; p=0.0009
Carotid - the minimal IMT	r=0.19; ns	r=0.29; p=0.0054
Femoral - the minimal IMT	r=0.24; p=0.0197	r=0.36; p=0.0004

In conclusion, the indexes reflecting generalized and coronary atherosclerosis are significantly correlated. It seems that increased IMT of extracoronary artieries, particularly on the right side, may indicate the co-existence of coronary atherosclerosis.

P3596 Comparison of "average total thickness" of carotid arteries and stress/rest myocardial scintigraphy for the detection of coronary artery disease

R. Holaj[1], J. Frohlich[2], S. Chan[3], M. Kiess[3], J. Mancini[4]. [1]3rd Medical Clinic, General University Hospital, Prague 2, Czech Republic; [2]Lipid Clinic, [3]Cardiology, St. Paul's Hospital, Vancouver; [4]Vancouver General Hospital, Jack Bell Research Centre, Vancouver, Canada

Background: An increase in intima-media thickness of the common carotid artery (IMT) has been confirmed as a surrogate marker for significant coronary artery disease (CAD). A mathematical model involving measurement of IMT and the areas of plaques in carotid beds may predict more accurately the atherosclerotic burden than IMT alone. One of these models the average total thickness of carotid arteries (ATT) was tested in our clinical trial.
Purpose: In this study we compared both parameters IMT and ATT respectively and results of stress/rest myocardial perfusion tomography performed with 99m-Tc-methylisobutyl-isonitrile (MIBI) for prediction of significant CAD.
Method: Carotid arteries were examined by ultrasound in consecutive patients referred to St. Paul's Hospital, Vancouver, Canada for MIBI test because of suspected significant CAD. Complete myocardial redistribution in rest and fixed myocardial perfusion defects were considered as positive MIBI test results. Values of IMT and ATT = 0,80 mm were considered cut-off points for significant CAD estimation.
Results: One hundred patients were eligible for the study (57 men and 43 women; average age, 60 ± 11 years). Positive MIBI test results were detected in 33 patients. Increased IMT was found in 38 patients and increased ATT was calculated in 73 patients. Accuracy both tests for prediction of positive MIBI test result is shown in the table (PV: predictive value).

Test	Sensitivity	Specificity	Positive PV	Negative PV	Odds ratio	P-value
IMT	0,52	0,69	0,45	0,74	2,33	0,05
ATT	0,88	0,34	0,40	0,85	3,79	0,02

Conclusion: According our results ATT value upon of 0,80 mm does not mean presence of myocardial perfusion defect. Lower value of ATT than 0,80 mm is significant negative predictive factor for myocardial perfusion defect. ATT calculation may thus reduce the number of patients undergoing stress/rest myocardial perfusion tomography.

P3597 Carotid lesion type is a marker of high risk coronary artery disease

S. Coscarelli[1], A. Desideri[1], A. Bonanome[2], R. Bigi[1], D. Vaccari[1], R. Pesavento[2], L. Cortigiani[1], L. Celegon[1]. [1]*Cardiovascular Research Foundation, S.Giacomo Hospital, Castelfranco Veneto, Italy;* [2]*San Giacomo Hospital, Internal Medicine University of Padova, Castelfranco Veneto, Italy*

Objectives: to evaluate which carotid lesion characteristics predict high risk coronary anatomy in pts with known or suspected coronary artery disease (CAD). Methods: 162 consecutive pts, 116 males (71%), mean age 64± 10 underwent coronary angiography for known or suspected CAD and bilateral Eco-Doppler evaluation of carotid arteries by means of high resolution technique. Angiographic variables considered were number of critical (>70%) stenotic vessels by quantitative coronary assessment analysis and type of culprit lesions (A, B or C). Plaques were classified according to Gray Weale criteria (1-5). Plaques 2 and 3 were also classified as non-homogeneous.
Results: the average number of critical stenotic coronary vessels/pt was 1.4 (DS ± 1.1). In addition, 30, 20, 23, 27% of pts showed, 0, 1, 2 or 3 critical CAD, respectively. C coronary type lesions were present in 59% of the patients. At Echo-Doppler evaluation 32,6,12,27, 15, 8% of cases were characterized as 0, 1, 2, 3, 4 or 5 carotid type lesions, respectively. Carotid non-homogeneous type 3 lesions by Echo-Doppler were significantly correlated to presence of type C lesion at coronary angiography ($p < 0.001$). Conclusions: Presence of non-homogeneous plaques at carotid ultrasound scan is an index, in pts with known or suspected CAD, of the existence of high-risk plaques at coronary angiography.

P3598 Association of the increased carotid intima-media thickness with the severity of coronary artery disease

A. Kablak-Ziembicka[1], T. Przewlocki[1], A. Sokolowski[2], P. Pieniazek[1], M. Konieczynska[1], W. Tracz[1]. [1]*The John Paul II Hospital, Dept of Cardiac and Vascular Diseases, Krakow, Poland;* [2]*Cracow University of Economics, Krakow, Poland*

Carotid intima-media thickness (IMT) is often used as a marker for coronary atherosclerosis. However, there is little evidence on the relationship between IMT and the advancing coronary artery disease. The present study aimed to investigate: 1) whether the increase in IMT is related to the severity of CAD, and 2) whether IMT might be instrumental in predicting patients with and without significant coronary atherosclerosis.
Methods: We examined 561 consecutive patients, (440 men, 121 women), aged 58,8 ± 9,2 years with suspected CAD. Coronary angiography, as well as ultrasound quantification of carotid artery IMT was performed in all patients. IMT was measured at both carotid arteries and expressed as the mean value, which was calculated for patients with normal coronary arteries, one-vessel CAD, two-vessel CAD and three-vessel CAD. A relation between IMT values and severity of CAD was determined by one-way variance analysis (ANOVA). Furthermore, nonparametric estimation of carotid mean IMT distributions was assessed with histograms using lognormal distribution in CAD patients and patients free of CAD. The positive and negative predictive values, as well as sensitivity and specificity were calculated to visualize the discriminating power of IMT. Results: On coronary angiography, 95 (16,9%) patients had normal coronary arteries. One-vessel CAD was diagnosed in 158 (28,2%) patients, two-vessel CAD in 100 (17,8%) patients and three-vessel CAD in 208 (37,1%) patients. In 90 patients a normal intima-media thickness (<1mm) was found, including 50 patients without atherosclerotic lesions on angiograms and 29 patients with one-vessel CAD. The mean measured value of IMT calculated for patients with normal coronary arteries was 1,01± 0,19 mm, with one-vessel CAD was 1,15 ± 0,20 mm, two-vessel CAD was 1,26± 0,27 mm, and three-vessel CAD 1,47 ± 0,34 mm. A statistically significant correlation between IMT and advancing CAD ($p<0.0000$ - ANOVA) was found. Notably, theoretical distributions of mean IMT revealed that patients with mean IMT value over 1,15 mm had 94% CAD probability, with sensitivity of 65% and specificity of 80%. We sought the cut-off points facilitating allocation of patients into one-, two- and three-vessel CAD. However, due to the overlapping distributions of IMT, this allocation procedure proved inadequate.
Conclusion: Ultrasound examination of carotid arteries can effectively predict atherosclerosis of coronary arteries. IMT increases with advancing CAD. Patients with mean IMT over 1,15 mm have high likelihood (94%) of CAD.

P3599 Changes in antibody titers against chlamydia pneumoniae after percutaneous transluminal coronary angioplasty

G. Yetkin[1], E. Yetkin[2], Y. Aksoy[3], M. Ileri[3], A. Mert[1], S. Cehreli[2]. [1]*SSK Educational Hospital, Microbiology Dept., Ankara, Turkey;* [2]*Inonu University Faculty of Medicine, Department of Cardiology, Malatya, Turkey;* [3]*Turkiye Yuksek Yhtisas Hospital, Dept. of Cardiology, Ankara, Turkey*

Objective: We performed a prospective study in patients who underwent percutaneous transluminal coronary angioplasty (PTCA) to investigate whether angioplasty procedure would have an influence on the specific humoral immune response against Chlamydia pneumoniae (Cpn) antigens.
Methods and Results: Seventy six patients were included in the study. Blood samples were drawn immediately before PTCA and 1 month after PTCA. Specific IgG and IgA antibodies to Cpn were determined by enzyme immunoassay. At the time of angioplasty 75% and 34% of patients had seropositive antibodies to EBs of classes IgG and IgA respectively. Mean titers of IgG antibodies before and one month after PTCA were 46±31 RU/ml and 50±28 RU/ml ($p>0.05$). One month after PTCA, 98% and %34 of the patients had seropositive antibodies to EBs of classes IgG and IgA respectively. We divided patients into two groups on the basis of IgG seropositivity (Group I: Cpn antibody IgG seronegative, group II: Cpn antibody IgG seropositive) before PTCA. Significant increase in antibody titers of IgG(12±5 RU/ml vs 40 ±18 RU/ml $p<0.001$) and IgA (0.6±0.33 RE/ml vs1.15±0.83 RE/ml $p=0.007$) was observed in group I patients one month after PTCA and 88% of them gained IgG seropositivity. There were not siginificant changes of IgG and IgA antibody levels in group II after PTCA.
Conclusion: We have showed a statistically significant rise in Cpn specific antibodies especially of IgG induced by PTCA in seronegative patients before PTCA. This finding highlights the difficulties of relying on serological diagnosis of infection in coronary artery disease.

P3600 Association between PET flow capacity and inflammation assessed from VCAM-1 and minimal coronary resistance at early coronary atherosclerosis

D. Baller[1], E. Pulawski[1], T. Brinkmann[2], P. Wielepp[3], R. Weise[4], K. Kleesiek[2], D. Horstkotte[1]. [1]*Heart Center North Rhine-Westphalia, Department of Cardiology, Bad Oeynhausen, Germany;* [2]*Heart Center North Rhine-Westphalia, Dept Laboratory Transfusion Medicine, Bad Oeynhausen, Germany;* [3]*Heart Center North Rhine-Westphalia, Dept. of Mol. Biophysics, Radiopharm., Bad Oeynhausen, Germany;* [4]*Heart Center North Rhine-Westphalia, Inst Mol Biophys, Radiopharm, Nucl Med, Bad Oeynhausen, Germany*

Coronary atherosclerosis is an inflammatory disease and endothelial vascular adhesion molecule (VCAM-1) exerts a pivotal role at early atherogenesis. Purpose of our study was to relate soluble VCAM-1 levels to myocardial blood flow (MBF) response in 20 patients with mild-to-moderate LDL hypercholesterolemia, mild angina pectoris (CCS class I-II or atypical angina), reduced coronary vasodilator capacity on dipyridamole (D) PET at baseline and minimal coronary disease on angiography (CAD) before and after 5-6 months of intensive lipid-lowering (fat-reduced diet combined with statin therapy), previously not receiving lipid-lowering drugs. Exclusion criteria were smoking, diabetes, hormonal replacement, significant LV hypertrophy and cardiomyopathies.
Methods: VCAM-1 was measured by ELISA technique. 15 apparently healthy age-matched (51-60 years) blood donors (10 males) served as controls: VCAM-1: 810± 243 ng/mL. For quantitative analysis with PET (Siemens ECAT 9.51) a 3-compartment model for MBF (~ 550 MBq N-13 ammonia) determination was applied. Pts had reduced mean global flow reserve (2.2±0.6) versus controls (4.0±1.3, $p<0.01$) on D-PET (0,56 mg D/kg). Dilator capacity was noninvasively assessed as minimal coronary resistance (MCR) normalizing D-MBF on mean perfusion pressure.
Results: Baseline data (mean ± SD): age 58±9, (14 males); VCAM-1 at baseline 1215±368 ng/mL, total cholesterol 244 ±43, HDL-C: 47±19 mg/dL. VCAM-1 decreased from 1215±368 to 850 ± 343 ($p<0.01$) and MCR from 0.495±0.09 to 0.37±0.10 mmHg/mL/min x 100 g ($p<0.01$). A positive correlation was obtained between VCAM-1 (x) and MCR (0.372+6.128 E-5x).
Conclusions: Lipid-lowering guided by statins and PET exerts a beneficial short-term effect on inflammation in terms of VCAM-1. Our data suggest an important relation between impairment of coronary dilator capacity, determined noninvasively by PET, and a molecular marker of inflammation, demonstrated to the best of our knowledge for the first time at early CAD with near normalization of MCR after statin therapy.

P3601 Cardiovascular risk factors profile and the risk of developing acute coronary syndromes, in Greece: final results from CARDIO2000 study

D.B Panagiotakos, C. Pitsavos, C. Chrysohoou, J. Skoumas, D. Antoniadis, C. Stefanadis, P.K. Toutouzas. *University of Athens, School of Medici, Cardiology Clinic, Athens, Greece*

Background: During the past decades several epidemiological studies have provided a portrait of the potential candidate for cardiovascular disease. Additionally, many differences arose in the coronary risk models, between populations as well as among individuals within populations that made extremely difficult the generalization of the results. The aim of this study is to model the coronary risk, based on several established and emerging risk factors, in a Mediterranean population and to compare the findings with other similar studies.
Methods: During 2000-2001 Athens Medical School and Hellenic Heart Foundation conducted a multicentre (35 coordinators from all regions) epidemiological study. 701 males and 147 females patients with first event of an acute coronary syndrome and 1078 matched by sex, age and region, controls, randomly selected from the daily listings of the cardiology clinics and completed a detailed questionnaire concerning more than 100 parameters. Conditional logistic regression analysis estimated the relative risks of developing coronary heart disease under several hypotheses and stage II meta-analysis compared our findings with other major epidemiological studies (The Seven Countries Study, The Framingham Heart Study).
Results: Mean age for first event in the series of male patients was 58±10 and for the females, 65±9 years old. The frequency ratio between males – females was 4-to-1. The hierarchical regression analysis showed that: sedentary life (OR=1.98, P-value < 0.001), hypercholesterolemia (OR=5.25, P-value < 0.001), adoption of Mediterranean diet (OR=0.90, P-value < 0.001), depression (OR=1.05, P-value < 0.01), hypertension (OR=2.79, P-value < 0.05), smoking (OR=2.27, P-value < 0.05), diabetes mellitus (OR=2.67, P-value < 0.05), family history (OR=2.47, P-value < 0.05), job stress (OR=2.23, P-value < 0.05), and educational level (OR=0.63, P-value < 0.05) were independently related with the risk of developing the disease. By the application of (stage II) meta-analysis we found many differences as well as many similarities (P-value < 0.01) with the stochastic models based on different populations.
Conclusion: With respect to any potential, systematic error we conclude that several emerging lifestyle risk factors in addition to the conventional, pose their particular challenge for further research, in this Mediterranean population. Moreover, the applied meta-analysis supported the hypothesis for heterogeneity of risk charts between populations and, consequently, the need for local epidemiological studies (Pyorala K. Eur Heart J, 2000).

P3602 Heavy metals ions seem to have no significant effect on extent of coronary artery disease

W. Kuliczkowski[1], B. Jolda-Mydlowska[1], J. Antonowicz-Juchniewicz[2], W. Kosmala[1], M. Kobusiak-Prokopowicz[1], J. Orzeszko[1]. [1]*Medical Academy, Department of Cardiology, Wroclaw, Poland;* [2]*Medical Academy, Internal and Occupational Medicine, Wroclaw, Poland*

There are still unsolved issues concerning the role of heavy metals ions (HMI) in pathogenesis and progression of atherosclerosis. Some of them like selenium (Se) and zinc (Zn) are thought to have positive effect on endothelium, others like lead (Pb), cadmium (Cd), manganese (Mn) and copper (Cu) can probably deteriorate its function. The link between HMI and extent of macroscopic atherosclerosis is unclear.
The aim of study was to find out the relation between blood and plasma concentration of HMI and extent of atherosclerosis in coronary arteries in patients (pts) with coronary artery disease (CAD).
Study population consisted of 60 pts (32 men and 28 women) mean age 62,4 ± 10,5 yrs, all former or current smokers with no history of working in environment with high exposure to HMI. The diagnosis of coronary artery disease was established upon coronary angiography in which 70% narrowing of the vessel was considered as significant. Pts were divided in to four groups according to the number of affected arteries (0, 1, 2, 3). Blood concentrations of Cd and Pb and plasma concentrations of Cu, Zn, Mn, Se were estimated by SAA method (Spectrophotometry Atomic Absorption).
Results are shown in the table.

Coronary artery disease extent groups	Zn (μg/dl)	Mn (μg/l)	Cu (μg/dl)	Cd (μg/l)	Se (μg/l)	Pb (μg/l)
0 (n=19)	97,63	1,27	108,96	0,31	58,41	40,15
1 (n=18)	93,09	1,10	119,00	0,09	67,47	39,88
2 (n=11)	104,37	1,52	122,11	0,27	63,75	46,51
3 (n=12)	98,57	1,41	115,75	0,38	57,62	47,10
Statisticaly significant differences	NS	NS	NS	NS	NS	NS

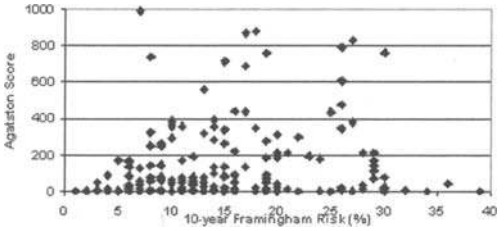
Blood concentrations of Cd and Pb were below threshold limit value for non-exposed population and plasma concentrations of Zn, Mn, Se, Cu were within normal limits. No significant differences in concentrations of HMI among studied groups were found out.

Conclusion: In conclusion we can state that in patients with CAD: 1. Blood concentrations of Cd and Pb and plasma concentration of Zn, Mn, Se and Cu do not differ from those in normal population. 2. There is no relation between blood and plasma concentrations of studied HMI and extent of atherosclerosis in coronary arteries.

P3603 Correlation between extent of coronary calcification and predicted cardiovascular risk based on risk factor models in primary prevention

S. Achenbach[1], A. Nomayo[1], D. Ropers[1], T. Menendez[1], K. Pohle[1], A. Schmermund[2], R. Maeffert[1], W.G. Daniel[1]. [1]*University of Erlangen, Cardiology & Internal Medicine II Dept, Erlangen, Germany;* [2]*University of Essen, Department of Cardiology, Essen, Germany*

We investigated the relationship between the extent of coronary calcifications (CC) quantified by electron beam tomography (EBT) and the predicted 10-year cardiovascular event risk based on Framingham and PROCAM data in primary prevention patients in order to verify whether EBT information is independent from and additive to that obtained by traditional risk factor analysis.
Methods: In 250 subjects (180 men, 70 women, mean age: 58 years), CC were quantified by EBT using the "Agatston Score" (AS). The predicted 10-year cardiovascular event risk was determined using the Framingham equation (FRA) and (in men) the PROCAM algorithm.
Results: In 186 subjects, CC was detected by EBT. Mean AS in all patients was 194. The mean FRA risk was 10.9% in patients without CC and 15.4% in patients with CC (p = 0.001). The mean PROCAM risk in men without CC was 5.4% vs. 7.9% in men with CC (p = 0.09). 49 subjects had a FRA risk > 20%, ("high-risk patients"). 8 of these had an AS of 0, which implies a very low cardiac risk. 2 of 97 patients with a FRA risk below 10% ("low risk") had an AS exceeding 400, which in turn implies a very high cardiac event risk. Only 30 of 62 subjects in the upper quartile of FRA risk (>19%) were in the upper AS quartile (AS > 171). The graph shows the correlation between FRA risk and AS (r^2=0.06).



"Agatston Score" vs. Framingham risk.

Conclusions: The presence and quantity of coronary calcifications shows no close relationship to the extent of traditional risk factors. Particularly, a substantial fraction of patients with high risk according to risk factor based prediction models have no coronary calcifications and thus may be at lower risk. The assessment of coronary calcium therefore yields independent and additional information to prediction models based on traditional risk factors.

P3604 Plasminogen levels and risk of coronary artery disease – A case-control study

A. Hoffmeister[1], D. Rothenbacher[2], N. Khuseyinova[1], H. Brenner[2], W. Koenig[1]. [1]*University of Ulm, Internal Medicine II, Ulm, Germany;* [2]*German Center for Research on Ageing, Epidemiology, Heidelberg, Germany*

Background: The plasminogen system has strong fibrinolytic and proteolytic properties and plays an important role in inflammatory and other cell migratory processes. Experimental studies suggest an importance of plasminogen-mediated proteolytic degradation of extracellular matrices in tissue remodeling events like atherosclerosis and restenosis. The aim of this case-control study was to investigate the association of systemic plasminogen levels and the presence of chronic coronary heart disease (CHD).
Methods: Cases included 312 clinically stable patients with CHD aged 40-68 years who underwent coronary angiography and who had at least 1 coronary stenosis >50%. Age- and sex-matched voluntary blood donors served as controls (N=479). Plasminogen activity was measured in double in citrate plasma by chromogenic assay (Chromogenix, Milano, Italy). Further sensitive markers of fibrinolysis, hemostasis and inflammation were determined.
Results: Plasminogen levels were not statistically significant different between patients with CHD (113.6% activity) and healthy controls (114.1% activity). Plasminogen levels were positively correlated with fibrinogen ($r=0.26$, $p<0.0001$), plasma viscosity ($r=0.34$, $p<0.0001$), serum amyloid A ($r=0.16$, $p<0.001$), C-reactive protein ($r=0.12$, $p<0.01$), apolipoprotein A1 ($r=0.16$, $p<0.001$), apolipoprotein A2 ($r=0.14$, $p<0.01$), and total cholesterol ($r=0.17$, $p<0.001$). After multivariable adjustment for age, sex, body mass index, smoking behavior, alcohol intake, years of school education, HDL-cholesterol, history of hypertension and diabetes, the odds ratio of stable CHD for elevated plasminogen levels (highest versus lowest quartile) was 0.8 (0.5-1.3).
Conclusion: Levels of plasminogen are not associated with the presence of CHD in this study population. Thus, measuring systemic plasminogen activity has no additionally benefit in predicting CHD at least in patients with stable angina.

SMOKING AND ITS EFFECTS ON THE CARDIOVASCULAR SYSTEM

P3605 Acute passive smoking induces oxidation of low-density lipoproteins and impairs endothelium dependent arterial dilatation

T. kato, M. yuhara, S. ariyama, T. tamaki, Y. maruyama, S. tanaka, N. yoshimoto. *saitama medical centre, third department of internal medicine, saitama, Japan*

Background: Passive smoking impairs endothelial function and is one of the major risk factors for atherosclerosis and coronary heart disease. The aim of the present study was to examine whether acute passive smoking (1) accelerates lipid peroxidation; (2) causes acute endothelial dysfunction, in nonsmoking healthy young men.
Methods: Study subjects were consisited of 14 healthy nonsmoking young men without history of hypertension, diabetes mellitus, or hyperlipidemia. Before and after a 30-minute exposure to environmental tobacco smoke, we measured the serum levels of malondialdehyde-modified low density lipoproteins (MDA-LDL) as an index of lipid peroxidation, and assessed flow mediated vasodilation (FMD) in the brachial artery using high resolution ultrasound (7.5 MHz) at baseline and during reactive hyperemia.
Results: Passive smoking acutely (1) increased the serum levels of MDA-LDL (98 ± 17 to 118 ± 18 U/L, $P < 0.05$); (2) impaired the FMD (11.6 ± 4.7 to $5.3 \pm 3.8\%$, $P < 0.01$).
Conclusions: Acute passive smoking substantially (1) induced lipid peroxidation assessed by the increased serum levels of MDA-LDL; (2) impaired endothelium-dependent vasodilation in the brachial arteries. The precise mechanisms by which acutely increased MDA-LDL causes this altered vascular reactivity remain unclear, however, these findings provide a clinical evidence that even an acute passive smoking may be dangerous.

P3606 Cigarette smokers and vascular damage: analysis of mechanisms that impair endothelium dependent vasodilatation

F. Bursi, R. Rossi, A.C. Nuzzo, T. Grimaldi, M.G. Modena. *Policlinico, Internal Medicin. Institute of cardiol, Modena, Italy*

Background: Cigarette smokers have an impaired endothelium dependent vasodilatation (EDVD). The precise mechanism of smoking related endothelial dysfunction is unknown, and may be multifactorial. An abnormal EDVD may be caused by decreased nitric oxide (NO) production or by increased NO inactivation due to the action of free radicals, or both.
Methods: To investigate this question, we enrolled 52 patients [age 48.5 ± 10.5 years (range: from 35 to 64); 53.8% males (n = 28)]: 25 of these (48% of the study population) chronic smokers and 27 (52%) control not-smoking subjects. Patients were studied after an overnight fasting period; an ultrasonographic study of the brachial artery was performed and a urine sample was collected for each patient. EDVD was evaluated by measuring the diameter of the brachial artery before and during reactive hyperaemia (induced after deflation of a blood pressure cuff inflated to suprasystolic pressure for 5 minutes) and was calculated from the diameters as: (reactive hyperemia - baseline)/baseline X 100%. Urine levels of Isoprostane 15-F2t-isoprostane (IsoP) (a stable metabolite of arachidonic acid) was dosed to represent an index of free radical production. Urinary escretion of nitrates was measured as the product of whole-body NO synthesis.
Results: (Data are expressed as mean value ± SEM). Greater EDVD resulted in the non-smoker group than in the group of cigarette smokers (6.3 ± 0.3 versus 2.6 ± 0.3; $p < 0.001$). Additionally we noticed higher urinary levels of IsoP in smokers (14.2 ± 3.8 versus 4.94 ± 2.7 ng/mg creatinine; $p < 0.05$). There was a significant inverse correlation between EDVD and urinary levels of IsoP in smokers ($r = -0.72$; $p < 0.0001$). Nitrate urine levels were similar in the two groups (765.6 ± 157.0 in smokers versus 647.1 ± 136.4 mmol nitrate/mg creatinine in the other group; p = ns).
Conclusions: Smoking is not accompanied by less total production of NO; abnormal EDVD is associated with enhanced oxidative stress due to overproduction of free radicals.

P3607 Acute cigarette smoking and endothelium. Effect of regular versus "light" cigarettes

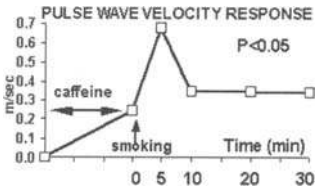
C. Papamichael[1], K. Aznaouridis[1], K. Stamatelopoulos[1], C. Vemmos[1], A. Protogerou[1], Th. Papaioannou[2], J. Lekakis[1], M. Mavrikakis[1]. [1]*Alexandra University Hospital, Dept. of Clin. Therapeutics, Athens, Greece;* [2]*Alexandra University Hospital, Clin. Therapeutics, Athens, Greece*

Acute cigarette smoking leads to temporary endothelial dysfunction. To examine the effect of regular versus "light" cigarettes on endothelium, 11 healthy individuals (6 women, 5 men, age 27.2±3.7 years) underwent measurement of endothelial function of the brachial artery (endothelium-dependent, flow-mediated dilatation, FMD). Measurements were performed before, immediately after and 30, 60 and 90 minutes after smoking one cigarette. Subjects were randomized to smoke either a regular cigarette (nicotine 0.9 mg, tar 12 mg) or the corresponding "light" cigarette (nicotine 0.6 mg, tar 8 mg). The following day, measurements were repeated after smoking the opposite kind of cigarette. Results: In the group of regular smoking FMD was 7.5±2.6% and was reduced to 1.7±3.8% immediately after smoking, 1.3±2.7% at 30 min, 5.0±3.0% at 60 min and 5.8±2.3% at 90 min. FMD reduction was significant immediately after smoking and at 30 min ($p=0.016$ and $p<0.001$ respectively). In the group of "light" smoking FMD was 6.1±1.7% and was reduced to 2.9±2.5% immediately after smoking, 4.4±3.8% at 30 min, 5.7±2.7% at 60 min and 6.5±2.8% at 90 min. FMD reduction was significant only immediately after smoking ($p=0.008$). FMD comparison between the two groups showed no difference before and immediately after smoking (ns), statistically significant difference at 30 min ($p=0.023$) and no difference at 60 and 90 min (ns). In conclusion, both regular and "light" cigarette acute smoking lead to endothelial dysfunction; the duration of endothelial dysfunction after acute smoking is shorter with "light" cigarette smoking.

P3608 Smoking a cigarette while drinking coffee: how badly is aortic function affected?

C. Vlachopoulos[1], F. Kosmopoulou[1], A. Sofianidou[1], V. Tzifos[1], C. Stefanadis[2], M. O'Rourke[3], S. Stamatelopoulos[1], P. Toutouzas[2]. [1]*Henry Dunant Hospital, Cardiology, Athens, Greece;* [2]*Athens Medical School, Cardiology, Athens, Greece;* [3]*University of New South Wales, Cardiology, Sydney, Australia*

Background: Aortic stiffness is an important determinant of left ventricular function and coronary blood flow and has been identified as a prognosticator of cardiovascular risk. We have previously shown that caffeine increases aortic stiffness. The habitual consumption of caffeine is often associated with smoking; however, their combined effect on aortic stiffness has not been defined.
Methods: We studied 10 healthy volunteers (age 30±5 years) in a randomized, placebo-controlled, crossover fashion (200 mg of caffeine orally -equivalent to 1-2 cups of coffee- and 60 min later smoking one standard cigarette -1.1 mg nicotine- or placebo and sham smoking). Carotid-femoral pulse wave velocity was measured as an index of aortic stiffness. Pulse wave velocity (=dL/dt, where dL is the distance travelled by the pulse and dt the time delay between the corresponding foot of pulse waves) was measured using an automated, non-invasive device (Complior®) that has been previously validated.
Results: Caffeine led to a substantial increase in pulse wave velocity (by 0.24 m/sec) that denotes increase in aortic stiffness. Smoking increased further pulse wave velocity (by 0.44 m/sec, figure). Pressures also increased (systolic: by 16.8 with caffeine and by an additional 7.5 mmHg with smoking; diastolic: by 10.8 with caffeine and by an additional 5.1 mmHg with smoking).



Smoking/coffee and aortic stiffness.

Conclusions: Smoking and caffeine have a synergistic adverse effect on aortic stiffness. This finding has important implications for left ventricular function and coronary blood flow and provides a new insight into the combined effects of smoking and caffeine on the cardiovascular system.

P3609 Immediate effect of cigarette smoking on the QT-interval in habitual smokers

G. Andrassy[1], A. Dunai[1], E. Simon[1], T. Nagy[1], Z. Trummer[1], A. Tahy[1], A. Varro[2], A. Szabo[3]. [1]*Szent Ferenc Korhaz, Cardiology, Budapest, Hungary;* [2]*Szeged University, Department of Pharmacology, Szeged, Hungary;* [3]*The Nottingham Trent University, Department of Life Sciences, Nottingham, United Kingdom*

Introduction: Conflicting results are available on the impact of smoking on ventricular repolarization, and the immediate effect of smoking on the QT interval has not been adequately studied yet. The aim of the present controlled study was to assess the effect of smoking on the QT interval duration in healthy smokers after an overnight cessation of smoking.
Methods: 19 healthy volunteers (32±13, range 18-58 years, 8 men) were enrolled. All patients had normal baseline ECGs. On the first day subjects simulated smoking with tobacco void cigarettes (sham-smoking). On the other day, subjects were asked to smoke 4 cm of a filter cigarette containing 0.9 mg of nicotine in 2 minutes. Carboxyhemoglobin levels were determined before the experiments to rule out prior smoking. Twelve-lead ECG-s were recorded in every 2 minutes, QT interval was measured in five consecutive cycles in lead II using a digitising board and computer. Bazett's square root, Fridericia's cubic root formulas and the linear equation of Sagie (QTLc = QT+0.154[1-RR]) were used to adjust the QT interval for heart rate.
Results: Smoking induced a statistically significant immediate increase in heart rate, whereas sham smoking had no significant effect on heart rate. After smoking QTc significantly increased, but neither smoking nor sham smoking influenced QTFc and QTLc values.

Table

Difference (post - pre)	Sham smoking	Smoking	P
HR (bpm)	-0,1±2,3	19,0±12,2	<0,001
QTc (ms)	-6,8±7,5	12,7±3,9	<0,0001
QTFc (ms)	-6,5±6,7	-3,7±9,0	NS
QTLc (ms)	-6,2±6,7	-4,4±9,0	NS

Conclusion: 1) Smoking seems to have no immediate effect on the corrected QT interval. 2) Our data indicate that the increase of QTc after smoking results from the higher heart rate, because QT values corrected with more accurate formulas remained unchanged. 3) We suggest that the application of the Bazett formula should be avoided when comparing groups for QT interval duration with different baseline heart rates.

P3610 Age related differences in variables associated with smoking habit in adolescence

G. Gaeta[1], E. Del Castello[2], L. Effuso[3], L. Gaeta[1], O. Silvestri[1], M. Trevisan[4], J. Lewis-Esquerre[5]. [1]*Antonio Cardarelli Hospital, Cardiology Dept., Naples, Italy;* [2]*ASL CE2, Centro di Igiene Mentale, Capua, Italy;* [3]*ASL Napoli 1, Distretto 44, Medicina dei Servizi, Naples, Italy;* [4]*State University of New York, Social and Preventive Medicine Dept., Buffalo NY, United States of America;* [5]*Brown University, Center for Alcohol and Addiction, Providence, RI, United States of America*

Background Adolescents cigarette smoking is related to several factors. However limited information exists about the differential role that these factors may play at different ages. In this study we investigated which factors were associated with smoking habit in two age group (14-16 and 17-19 years) high school students.
Methods The smoking habit of 904 students (506 males, 398 females) attending a high school located in Naples, Italy, was evaluated by an anonymous, self-administered questionnaire including questions on student, parents, sibling(s) and peer smoking habit, student alcohol and illicit drug use and attitude towards smoking.
Results The smoking habit was as common in girls as in boys and increased with age. In the group as a whole and in the two age groups, smoking habit was related to number of hours spent with friends of opposite sex (p=.004), age of first puff (p<.001), positive attitude towards smoking (p=.002), smoking in home with parents (p=.024) and illicit drug use (p=.004). In the younger age group other factors related to smoking were: money avalaibility (p=.041), have smoked a cigar (p<.001), percent of friends who try to smoke (p=.060), number of days in which the student drank (p<.001), have drunk beer in the last month (p=.001) and get drunk at least once (p=.057). In the older age group other factors associated with smoking were: intention to leave the school (p=.055), have a sibling who smoke (p=.004), smoking habit of best friend of same sex (p=.032) and have drunk spirit in the last month (p=.006).
Conclusions: Adolescents smoking habit is associated with several age-related factors. Those factors specifically related to smoking in younger students witness their intention to seem "adult" whereas, in older students, the distinctive factors related to smoking are expression of the process aimed to construct an own self-identity. This observation might have relevant preventive implications.

P3611 Smoking and inflammatory indices – Dependent or Independent risk factors for coronary artery disease

K. Mizia-Stec[1], B. Zahorska-Markiewicz[2], T. Mandecki[1], J. Janowska[2], A. Szulc[1], E. Jastrzebska-Maj[1], M. Mizia[2], Z. Gasior[1]. [1]*Silesian University School of Medicine, Department of Cardiology, Katowice, Poland;* [2]*Silesian University School of Medicine, Department of Pathophysiology, Katowice, Poland*

Background: Smoking-induced endothelial dysfunction may lead to cytokine- and adhesion molecule-mediated inflammatory activation within a vascular wall.
The aim of the study was to assess the relationship between the smoking status and serum levels of TNF (Tumor Necrosis Factor)alpha, sTNFR (soluble form of TNF receptor) 1 and 2, and selected adhesion molecules (AM): E-selectin, P-selectin, VCAM-1 (Vascular Cell AM-1) and ICAM-1 (Intercellular AM-1) in patients (pts) with coronary artery disease (CAD).
Methods and Results: The study group consisted of 101 consecutive admissions with stable CAD (class II/III CCS; age: 58.9±9): 27 current smokers (group 1; age: 53.6±9), 30 ex-smokers (group 2; age 56.1±7) and 44 pts who have never smoked (group 3; age: 62.8±8). 20 healthy volunteers were the controls (group C; age: 55.3±6). Serum TNFalpha levels were higher in pts with CAD (1: 17.8±2 pg/ml; 2: 16.5±3pg/ml; 3: 17.7±5 pg/ml; p<0.001) than in healthy subjects (8.3±1.4pg/ml). Mean serum concentrations of sTNFR 1 were significantly higher in group 3 (1595±660 pg/ml; p<0.05) in comparison both to group 1 (1306±433 pg/ml) and the controls (1094±457 pg/ml). AM determinations revealed the following: elevated serum E-selectin in all patient groups as compared to group C - with the highest concentrations found in group 1; VCAM-1 elevation in groups 1 and 2 as compared to the controls. P-selectin levels were increased in CAD pts regardless of their smoking status. There were no differences between ICAM-1 levels in the groups examined.
Conclusions: Serum concentrations of some cytokines and adhesion molecules are increased in pts with CAD. Cigarette smoking influences the E-selectin and VCAM-1 serum levels. CAD pts who have never smoked are characterized by delayed onset of angina that might be partly related to the elevation of sTNFR 1 concentration.

P3612 Documentation of slow coronary flow by the TIMI frame count in habitual smokers with normal coronary arteries

E. Yetkin[1], H. Turhan[2], R. Atak[2], M. Ileri[2], K. Senen[2], O. Yetkin[3], I. Tandogan[1], S. Cehreli[1]. [1]Inonu University Faculty of Medicine, Department of Cardiology, Malatya, Turkey; [2]Turkiye Yuksek Yhtisas Hospital, Dept. of Cardiology, Ankara, Turkey; [3]Ankara University Faculty of Medicine, Chest Disease, Ankara, Turkey

Background: It is well known that cigarette smoking impairs the endothelial function, alters the neurohumoral and autonomic regulation. It has been suggested that in healthy subjects, the long-term effects of smoking is related to abnormal coronary vasomotion, presumably induced by an interplay of regional endothelial dysfunction and autonomic dysregulation. Thrombolysis in Myocardial Infarction (TIMI) frame count is a simple clinical tool for assessing quantitative indexes of coronary blood flow. In this study we aimed to evaluate the effects of long-term cigarette smoking in patients with angiographically proven normal coronary arteries.
Methods: Between May 2001 and January 2002, 41 habitual smokers and 41 sex-matched nonsmokers with angiographically proven normal coronary arteries were included in the study. Patients were divided into two groups; group I consisted of 41 patients; 29 men, 12 women mean age=46, range from 39 to 62)who were heavy habitual cigarette smokers, as determined by the high Fagestrom scale. Nonsmokers (group II, mean age=49 range from 42 to 66) were defined as who had never smoked a single cigarette, cigar or pipe.
Results: Resting heart rate was significantly increased in smokers compared with nonsmokers (76±6 vs 71±7 beats/min, $p<0.05$). TIMI frame count of the smoking group was significantly higher than those of nonsmokers for all three coronary arteries: left anterior descending (corrected TIMI frame count), 39±13 vs 22±8 respectively, right coronary artery, 35±13 vs 24±11 respectively left circumflex artery, 37±13 vs 25±8 respectively ($p<0.001$ for all). The smoker patients were tended to be younger than nonsmoker patients (46±7 years vs 49±9 years respectively p=0.07).
Conclusion: We have shown that TIMI frame count is significantly increased in habitual smokers with angiographically proven normal coronary arteries when compared with nonsmokers. Increased TIMI frame count in smokers can be regarded as the index of harmful effects of smoking on coronary flow regardless of the underlying mechanisms.

P3613 Characteristics of coronary patients who smoke

S. Aczel[1], W. Benzer[2], C. Saely[1], P. Langer[1], T. Marte[1], H. Holzmueller[2], H. Drexel[2]. [1]VIVIT-Institute, Feldkirch, Austria; [2]LKH-Feldkirch, Innere Medizin, Feldkirch, Austria

Background: Smoking increases the risk of coronary atherosclerosis (CA). Therefore, the characteristics of coronary patients who smoke are of particular interest.
Materials and Methods: We investigated 767 consecutive patients undergoing coronary angiography. Of these patients, 156 were current smokers and 319 had never smoked. Comparisons were made between these 2 groups. The remaining patients had quit smoking and are not reported here.
Results: Among smokers the prevalence of CA was higher (83 vs. 73%; p=0.016), and there were more men (81 vs. 44%; $p<0.001$), more patients with diabetes (28 vs. 19%; p=0.037), and fewer patients with a family history of atherosclerotic disease (41 vs. 58%; p=0.001). In this group, mean age was lower (55 vs. 66 years; $p<0.001$), body mass index (27.9 vs. 26.6 kg/m^2; p=0.003), waist/hip ratio (0.97 vs. 0.91; $p<0.001$), and alcohol consumption (11.7 vs. 3.9 g/day; $p<0.001$) were higher; HDL cholesterol (44 vs. 53 mg/dl; $p<0.001$) was lower, and apolipoprotein B (120 vs. 112 mg/dl; p=0.002) was higher, whereas LDL cholesterol was unchanged (133 mg/dl in both). Fasting plasma glucose (119 vs. 112 mg/dl; p=0.037), CRP (10.8 vs. 8.2 mg/dl; $p<0.001$), fibrinogen (366 vs. 339 mg/dl; p=0.004) and leukocyte count (8.9 vs. 6.8 G/dl; $p<0.001$) were increased in smokers. Moreover, in smokers the severity (average percentage of all coronary stenoses), but not the extent (number of coronary stenoses) of CA was increased (p=0.002).
Conclusions: In coronary patients smoking is associated with a large scale of cardiovascular risk factors. Morphologically, the severity rather than the extent of CA is increased by smoking.

P3614 Association of smoking with markers of systemic inflammation: results of a population-based study

M. Fröhlich[1], M. Sund[2], H. Löwel[3], A. Imhof[1], A. Hoffmeister[1], M.B. Pepys[4], W. Koenig[1]. [1]University of Ulm Medical Center, Internal Medicine, Cardiology, Ulm, Germany; [2]Institute of Health Economics, GSF, Neuherberg, Germany; [3]Res. Ctr. for Environment and Health, GSF, Neuherberg, Germany; [4]Royal Free and Univ. Coll. Med. School, Department of Medicine, London, United Kingdom

Smoking is capable of inducing a low-grade inflammatory response and inflammation in the arterial wall plays an important role in atherosclerosis. We sought to investigate the association between various markers of systemic inflammation and a detailed history of smoking in a large representative sample of the general population.
We measured the effects of chronic smoking on white blood cell (WBC) count, fibrinogen (FIB) and albumin (ALB), plasma viscosity (PV), and high-sensitivity C-reactive protein (CRP) in 2285 men and 2201 women, age 25-74 years, participating in the third MONICA Augsburg survey 1994/95.
Current smokers showed statistically significantly higher values for WBC count, FIB, PV, and CRP, compared to never smokers (all $p<0.001$), with intermediate, but only slightly increased values for ex-smokers and for occasional smokers. No associations were seen with ALB. Duration of smoking was positively correlated with markers of inflammation as were pack-years of smoked cigarettes. Conversely, duration of abstention from smoking was inversely related to these markers. Adjustment for multiple covariates did not appreciably alter these associations. No clear relationship was found between markers of inflammation and indicators of passive smoking.
Data from this large representative population thus show strong associations between smoking and various markers of systemic inflammation in both sexes and various age groups. They also show that cessation of smoking decreases the inflammatory response, which may represent one mechanism responsible for the reduced cardiovascular risk in these subjects.

PRIMARY PREVENTION

P3615 Prevention of contrast media-induced renal failure after coronary angiography – First results of the "Diuresis versus Dialysis (DVD) study"

H. Reinecke[1], T. Dieckmann[2], J. Fleiter[2], M. Fobker[3], F. Matzkies[2], C. Harz[4], R. Schaefer[5]. [1]Universitätsklinikum Münster, Medizinische Klinik und Poliklinik C, Münster, Germany; [2]Münster, Germany; [3]Inst. f. Klinische Chemie-Zentrallabor, Universitätsklinikum Münster, Münster, Germany; [4]Clin. Dev. Diagnostics, Schering AG, Berlin, Germany; [5]Medizinische Klinik und Poliklinik D, Universitätsklinikum Münster, Münster, Germany

Different stragies for prevention of contrast media induced acute renal failure (ARF) have been investigated demonstrating the importance of hydration with hypotonic infusions (2x1000 ml 0.9% NaCl + 5% glucose, Solomon, N Engl J Med 1994) as well as a significant reduction of ARF by administration of 2x600 mg n-acetylcystein (NAC) over 2 days (Tepel, N Engl J Med 2000).
In a prospective randomized trial with patients (NYHA I-II) undergoing elective coronary angiography with the non-ionic contrast dye iopromide, we included until now 136 patients with moderate chronic renal failure (creatinine 1.3-3.5 mg/dl) and randomized them to one of the following treatments: hydration alone (n=46), hydration + NAC (n=38), and hydration + onetime hemodialysis (n=45). Target is the inclusion of 402 patients, with a statistical power to detect a 25% difference of one of the treatments. Clinical endpoint is ARF (defined as an increase in enzymatically determined creatinine of 0.5 mg/dl). Further, laboratory parameters were monitored as serum creatinine levels, measurement of creatinine clearences, microalbuminurie, and cystatin at baseline, 24 h, 48 h, and 1 month after angiography. Between the three groups, there were no differences in age, gender, frequency of risk factors as hypertension, or dyslipoproteinemia. Average amount of contrast media was 190±11 ml in each group. The most important parameters at baseline and after contrast media exposition are shown in the table, with no significant differences. Frequency of diabetes ranged from 25.7 to 31.3% in the groups. Of the 11 patients with ARF, 7 were diabetics (64%). Hydration alone showed a higher rate of ARF (30%) in diabetic patients compared to addition of NAC or dialysis (each 15%, n.s.).

Patient's characteristics

	Hydration	Hydration+NAC	Hydration+dialysis
Baseline crea, mg/dl	1.46±0.22	1.68±0.47	1.51±0.26
Increase in crea, mg/dl	0.10±0.21	0.21±0.34	0.13±0.15
Filtration rate, ml/min	90.5±48.4	72.4±37.3	77.6±43.5
Decrease in filtration, ml/min	11.8± 36.2	19.8±27.2	16.5±28.2
Patients with ARF, n (%)	4 (8.2%)	4 (9.8%)	3 (6.5%)

At this time, no significant difference in frequency of ARF after coronary angiography between the different treatment groups could be found.

P3616 The combined family history risk score: a prognostic risk factor of acute coronary syndromes. The CARDIO2000 Study

D.B Panagiotakos, C. Pitsavos, C. Chrysohoou, J. Skoumas, D. Antoniadis, C. Stefanadis, P.K. Toutouzas. *University of Athens, School of Medici, Cardiology Clinic, Athens, Greece*

Background: Although the family history of premature coronary heart disease (CHD) is considered a significant risk factor in the development of acute coronary syndromes (ACS), data regarding the importance of the other risk factors that aggregate in families are sparse in the literature. In this work we present a risk score for developing ACS based on family history of hypertension, hypercholesterolemia, obesity, diabetes mellitus, premature CHD and family smoking habits.
Methods: The studied population consisted of 848 randomly selected patients with first event of ACS and 1078 matched, by sex-age-region controls admitted to the same hospitals for minor operations and without any suspicion of cardiovascular disease in their life. The investigation of family history score in the development of ACS was based on Fisher's discriminant function and on conditional logistic regression (odds ratio; 95% confidence interval), controlling for demographic variables as well as for the mutual confounding effects of the other risk factors.
Results: The introduced combined family risk score was positively related with the risk of developing ACS (P for trend < 0.001). In particular, the additive risk model showed that family history of CHD increases by 33% the individuals' coronary risk (OR=1.33; 1.21-1.78). In addition, presence of hypercholesterolemia, within the family, increases the previous risk by 39% (OR=1.39; 1.23-1.88); hypertension by 45% (OR=1.45; 1.23-2.12); diabetes mellitus by 78% (OR=1.78; 1.38-2.23); obesity by 97% (OR=1.97; 1.43-2.52); and family smoking habits by 103% (OR=2.03; 1.78-2.78). Also, presence of any 3 of the investigated risk factors within the family constitutes a crucial cut-off point that increases the individuals' coronary risk by 67% (1.67; 1.35-2.11, $P<0.01$) and discriminant analysis showed that score >3 allocate coronary patients with high accuracy (Wilks lamda = 0.881, $P<0.001$).
Conclusions: The application of the suggested family risk score could be a useful tool in the primary prevention of ACS, as well as in detecting and understanding associations between genetic vulnerability and cardiovascular risk factors.

P3617 Sex differences in cardiovascular risk factors and the risk of developing acute coronary syndromes: the CARDIO2000 study

C. Chrysohoou, D.B Panagiotakos, C. Pitsavos, J. Skoumas, G. Koutsibanis, N. Marinakis, C. Stefanadis, P.K. Toutouzas. *University of Athens, School of Medici, Cardiology Clinic, Athens, Greece*

Background: Coronary heart disease (CHD) is markedly more common in men than in women. In this study, we analyzed the extent in which cardiovascular risk factors may influence the sex difference in CHD risk, in a Mediterranean population.
Methods: During 2000-01, we randomly selected from all Greek regions 848 hospitalised patients with a first event of an acute coronary syndrome and 1078 paired, by sex, age, and region controls, without any suspicious for CHD. In order to evaluate sex differences in the risk factors we developed multivariate risk models with respect to gender.
Results: Women patients were significantly older than men (65.3 ± 8 vs. 59.7 ± 10 years old, $p < 0.01$). The frequency ratio of males to females patients was 4 to 1. The effect of the family history of premature CHD on the risk of developing acute coronary syndromes seems to be related more consistent in males (difference in odds ratio: delta-OR = 1.93, $p<0.01$). The presence of hypertension affects more significantly females (delta-OR = 3.36, $p<0.05$), while hypercholesterolemia is associated with the coronary risk, more consistent in men (delta-OR = 2.58, $p<0.05$). The higher education level as well as the adoption of Mediterranean diet seems to be more protective in females (delta-OR = 0.47, and delta-OR = 0.16, respectively, $p<0.05$), while, depression is associated with higher risk of developing CHD in women (delta-OR = 1.35, $p<0.05$).
Conclusions: This study arose a marked difference in CHD risk between sexes. Lifestyle characteristics as well as several clinical symptoms or laboratory measurements seem to play significant role in the distinction of the risk factors profile between sexes. However, much remains to be learned about the mechanisms that relate CHD risk and sex.

P3618 The influence of previous participation in EUROASPIRE I on the performance of centers participating in EUROASPIRE II

A. Manginas[1], D.V. Cokkinos[1], P.K. Toutouzas[2], G. De Backer[3], D. De Bacquer[3], D.A. Wood[4]. *[1]Onassis Cardiac Surgery Center, Cardiology, Athens, Greece; [2]University of Athens, Athens, Greece; [3]University Hospital, Public Health, Gent, Belgium; [4]National Heart and Lung Institute, Cardiovascular Medicine, London, United Kingdom*

Introduction: In EUROASPIRE I (1995-1996), 9 European countries participated. The second EUROASPIRE II survey was conducted in 1999/2000 with the addition of 6 more countries. We investigated whether the centers involved in both the first and second survey (Group A) showed an overall different management of their patients (pts) compared to those participating for the first time in EUROASPIRE II (Group B).
Methods: The following parameters were compared: a) Information on risk factor (RF) history: Hypertension, hyperlipidemia, smoking, medication use. Measurment of height, weight, blood pressure (BP) on admission. b) Availability of similar data at discharge. c) Percentage of pts interviewed, 18 months later. d) At interview, advice about lifestyle modification efforts, and use of drugs.
Results: 1) When both hospital admission and discharge data were compared, Group A centers performed better in 18 indices of performance (A better in 14, B in 4, $p< 0.031$). Interview participation was also greater in Group A. 2) As regards lifestyle modification overall differences were NS. 3) When use of drugs at discharge and interview were compared, Group A increased â-blockers and ACE inhibitors more, while Group B statins. 4) Centers in Groups A and Group B had a similar GNI per capita, North/ South distribution and mean abstract submission to ESC Congress, 2000.
Conclusions: More experienced groups seem to perform better as regards hospital data management. However, the differences in lifestyle advice modification and drug use are not different among countries participating in both EUROASPIRE I and II vs those only in II. European harmonization of physician practices may be responsible for the latter finding.

P3619 Physical activity may prevent subsequent coronary events in unstable angina through autonomic nervous system modulation

O. Manfrini[1], C. Pizzi[1], T. Aranzulla[1], F. Crea[2], R. Bugiardini[1]. *[1]University of Bologna, Med. Intern., Cardioangiol., Epatol., Bologna, Italy; [2]Cattolica Sacro Cuore University, Cardiology Unit, Roma, Italy*

Background: Exercise training has assumed a major role in both the primary and secondary prevention of coronary heart disease (CHD). However, which mechanisms mediate these benefits is still a matter of continuing debate. This study sought to determine whether the intensity and frequency of recreational activity may influence autonomic nervous system balance, and exert possible benefits in high risk CHD pts.
Methods: Patients were selected from the "Studio sulla Prognosi della Angina Instabile" (SPAI; recruited 1999-2000), which was designed to assess factors able to early identify pts at high risk for subsequent coronary events. Only pts admitted to CCU with a diagnosis of rest unstable angina were enrolled in the study. Exclusion criteria were: previous history of CHD, low ejection fraction (<40%), diabetes mellitus and atrial fibrillation. Health habits, medical history, recreational and work-related total physical activity as recorded with a validated protocol were obtained at baseline and at 6 months follow-up. Vagal and sympathetic activity were assessed, at admission, by time domain measurements of heart rate variability (pNN5O and SDANN, respectively).
Results: Hundred five pts were followed for 6 months. 32 pts (Gr1) had a major coronary event (6 deaths, 8 non fatal acute myocardial infarction, 8 hospital readmission due to documented ischemic attacks, and 10 urgent CABG or PTCA). The remaining 73 pts showed good clinical outcome, and served as control (Gr2). Total weekly energy expenditure was stratified as low (<600 kcal/wk), moderate (600-1500 kcal/wk) or high (>1500 kcal/wk). Twenty of the 32 Gr1 pts (62%) expended less than 600 kcal/wk. Ten of the 73 Gr2 pts (14%) behaved similarly. Analysis of the heart rate variability showed that extremely low (<3%) values of pNN50 predicted mortality and total events. A pNN5O <3% was found in 18/32 Gr1 pts (56%) vs 2/73 Gr2 pts (0.8%). There was a significant relationship between kcal/wk and pNN50. These findings persisted after adjustment for other life-style variable. Conclusions. (1) A shift in the autonomic balance with a loss of vagal tone (pNN50<3%) may be observed in a great portion of pts having unstable angina and an adverse outcome. (2) This could be a reason for coronary vascular instability, and subsequent coronary events. (3) Even moderate physical activity is associated with favorable sympathetic-parasympathetic balance, and better CHD prognosis.

P3620 FLUVACS: flu vaccination in acute myocardial infarction. A pilot study

E. Gurfinkel[1], E. Beck[2], J. Bono[3], J. Santopinto[4], G. Bozovich[5], B. Mautner[5]. [1]Favaloro Foundation, Cardiology, Buenos Aires, Argentina; [2]Hospital "Dr. Carlos A. Durand", Coronary Care Unit, Buenos Aires, Argentina; [3]Sanatorio Allende, Intensive Care, Cordoba, Argentina; [4]Hospital Leonidas Lucero, Cardiology, Bahia Blanca, Argentina; [5]Favaloro Foundation, Cardiology, Buenos Aires, Argentina

Background: Previous studies showed that germ-free chickens infected with a herpes virus developed atherosclerotic lesions and that immunization with a turkey herpes virus prevented the development of atherosclerosis. Recent reports detected an increased number of patients (pts) with acute coronary syndromes (ACS) during the flu season. In addition, the World Health Organization recommended vaccination against Influenza infection for the Southern Hemisphere winter 2001.In the present study, we evaluated the impact of a preventive vaccination in acute myocardial infarction (AMI).Methods: A total of 200 pts admitted in the first 72 hours of an AMI were included in a multicenter prospective registry, during the winter season 2001 in Argentina. All pts received a standard therapy for AMI, 100 pts were allocated as Group A for a single unique parenteral vaccination containing A/Moscow/10/99-like virus, A/New Caledonia/20/99 (H1N1)-like virus, and AB/Sichuan/379/99-like virus. A control group of 100 pts were allocated as Group B. Exclusion criteria were absolute contraindication for vaccination and Killip Class D. Combined end points (death, reinfarction, and rehospitalization because of ischemia) were collected at 6-months follow-up. The comparison of categorical variables between the two groups was performed by means of the Mantel-Haenszel Chi squared statistic or the Fisher' s exact test.Results: There were 17% of ischemic events during the study. The first primary outcome - a composite of death, nonfatal AMI, or severe ischemia - occurred in 10% of the vaccine group and 24% in controls (relative risk (RR) 0.42; 95% confidence interval (CI) 0.21 to 0.83; P=0.008). The double end-point rates were 6% and 12% in A and B, respectively (p = 0.03). Cardiovascular death as a single end-point: RR with vaccine as compared with controls, 0.25; 95%, CI 0.05 to 1.15; p = 0.05.Conclusion: This study is the first to test the use of prophylactic influenza-vaccine in ACS showing a positive trend in reducing subsequent death and ischemic events in AMI.This could be related to an enhaced humoral immune response, particularly during flu season and may reflect a rapid migration of committed B-lymphocytes

P3621 Prevalence of patients with MADIT II risk factors in the prospective German PreSCD registry including 4565 post-myocardial-infarction-patients

D. Boecker[1], S. Reek[2], W. Kamke[3], S. Behrens[4], T. Fetsch[5], A. Suciu[6], K. Contzen[6]. [1]University Hospital, Cardiologie, Münster, Germany; [2]University Hospital, Cardiologie, Magdeburg, Germany; [3]Klinik am See, Cardiologie, Rüdersdorf, Germany; [4]Humboldt-Krankenhaus, Cardiologie, Berlin, Germany; [5]IKKF, München, Germany; [6]GUIDANT, Clinical Science, Karlsruhe, Germany

Objectives: The PreSCD-project (Prevention of Sudden Cardiac Death) is an ongoing prospective registry in Germany to determine the prevalence of patients (pts) post non-acute (>21 days) myocardial infarction (MI) under the cascaded level of risk defined by the MADIT I/MUSTT trials. Recently the MADIT II trial was terminated early by the Data and Safety Monitoring Board due to significantly reduced total mortality in favor of the ICD limb compared to conventional therapy. In contrast to MADIT I, pts surviving a previous MI were eligible for MADIT II without additional risk factors other than depressed left ventricular ejection fraction (LVEF) <= 30%. How many patients this represents is therefore an important clinical issue, and the aim of this subanalysis is to evaluate the prevalence of MADIT II type pts within the PreSCD-registry.
Methods: 40 physicians in private practice consecutively screen their post-MI-Pts according to combined MADIT I/MUSTT criteria: i.e. LVEF is evaluated for all patients with MI>21 days Pts with LVEF <= 40% undergo a 24-h-Holter-ECG, and those with non-sustained ventricular tachycardia (nsVT) are referred to electrophysiological (EP) testing (excluding those with treatable ischemia). Pts with ischemia undergo revascularization whenever possible and redo the screening cascade after procedures. Pts are followed up regularly at 6, 12, 18 and 36 months to determine any of the following events: death (cardiac, SCD, non-cardiac, unknown reason), syncope, resuscitation, Re-MI, PTCA, CABG, ICD implant or none of these. In case of EP-testing or ICD-implant detailed information on induction modes and occurrence of ICD-therapy is recorded.
Results: 4565 post-MI-pts were screened up to date with available LVEF-values. 240 (5.26%) of these pts presented with LVEF <= 30%. In 178 (74.2%) of pts with low LVEF <= 30% nsVT could be not documented, and therefore these pts were not referred to EP testing and further risk stratification. Less than 1% of all post-MI patients fulfill the criteria of MADIT I. In comparison, MADIT II patients are 5 times more frequent than MADIT I patients.
Conclusion: MADIT II patients are 5 times more frequent than MADIT I patients. Identification of these patients by practitioners is feasible using routine procedures.

BETA BLOCKERS IN HEART FAILURE

P3622 Efficacy and safety of carvedilol during initiation of therapy in patients with severe chronic heart failure: results of the COPERNICUS study

E.B. Roecker[1], H. Krum[2], A.J.S. Coats[3], H.A. Katus[4], P. Mohacsi[5], J.L. Rouleau[6], M. Tendera[7], M. Packer[8] on behalf of the COPERNICUS Study Group. [1]University of Wisconsin, Biostatistics and Medical Informatics, Madison, USA; [2]Monash University, Prahran Victoria, Australia; [3]Royal Brompton Hospital, London, United Kingdom; [4]Universitaets-Klinikum Luebeck, Luebeck, Germany; [5]University Hospital Bern, Bern, Switzerland; [6]Mount Sinai Hospital, Toronto, Canada; [7]Siliesian School of Medicine, Katowice, Poland; [8]Columbia University, College of Physicians and Surgeons, New York, USA

Background: Despite their established utility, some physicians remain hesitant about using beta-blocking agents for the management of heart failure because of concerns that initiation of treatment produces few immediate benefits and carries important risks.
Methods: We evaluated the efficacy and safety of initiating carvedilol in a randomized placebo-controlled trial that enrolled 2289 patients with severe heart failure. Such patients are generally perceived to have the most difficulty being started on treatment with a beta-blocker.
Results: During the initiation and uptitration period (the first 8 weeks of the trial), the carvedilol group (CRV) had a lower instantaneous risk of death, death or hospitalization, and death, hospitalization or permanent withdrawal of double-blind treatment than the placebo group (PBO). The direction and magnitude of the effects during the first 8 weeks were similar to those observed during the entire study and were apparent even in a subgroup of high-risk patients with recent or recurrent decompensation or a very depressed ejection fraction. (Kaplan-Meier rates and Cox model hazard ratios (HR) are shown in the table below.) The differences in favor of carvedilol became apparent after 14-21 days of treatment. During the first 8 weeks, only one serious adverse event was reported with a frequency >2% (worsening heart failure), and it was reported with a similar frequency in the PBO and CRV groups (All pts: PBO 6.4% vs CRV 5.1%; high-risk pts: PBO 11.4% vs. CRV 8.8%).

		8 wk PBO rate (%)	8 wk CRV rate (%)	HR <8 wks	HR overall
All pts	Death	2.31	1.73	0.75	0.65
	Death or hospitalization	14.38	12.32	0.85	0.76
	Death, hosp. or perm. w/d	17.48	14.78	0.83	0.76
High-risk pts	Death	4.99	1.02	0.20	0.61
	Death or hospitalization	20.94	14.97	0.71	0.71
	Death, hosp. or perm. w/d	25.01	17.32	0.67	0.68

Conclusions: These findings do not support concerns about the efficacy and safety of initiating therapy with carvedilol in patients with chronic heart failure and provide the reassurance needed to encourage the high levels of use that are warranted by the results of clinical trials.

P3623 Carvedilol blunts the anti-natriuretic effect of norepinephrine in humans

C.C. Lang, R. Herman, P. Jesudason, R. Husain, W. Azman, Z. Imran, K.H. Tan, A.M. Choy. University of Malaya, Medicine, Kuala Lumpur, Malaysia

Activation of the sympathetic nervous system contribute to sodium retention in chronic heart failure (CHF). With beta-blockers use becoming more prevalent in treating CHF, the choice of drugs raises important theoretical and practical questions. The functional importance of the peripheral alpha-1-adrenergic blocking property of carvedilol has not been fully defined. In this study, we have tested the hypothesis that the alpha-1-adrenergic blocking property of carvedilol will blunt the anti-natriuretic effect of norepinephrine (NE) in humans. The effects of intravenous NE (0.075 ug/kg/min for 60 min) and carvedilol pre-treatment (25 mg bid for 7 days), alone and in combination, on urinary sodium excretion (UNaV), glomerular filtration rate (GFR) and segmental tubular function were studied in a single blind placebo-controlled cross-over 4 day study involving 8 healthy male subjects aged 25.5±0.3 years. All subjects were studied undergoing maximal water diuresis. Proximal tubular reabsorption was evaluated by estimation of the fractional excretion of lithium (FELi). NE alone decreased UNaV by 27% from 166±14 to 122±11 μmol/min ($P<0.05$) without altering GFR. FELi was increased by NE from 17±1 to 14±1% ($P<0.05$). Carvedilol pre-treatment significantly attenuated the fall in UNaV to only 10% from 146±9 to 131±10 μmol/min ($P<0.05$, placebo+NE versus carvedilol+NE). Carvedilol pre-treatment had a similar attenuating effect on the NE-induced increase in fractional reabsorption of sodium in the proximal tubule ($P<0.05$). The pressor response to NE was blunted by carvedilol pre-treatment ($P<0.05$). We have therefore shown that carvedilol is capable of blunting the anti-natriuretic effect of NE which suggests a functional importance for its alpha-1-adrenergic blocking property.

P3624 Increasing β-bockers prescription in a heart failure clinic

F. Ribeiro Santos[1], J. Silva-Cardoso[2], M. Campelo[2], B. Moura[2], C. Gavina[2], E. Martins[2], S. Amorim[2], C. Abreu-Lima[3]. [1]*Unidade I&D/Medical School, Cardiology/H.S.João, Porto, Portugal;* [2]*Department of Cardiology, Heart Failure and Transplant Clinic, Porto, Portugal;* [3]*Hospital São João, Cardiology, Porto, Portugal*

B-Blockers (BB) and ACE inhibitors are the first line therapy in systolic heart failure (HF). Some authors suggest that 80 to 85% of the patients (pts) with systolic HF should be under BB. However the use of BB in clinical practice is still much less frequent as reported in the EPICA study and in the Euroheart Survey HF. Between 1996 and the end of 2000 BB were prescribed to 42% of the pts of our HF clinic. Logistical problems were the main reason for not reaching higher levels of BB prescription.

The present study tried to evaluate if during the period of one year we could increase the level of prescription of BB by giving a particular emphasis to the implementation of current HF therapy guidelines.

During 2001 we observed 179 pts with severe HF; 24 had no indication for BB according to the European Society of Cardiology guidelines. From the remaining 155 pts 122 (79%) were on, or initiated BB. This represented a very significant increase comparing to the prescription level registered until the end of 2000 (122 (79%) out of 155 pts vs 82 (42%) out of 195 pts; $p < 0.00001$). Carvedilol was the BB used in 99 (81%) of the cases. The age of the pts on BB was 50±12 years and 84% of them were males. Left ventricular ejection fraction (EF) was 29±8%; 86 (70%) of the pts were on NYHA class II or III. Ninety eigth percent were on ACE inhibitors.

The reasons for not using BB in the remaining 33 pts were: the presence of contra-indications in 13 (39%) pts (in 9 of them they were of a non-cardiac nature), NYHA unstable class IV in 1 (3%), fluid retention in 4 (12%), bad patient compliance in 2 (6%) and logistical reasons in 13 (39%).

In the everyday conditions of an outpatient heart failure clinic of a university hospital it is possible to significantly increase the level of prescription of BB during a one year period. We reached the target suggested by others. Logistic constraints and the presence of contra-indications were the main reasons that limited an even higher prescription of BB.

P3625 Left ventricular diastolic function and coronary flow reserve in low-symptomatic patients with dilated cardiomyopathy during bisoprolol therapy

I. Jedlinski[1], R. Dankowski[2], K. Poprawski[2], M. Wierzchowiecki[2], M. Jedlińska[3], K. Zawilska[3], M. Michalski[4]. [1]*Poznan, Poland;* [2]*K.Marcinkowski Univesity of Medical Sc, 2nd Dept.of Cardilogy, Dept.of Radiolo, Poznan, Poland;* [3]*J. Strus Hospital, Internal Medicine and Hematology, Poznañ, Poland;* [4]*University of Medical Sciences, 2 nd Department of Cardiology, Poznan, Poland*

The aim of this study was to assess the degree of LV diastolic function by transthoracic Doppler echocardiography (TTE-DOPPLER) and to investigate coronary flow reserve (CFR) assessed using transoesophageal Doppler echocardiography (TEE-DOPPLER) in dilated cardiomyopathy (DC) patients (pts) treated with bisoprolol.

Material and method: The study population consisted of 19 pts (17 men), mean age 56±21 years, with DC and angiographically proven normal coronary arteries. In all pts, the LV inflow pattern at the level of the mitral anulus was assessed using TTE-DOPPLER method. The Doppler parameters: peak velocity of early diastolic LV inflow (E), peak velocity of late diastolic LV inflow (A) and E wave deceleration time (EDT) were measured at baseline. At rest and after intravenous infusion of dipyridamole (0.84 mg/kg/10 min), peak diastolic coronary flow velocities were measured in the proximal part of the left anterior descending coronary artery using TEE-DOPPLER. CFR was calculated as a ratio of maximal diastolic coronary flow velocity after dipyridamole infusion to maximal diastolic coronary flow velocity at baseline. Both examinations were performed before and 3 months after start of bisoprolol therapy.

Results: In the study group the E/A ratio after bisoprolol treatment was significantly higher compared to baseline examination 0.70 ± 0.09 versus 1.17 ± 0.2 ($p<0.05$). EDT significantly increased after bisoprolol therapy ($p<0.01$). The systolic CFR and diastolic CFR significantly enhanced after bisoprolol therapy (1.36 ± 0.16 vs 1.53 ± 0.17 -$p < 0.05$; 1.61 ± 0.17 vs 1.80 ± 0.19 - $p < 0.01$.

Conclusion: Three-months bisoprolol therapy leads to improvement of left ventricular diastolic function and coronary flow reserve in low-symptomatic pts with DC.

P3626 Carvedilol versus perindopril in idiopathic dilated cardiomyopathy

K. Sliwa[1], A. Woodiwiss[2], G. Norton[2], D. Badenhorst[2], G. Candy[3], C. Libhaber[3], R. Essop[1], P. Sareli[3]. [1]*Baragwanth Hospital, Cardiology, Johannesburg, South Africa;* [2]*University of the Witwatersrand, Physiology Dept., Johannesburg, South Africa;* [3]*Baragwanath Hospital, Cardiology Dept., Johannesburg, South Africa*

Background: Both beta-blocking agents and ACE-inhibitors are standard therapy for heart failure. To evaluate their benefit individually and in combination on symptoms and left ventricular function we designed a protocol in which patients with NYHA FC II-III idiopathic dilated cardiomyopathy were randomised at baseline to a beta-blocking agent (Carvedilol) or Ace-inhibitor (Perindopril) and after 6 months commenced on the combination. Herein we report the 6 month data (Phase I).

Methods: In this prospective, randomised, open-labelled study we enrolled 59 consecutive patients with newly diagnosed idiopathic dilated cardiomyopathy in NYHA FC II-III. Patients were randomised to maximum dose of Carvedilol or Perindopril in addition to diuretics and digoxin. Echocardiograms, radionuclide studies, and NYHA FC were determined on admission and after 6 months of treatment.

Results: There were no differences in the baseline characteristics between the study groups. After 6 months 8 patients died (4 in each group) and 4 patients did not complete the trial for non-medical reasons. Left ventricular dimensions were reduced and radionuclide ejection fraction increased in the patients treated with Carvedilol. There were no changes in the Perindopril group (table).

	P (n=24) Baseline	6 months	p	C (n=23) Baseline		p 6 months
EDD (mm)	64 (8)	63 (6)	NS	66 (7)	62 (8)	0.005
ESD (mm)	55 (7)	54 (3)	NS	58 (8)	52 (11)	0.001
EF (%)	23.9 (9)	27.6 (9)	NS	21.4 (9)	33.3 (9)	0.0008
NYHA FC	2.5 (0.9)	1.9 (0.8)	0.005	2.6 (0.7)	1.6 (0.7)	0.0005

p=baseline versus 6 months within each group; values are mean (standard deviation); P=Perindopril, C=Carvedilol

Conclusion: Carvedilol monotherapy resulted in a sustained improvement of both symptoms and left ventricular function at 6 months. These results are encouraging and may suggest a new therapeutic approach in patients with idiopathic dilated cardiomyopathy.

P3627 Geographical variation in beta-blocker, spironolactone and digitalis use in chronic heart failure

J. McMurray on behalf of the CHARM Committees and Investigators. *University of Glasgow, CRI in Heart Failure, Glasgow, United Kingdom*

Background and Methods: There is now a strong evidence base, from large randomised trials, for the treatment of low left ventricular ejection fraction (LVEF) chronic heart failure (CHF). This evidence has been summarised in new international guidelines. Consequently, geographical variation in treatment should be less prominent than previously. We have examined variation in treatment practice in the 26 participating countries in the Candesartan in Heart Failure - Assessment of Reduction in Mortality and morbidity (CHARM) programme. CHARM Added randomised 2548 ACE inhibitor treated patients with a LVEF < 0.40 to placebo or candesartan. The 26 participating countries were grouped as follows: 1. Belgium, Netherlands, France, Luxembourg 2. UK, Ireland, Australia, South Africa 3. Czech Republic, Hungary, Poland 4. Germany, Switzerland 5. Norway, Denmark, Sweden, Iceland, Finland 6. USA 7. Canada. Italy/Spain/Portugal [n=50], Malaysia/Singapore [n=59] and Russia [n=15] were excluded from this analysis, because of small numbers. The table shows treatments used in CHARM Added.

Treatment (%)	Geographical region						
	1	2	3	4	5	6	7
number of patients	280	197	219	371	403	597	357
beta-blocker	56	32	59	74	55	57	50
spironolactone	23	12	22	15	13	15	17
digitalis	33	46	59	65	44	75	66

Conclusions: While the overall use of beta-blockers in CHARM is much higher than in prior CHF studies, there is still a surprising 2-fold or greater regional variation in use of these agents. There is similar variation in the use of spironolactone. Digitalis is now used no more frequently than beta-blockers.

P3628 Limited predictive value of cardiopulmonary exercise indexes in chronic heart failure patients treated with carvedilol

U. Corrà, A. Mezzani, E. Bosimini, F. Scapellato, E. Eleuteri, P. Giannuzzi. *"S. Maugeri" Foundation - IRCCS Veruno, Cardiology, Veruno, Italy*

Peak oxygen consumption (pVO2) derived during cardiopulmonary exercise testing (CPX) is a powerful predictor of mortality in chronic heart failure (CHF). Up to now, the prognostic role of CPX in CHF cohorts treated with b-blockers has not been addressed. Therefore, we studied 508 consecutive CHF patients (pts) who performed symptom-limited CPX with a peak respiratory exchange ratio (RER) >=1.05: mean age, pVO2, the rate of increase of minute ventilation per unit of increase of carbon dioxide production (VE/VCO2 slope) and left ventricular ejection fraction (LVEF) were 59±9 years 13.9±3 ml/kg/min, 32±2 and 25±7%, respectively. Composite end-point was death due to cardiovascular disease and urgent heart transplantation. Pts were divided according to carvedilol treatment (C and noC pts): 236 C pts (46%), with a mean dose of 25±13 mgr. Follow up lasted 856±541 days and 105 pts (21%) had major composite events. Multivariate analysis revealed VE/VCO2 slope, LVEF, pVO2, and C treatment as independent and additional predictors of cardiac events in total population (χ^2=64.2, 21.3, 9.7, 7.4, all with p=0.001), VE/VCO2 slope, LVEF, and pVO2 in noC pts (χ^2=44.2, 12.3, 7.2, all with p<0.001) and only peak VO2 in C pts(χ^2=7.5, p<0.01). As regards pVO2, pts were stratified into 4 groups: pVO2 <=10 ml/kg/min., >10 to <=14 ml/kg/min, >14 to 18 ml/kg/min and >=18 ml/kg/min:in the noC, total mortality rates were 55%, 28%, 26% and 0% respectively (p<0.0001) whereas, in the C group, total mortality rates were 26%, 11%,10% and 4%, respectively (p<0.05). Notably, in the 213 C pts with pVO2 >10 ml/kg/min, no significant difference in total mortality rates according to pVO2 classification was observed and no additional outcome indexes were selected.

Conclusions: in chronic heart failure patients treated with Carvedilol, pVO2 provides limited predictive information and no additional gas exchange parameters, i.e. exertional ventilatory response, yields supplementary prognostic advice.

P3629 Restoration of baroreflexes by slow controlled breathing and beta-blockade in heart failure patients

A. Radaelli[1], P. Meregalli[1], R. Raco[1], G. Ragonesi[1], A. Viola[1], G. Signorini[2], A.U. Ferrari[3]. *[1]Div Cardioriabilitazione, Az Osp Vimercate, Seregno, Seregno, Italy; [2]Politecnico di Milano, Bioingegneria, Milano, Italy; [3]Centro Fisiologia Clinica Ipertensione, Dipt Med., Prev. e Biotecnol. Sanit., Milano, Italy*

Controlled breathing at a slow rate has been proposed as a therapeutic intervention in CHF patients because of its beneficial effects on chemoreflex function. On the other hand little information exists whether slow controlled breathing also favourably affects arterial baroreflex function, which in these patients is impaired and is associated with an adverse prognosis. Further issues that have not been clarified are whether beta-blocker treatment also potentiates the arterial baroreflex in CHF patients and whether such putative effect is additive rather than redundant to that of slow breathing. We therefore tested in CHF patients the effects of slow controlled respiration and/or chronic beta-blocker treatment on the bradycardic and depressor responses to carotid baroreceptor stimulation induced by neck suction.

In 10 CHF patients aged 60±1.4 yrs (NYHA class II-III, peak VO2 14.3±2.9 ml/min/kg, ejection fraction 31.0±1.9%), blood pressure (Finapres), RR interval (ECG) and respiration (impedance) were recorded beat-to-beat. Each patient was subjected to carotid baroreceptor stimulation by -40 mmHg neck suction obtained via a pneumatic collar and maintained for 90 sec; the stimulation was applied during spontaneous respiration as well as during slow controlled respiration (6 cycles/min). A repeat study during chronic treatment with carvedilol (25-50 mg/day) was obtained in 6 patients.

Baseline values of systolic blood pressure were 118.9±8.2 and 106.6±7.5 mmHg during spontaneous and slow breathing, respectively (p<0.01), the corresponding values of RR interval being 738±54 and 770±36 msec (p<0.05). Both the depressor and the bradycardic responses to neck suction were significantly larger during slow (-10.6±1.3 mmHg and +52.3±6.8 msec, respectively) than during spontaneous breathing (-4.7±1.6 mmHg and +28.1±6.3 msec, both p<0.01). The responses to neck suction were found to be enhanced during chronic carvedilol treatement and were even further enhanced when the carvedilol-treated patients were subjected to slow breathing (carvedilol: -10.9±3.1 mmHg, +76±9.9 msec; carvedilol+slow breathing: -17.4±2.2 mmgH, +120±26.1 msec).

In summary, in patients with CHF i) slow breathing as well as beta-blocker treatment restore the impaired arterial baroreflex function typical of this condition; ii) both the cardiac and the vascular components of the baroreflex are affected, and iii) the effect of these interventions on the baroreflex is additive so that combination of the two brings about baroreflex responses comparable to those seen in healthy subjects.

P3630 Application of carvedilol early after acute myocardial infarction prevents remodelling in patients with left ventricular dysfunction

N. Karanovic, S. Salinger, Z. Perisic, M. Randjelovic, I. Burazor. *Clinic of Cardiovascular Diseases, Clinical Center, Nis, Yugoslavia*

In order to evaluate the potential effects of carvedilol on reduction of LV mass and on LV remodelling after first myocardial infarction (AMI), sixty-five patients aged 46 ± 5 years with LV ejection fraction <45% were followed up for 6 months.

Methods: All of a.m. patients received streptokinase, aspirin and heparin in the acute phase of AMI. Thirty-one of them received carvedilol twelve hours after fibrinolysis in the initial dose of 3.125 mg twice daily and enalapril in the initial dose of 2.5 mg twice daily. The dose of carvedilol was increased to a maximum given dose of 25 mg twice daily at the end of the first month if the blood pressure was >110/80 and the heart rate was >55 beats per minute. The control group was made of 34 pts. who received only enalapril in the initial dose of 2.5 mg twice daily. In both groups the dose of enalapril was increased to a maximal given dose of 10 mg twice daily at the end of the first month. Echocardiography was performed before discharge (10 ± 2 days after admission) and at three and six months after AMI. LV wall thickness, chambre diameter, LV mass and LV ejection fraction were followed up.

Results: Systolic and diastolic blood pressures were significantly decreased at the discharge and at six months control in both groups. A significant reduction in heart rate was found in the carvedilol group in comparison at the discharge and at 6 months control (74 ± 14 vs. 65 ± 12 beats/min; p<0.001). Significant differences in heart rate between groups were also found (74 ± 14 vs. 81 ± 11; p<0.005 at discharge and 65 ± 12 vs. 74 ± 11; p<0.01 at six months control). Left ventricular non-infarcted wall thickness decreased in the carvedilol group (11.8 ± 1.2 vs. 12.5 ± 1.8 mm; p<0.01) at 6 months control. There weren't significant differences for this parameter in comparison of two groups at 6 months control. LV mass decreased both in carvedilol (275 ± 28 g vs. 245 ± 23 g; p<0.05) and in the control group (256 ± 31 g vs. 236 ± 22 g; p<0.05) at 6 months control (p=NS). LV ejection fraction increased in carvedilol group at 6 months (42 ± 5% vs. 52 ± 10%; p<0.05), while in control group we didn't find statistically significant improvement (40 ± 4 vs. 45 ± 6; p=NS).

Conclusion: Early application of carvedilol shows potential role in prevention of remodeling process in patients with LV dysfunction after AMI by decreasing the chambre diameter, reversion of LV hypertrophy and improving of LV ejection fraction.

P3631 The effects of alpha- and beta-blockade on ventilatory responses to exercise in chronic heart failure

K.K.A. Witte, S.D.R. Thackray, N.P. Nikitin, L.J. Goodge, J.G.F. Cleland, A.L. Clark. *Hull, United Kingdom*

Background: Patients with chronic heart failure complain of exercise intolerance, usually due to breathlessness and fatigue as demonstrated by a reduction in peak oxygen consumption (pVO2) during incremental exercise testing with metabolic gas exchange analysis. There is also an increased ventilatory response to exercise as shown by an increase in the slope relating ventilation (VE) to carbon dioxide (CO2) production (VE/VCO2 slope). This is strongly linked to prognosis, but the cause of this abnormal ventilatory response is not clearly understood. It might be linked to the effects of the sympathetic nervous system on skeletal muscle ergoreceptors or central chemoreceptors.

Aim: The aim of the present study was to assess the influence that short-term alpha-and beta-blockade has on the ventilatory response to exercise and symptoms of breathlessness in patients with chronic heart failure and a group of control subjects.

Methods: 11 patients with chronic heart failure and 11 control subjects underwent repeated exercise testing with metabolic gas exchange after random, double-blind administration of either an alpha blocker and placebo, a beta-blocker and a placebo, both an alpha blocker and a beta-blocker or double placebo.

Results: Patients had a significantly lower pVO2 (20.7 (4.9) v 37.6 (9.6), p<0.0001), and a steeper VE/VCO2 slope (26.5 (4.1) v 37.1 (8.2), p=0.0011), than controls. The blood pressure at rest and at peak exercise was significantly lower in both patients and controls for the tests following alpha and beta-blockade (p<0.05) and there were lower gradients of the slopes relating heart rate to oxygen consumption during the tests following beta-blocker ingestion (p<0.05). There were no significant differences in exercise time or peak ventilatory variables following beta or alpha-blocker ingestion. The pVO2, VE/VCO2 slope and tidal volume at peak exercise were not different. There was a significant reduction in VE in the first two stages of exercise following the active medication. The combination capsule produced the greatest difference (P<0.005), but the alpha- and beta- blockers alone also reduced ventilation (P<0.05). There was no difference in perceived exertion during exercise for any of the capsules.

Conclusion: Acute sympathetic inhibition can reduce ventilation during exercise in patients with heart failure and control subjects.

P3632 Prediction of cardiovascular events in the patients with heart failure on beta-blocker therapy by haemodynamic and functional capacity assessment

M. Metra[1], S. Nodari[1], E. Vizzardi[1], N. Pezzali[1], C. Giovanelli[1], E. Trussardi[1], G. Parinello[2], L. Dei Cas[1]. [1]*Chair of Cardiology, University of Brescia, Brescia, Italy;* [2]*Unit of Medical Statistics, University of Brescia, Brescia, Italy*

The prognostic value of the parameters commonly used in the patients with heart failure (HF) may be changed when they are assessed on beta-blocker (BB) therapy. One-hundred eighty-four patients with chronic HF (LVEF, 20±7%; peak VO2, 14.3±4.5 ml/k/min) were assessed by MUGA and cardiopulmonary exercise (ex) testing with invasive hemodynamic monitoring before and, in the 164 patients (89%) who survived, after 9-12 months of maintenance therapy with carvedilol (n=102; 41±17 mg/day) or metoprolol tartrate (n=62; 106±45 mg/day). Chronic BB therapy was associated with an improvement in NYHA class (from 2.68±0.56 to 2.03±0.76, p<0.00001), hemodynamic parameters and LV ejection fraction (EF) (from 20±7 to 29±13%, p<0.00001) without significant changes in peak VO2 (from 14.7±4.4 to 15.0±4.7 ml/k/min) or in the slope of minute ventilation to carbon dioxide production (VE/VCO2 slope) (40±12 to 39±12). During the 29±20 months of follow-up after the reassessment on BB therapy, 28 (18%) patients died, 16 underwent heart transplantation (Tx), 67 (41%) died or were hospitalized for cardiovascular reasons (CVhosp) and 58 (35%) died or were hospitalized for worsening HF (HFhosp). Using Cox multivariate regression analysis with the variables obtained before BB therapy, total mortality was significantly related to peak VO2 (p=0.0002) and serum creatinine (creat) (p=0.002); mortality+Tx was related to peak VO2 (p=0.002), NYHA class (p=0.004) and creat (p=0.007); mortality+CVhosp was related to peak VO2 (p=0.00005), CI (HR, 0.46; p=0.001), NYHA class (p=0.015) and atrial fibrillation (p=0.03) and mortality+HFhosp was related to peak VO2 (p<0.00001), CI (p=0.02) and LVEF (p=0.04). In contrast, when the variables obtained during BB therapy were used, total mortality was related to creat (p=0.005), VE/VCO2 slope (p=0.0086), age (p=0.027) and resting PWP (p=0.035); mortality+Tx was related to PWP (p=0.00005), VE/VCO2 slope (p=0.0003), creat (p=0.008) and NYHA class (p=0.02); mortality+CVhosp was related to NYHA class (p=0.005), PWP (p=0.007) and VE/VCO2 slope (p=0.02) and mortality+HFhosp was related to VE/VCO2 slope (HR, 1.05; p=0.004), the ischemic cause of HF (p=0.016), NYHA class (p=0.014) and LVEF (p=0.04). Thus, BB treatment may lower the prognostic value of peak VO2 and the prognosis of the patients on BB seems to be mainly related to renal function, functional class, PWP and the ventilatory response to ex.

P3633 Enoximone echocardiography for the evaluation of left ventricular contractile reserve in heart failure patients under chronic beta-blockade

S. Ghio[1], C. Constantin[1], C. Raineri[1], A. Fontana[1], C. Klersy[2], L. Monti[1], C. Campana[1], L. Tavazzi[1]. [1]*IRCCS S. Matteo Hospital, Cardiology, Pavia, Italy;* [2]*IRCCS San Matteo, Biometry, Pavia, Italy*

Background Recent studies suggest that inotropic reserve evaluated by dobutamine echocardiography is an independent predictor of survival in patients with heart failure. The inotropic response to adrenergic stimulation might be attenuated in patients receiving beta-adrenoceptor blockers. Enoximone is a positive inotropic agent that acts via selective inhibition of the cyclic adenoide monophosphate-specific phosphosdiesterase.
Objective To test the hypothesis that enoximone could represent a valid alternative for the evaluation of inotropic reserve in heart failure patients receiving chronic beta-blocker therapy.
Methods We studied 26 pts (mean age 58±10 years) with either idiopathic (n=20) or ischemic (n=6) cardiomyopathy. Mean left ventricular ejection fraction (LVEF) was 30±7%. Eleven pts were not receiving betablockers (group A); 15 pts were receiving carvedilol at the mean dose of 34 mg/day (group B). All pts underwent low-dose dobutamine and enoximone stress echocardiography in two consecutive days. Dobutamine was infused at incremental doses of 5, 10 and 15 μ/kg/min, with 10 minute steps. Enoximone was infused at the dose of 1.5 mg/kg, at the concentration of 2.3 mg/ml, over 10 minutes. Cuff blood pressure and a three lead electrocardiogram were continuously monitored; LVEF was measured and colour tissue Doppler (in 4 and 2-chamber projections) was recorded before the test and at each step of infusion. Tissue velocities were obtained by analysing off-line the mean velocity profiles at the level of the annulus (septal, lateral, inferior and anterior) and at the level of basal and medium segments of septum, lateral, inferior and anterior walls.
Results LVEF increased by a similar extent with dobutamine and enoximone in both groups (respectively +9.6 vs +8.7 units in group A and +7.5 vs +8.9 in group B, NS). Dobutamine increased tissue Doppler velocities more than enoximone in 5 out of 12 segments in group A (lateral medium, inferior annulus, inferior basal, anterior annulus and anterior basal); the two drugs had similar effects in group B. Dobutamine induced non-sustained ventricular tachycardia in 3 patients and supraventricular tachycardia in 1, while enoximone did not induce repetitive arrhythmias.
Conclusions Enoximone proved to be as potent as dobutamine in evaluating the inotropic reserve of heart failure patients receiving chronic beta-blocker therapy. The absence of arrhythmias and the major feasibility of the test makes it preferable for such purpose.

P3634 Myocardial contractile response under low dose dobutamine identifies chronic heart failure patients who take benefit from Carvedilol

P. Jourdain[1], F. funck[1], A. hagege[2], J. loiret[2], B. thebault[1], M. desnos[2]. [1]*René Dubos Hospital, Cardiology Dept., Pontoise, France;* [2]*Hopital G. Pompidou, Cardiology Dept., Paris, France*

Background: β-blockers (BB) like Carvedilol improve survival and reduce hospitalization rate in chronic heart failure (CHF) by improving left ventricular ejection fraction (LVEF). However, Carvedilol acutely reduce LVEF by pharmacologic withdrawal of adrenergic support to the failing heart. Clinical baseline data are not able to appreciate the LVEF improvement with Carvedilol. We want to see if myocardial viability, as determined by low dose dobutamine stress echocardiography (LDDSE) will predict EF improvement with Carvedilol.
Methods: 100 patients with Class II/III CHF were studied with LDDSE prior to receiving treatment with Carvedilol.. Contractile reserve was defined as a change in LVEF before and with dobutamine > 20%.LVEF was measured before introducing Carvedilol and 6 month after optimal dose reached. Group A contains patients with myocardial contractile reserve (N=59), group B patients without contractile reserve (N=41). Death or CHF hospitalization and improvement of LVEF with Carvedilol were measured in the two groups
Results: The two groups showed comparable rest LVEF, Heart rate and Arterial pressure. Patients in group A had lower BNP plasma level and higher 6 minute walk test performance.
In multivariate analysis (Age, rest LVEF, MCR, rest E/A ratio, rest Heart rate, Systolic arterial pressure, BNP plasma level, 6 minutes walk test performance), the sole existence of MCR could predict the improvement of rest LVEF under Carvedilol treatment in patients with chronic heart failure (p<0,0001). At the end of the follow up, hospitalizations and mortality is lower in group A than in group B (respectively p<0,04, p<0,01)
Conclusions: Presence of contractile reserve with low dose dobutamine stress echocardiography predicts improvement in LVEF with β-blocker therapy (Carvedilol) in patients with CHF. dobutamine stress echocardiography could help to detect patients who will take the best benefit with β-blocker therapy in term of mortality, morbidity and LVEF.

PREVALENCE AND POPULATION SURVEYS IN HEART FAILURE

P3635 Hospitalization for heart failure in the aging population. The analysis of Trieste database (1997-2000)

A. Di Lenarda[1], P. Goliani[2], M. Grella[2], G. Sabbadini[3], M. Driussi[1], G. Sinagra[1]. [1]*Ospedale Maggiore, Cardiology Department, Trieste, Italy;* [2]*Health Agency n.1, Legal Medicine, Trieste, Italy;* [3]*Institute of Geriatrics, Department of Internal Medicine, Trieste, Italy*

Background: Since 1995, the reimbursement of hospital healthcare expenditure in Italy has been based upon the so-called Diagnosis Related Groups (DRGs). The DRG 127 includes all the cases in which the main clinical diagnosis is "heart failure (HF) or shock" and, therefore, it can be used to obtain epidemiological data concerning HF. The analysis appears to be of relevant interest, since in the district of Trieste the phenomenon of progressive aging of general population is very pronounced.
Methods: In this study, we evaluated the epidemiological data and clinical outcome of patients hospitalised for DRG 127 in the district of Trieste from 1997 to 2000 (5556 hospital admissions and 69236 days of hospital stay), using the database of the regional health system.
Results: The DRG 127 accounted for 2.6% of total hospital admissions and for 4% of total days of hospital stay; moreover, it resulted the first cause of hospitalisation for medical DRGs (18%) as well as the first cause of hospitalisation and days of hospital stay for cardiovascular DRGs (27.5 and 40.5%, respectively). Seventy-two percent of patients admitted for DRG 127 was older than 75 years. In 1997, a mean of 4/1000 inhabitants of the district of Trieste were hospitalised for DRG 127 (4.6 hospital admissions and 63 days of hospital stay/1000 inhabitants). Over the four years, the number of hospital admissions for DRG 127 increased by 20.3%, the days of hospital stay by 11.1%, and the related healthcare costs by 36.7%. Most of patients (89%) were admitted in Internal or Geriatric Clinics. By using suitable corrective factors, the prevalence rate of heart failure in 1997 was estimated as 6.4‰ (<65 years: 1.8‰, 65-74 years: 10.3‰, 75-84 years: 22.3‰, >84 years: 47.4‰). Based upon the first hospital admission, the incidence rate was estimated as 2.4‰ (<65 years: 0.8‰, 65-74 years: 2.2‰, 75- 84 years: 9.3‰, >84 years: 20.4‰). In-hospital, 1, 2 and 3-year survival rates from first hospital admission for HF were, respectively, 92, 80, 68 and 56% and was significantly affected by the age of patients. The most frequent aetiology was the ischemic heart disease (IHD)(50%), followed by hypertensive (26%) and valvular (7%). IHD showed the worst prognosis (3-year survival of 44%).
Conclusions: The analysis of the hospitalisations for DRG 127 in the district of Trieste may contribute to outline the national epidemiological scenario and the healthcare demand for HF in the next decades, and may be useful to plan effective models of integrated home-hospital care for the increasing number of affected subjects.

P3636 The coronary sinus anatomy in patients with advanced heart failure – A European registry

A. Curnis[1], G. Mascioli[1], F. Bianchetti[1], P.N.W.N. Breuls[2], D. Gras[3], C. Duby[4]. [1]*Spedali Civili, Divisione di Cardiologia, Brescia, Italy;* [2]*Albert Schweitzer Ziekenhuis, Dordrecht, Netherlands;* [3]*Polyclinique St Henry, Cardiologie, Nantes, France;* [4]*Guidant, CRM, Diegem, Belgium*

Cardiac resynchronization therapy can be complicated by unusual coronary sinus (CS) anatomy.
Methods: This European registry studied the efficacy of a new series of 5 Guide Catheters (GCs) used with the endocardial EASYTRAK (EZT) over-the-wire left ventricular lead (GUIDANT, St-Paul). The clinical and anatomical parameters of the Coronary Sinus (CS) were studied within this registry.
Results: The 256 implants have been performed in 117 European centers by electrophysiologists, PTCA experts, and cardiac surgeons. All patients presented symptoms of heart failure of NYHA 3.0±0.6 with a left ventricular ejection fraction of 25±7%, and a cardiothoracic index of 57±8%. Some 80% were male and the mean age was 69 years. The CS ostium position in anterior-posterior view was in mid position for 55%, low for 39%, and high in 6% of patients. The CS ostium position in left anterior oblique incidence was 61% and 39% for proximity to the tricuspid valve, and more posterior toward the inferior vena cava, respectfully. The CS orientation is listed in the table.

CS orientation	% of patients
Horizontal	16
Steeply upwards	40
Angulation	29
Siphon	4
Early Bifurcation	7
Other	4

Conclusion: This registry has demonstrated that 85% of patients suffering from advanced heart failure have only 3 main CS orientations, and 15% of patients have another orientation.

P3637 The Euroheart failure survey: the value of the electrocardiogram in the evaluation of heart failure

N.K. Khan[1], A.A. Louis[1], R. de Silva[1], K.K.A. Witte[1], F. Follath[2], M. Komadja[3], K. Swedberg[4], J.G.F. Cleland[1] on behalf of Euroheart Failure Investigators. [1]*Academic Department of Cardiology, Hull, United Kingdom;* [2]*University Hospital, Internal Medicine, Zurich, Switzerland;* [3]*Pitie-Salpetriere, Cardiology C.H.U., Paris, France;* [4]*Sahlgrenska University Hospital Ostra, Medicine, Gothenburg, Sweden*

Background: The 12-lead ECG may be helpful as a way of excluding heart failure (HF), as a means of diagnosing its cause and to assist in making key therapeutic decisions such as the need for anticoagulation or cardiac resynchronisation.
Aims: To describe the ECG abnormalities relevant to clinical practice in an epidemiologically representative group of patients with suspected HF included in a large international survey.
Methods: In 25 countries belonging to the ESC, the EuroHeart Failure survey screened >40,000 hospital deaths and discharges from medical wards and identified >11,000 patients with suspected HF. 45% were reported to have moderate or severe left ventricular dysfunction. 14% died during 12-weeks follow-up. Copies of ECG's were requested from all patients and were read in a core laboratory (Kingston-upon-Hull) by a group of cardiologists. ECG measurements (time intervals, S&R wave height in leads V1&V6, septal q-waves) were made manually using calipers and each ECG was clinically reported.
Results: 800 ECG's have been reported so far; 5,000 will be reported by August. Clinical reporting revealed 2.9% of ECGs that were classified as normal and 38.6% classified as minor abnormalities only, whilst 31.6% had Q-waves consistent with a myocardial infarction. 67.2% of patients were in sinus rhythm, 25.8% in atrial fibrillation, 4.9% with paced rhythm and 2.1% in atrial flutter. The mean RR, PR (sinus rhythm only), QRS and QT intervals were 771 msecs, 142 msecs, 109 msecs, 378 msecs respectively. The proportion of patients with QRS >150msec, >130msec and >120msec were 9.9%, 18.3% and 24.5% respectively. 8.6% had voltage criteria for left ventricular hypertrophy.
Conclusions: This is the first large, international study of the ECG in suspected heart failure in a representative population of patients with heart failure. A normal ECG is uncommon; ECG abnormalities are common and should be an important guide to diagnosis and therapeutic decision-making.

P3638 Differences between genders in patients with heart failure

C. Montoto[1], P. Conthe[2], P. Roman[3], J. Forteza[4], J. García-Alegría[5] on behalf of Working Group on Heart Failure (Spanish Society of Internal Medicine). [1]*Gregorio Marañon, Medicina Interna, Madrid, Spain;* [2]*Hospital Gregorio Marañón, Internal Medicine, Madrid, Spain;* [3]*Hospital General de Requena, Internal Medicine, Valencia, Spain;* [4]*Hospital Son Dureta, Internal Medicine, Palma de Mallorca, Spain;* [5]*Hospital Costa del Sol, Internal Medicine, Marbella, Spain*

Elderly women with heart failure represent a high percentage of hospital admissions by this prevalent pathology. Little is known about this population, although in the past decade several studies have shown that the clinical manifestations and prognosis in women with heart failure could differ significantly from those of men. In most of recent clinical trials of medical therapy for heart failure less than 25% of patients enrolled were women.
Objective: to evaluate differences between men and women with heart failure in psycosocial factors, comorbidity, aetiology and management.
Patients and methods: This study was planned from the Working Group on Heart Failure in the Spanish Society of Internal Medicine. The registry involved 50 hospitals all over Spain. Patients suffering this pathology and admitted in Internal Medicine Departments were studied. The data were obtained checking the clinical history and interviewing the patients from October 2000 to February 2001.
Results: The sample included 2145 patients who were age-matched. The patients median age was 77,2 ±10,5 years. 57,3% were women (median age 78,8) and 42,7% were men (median age 75,12). The percentage of illiterate and low cultural level women was significantly higher than in men, as well as the number of women with impaired physical and cognitive functions. There was a high comorbidity but there were different patterns (more hypertension and diabetes for women, and chronic lung disease and chronic renal failure significantly higher in men). The aethiology was unknown in more women than in men in the group of patients older than 77 (42,3% vs 32,7%). The underlying aethiologies in women were hypertension and valvular heart disease. Echocardiography was not performed before the admission mainly in old women (62,9%women vs 55,2%men $p<0.05$) and the eyection fraction in women was significantly higher than in men. Clinicians use more loop diuretics and digoxin and less spironolactone, betablockers and ACEIs in women than in men.
Conclusion: Women hospitalized for Heart Failure in Internal Medicine Departments have a different profile than men, and they are managed in a different way in clinical practice, far from current guidelines and trials.

P3639 Sleep apnoea in chronic stable heart failure: prevalence in general cardiology practice

G. Morgan-Hughes, L. Coates, G. Haywood, P. Hughes. *South West Cardiothoracic Centre, Cardiology Department, Plymouth, United Kingdom*

Background Estimates of the prevalence of sleep disordered breathing in patients with chronic stable heart failure vary widely (40-82%). Also these estimates come from selected cases in specialist units and may not be representative. The mechanism for the overwhelming majority is central rather than obstructive apnoea. The diagnosis of central sleep apnoea confers an adverse prognosis, possibly because sleep disruption and hypoxia lead to an increase in circulating catecholamines.

Method We aimed to measure the prevalence of apparently asymptomatic sleep apnoea in patients with chronic stable heart failure in a general cardiology practice. We performed overnight oximetry on 20 consecutive patients with stable heart failure, admitted to hospital for a variety of clinical reasons. All were NYHA Class II-III and had an EF<40%. Those with known abnormal sleep patterns, BMI >30 or signs of pulmonary disease were excluded. Age range was 35 – 74 yrs, male sex predominant (80%) and aetiology IHD (60%) or idiopathic DCM (40%). All patients were taking ACE inhibitors, 80% diuretics and 60% beta-blockers. We used a mean dip rate (desaturation > 4% from baseline) of >15/hr to diagnose sleep apnoea.

Results Mean EF was 23% (SD±8) and both mean FEV1 & FVC were >80%. Overall 30% of patients had sleep apnoea, with a mean dip rate of 21.4 (SD±7) dips/hr. Patients fell into two clearly separate groups. In those with apnoea the dip rates ranged from 16 to 35/hr; in those without dip rates were uniformly below 10 (mean 4.3 (SD±2.7))dips/hr. We did not identify any correlation between Epworth (daytime sleepiness) scores (mean 10.6 (SD±2.7)) and sleep apnoea in this relatively small patient group of whom 80% were NYHA Class III.

Conclusion In general cardiology practice sleep apnoea is prevalent in heart failure patients, with no obvious evidence of sleep disordered breathing, and the diagnosis is of prognostic relevance. Evidence is accumulating that treatments for central sleep apnoea improve symptoms, cardiac function and result in a reduction in circulating catecholamines. Identification of patients for formal sleep studies using pulse oximetry is straightforward and should be considered part of non-invasive assessment.

CARDIAC ASSIST DEVICES

P3640 Predictors of survival for patients treated with aortic balloon counterpulsation (IABP)

P. Urban[1], J.T. Christenson[2], J.J. Ferguson[3], M. Cohen[4], R.J. Freedman Jr[5], M.F. Miller[6], D.L. Joseph[7] on behalf of the Benchmark investigators. *[1]La Tour Hospital, Cardiovascular Department, Meyrin-Geneva, Switzerland; [2]University Hospital, Geneva, Switzerland; [3]Texas Heart Institute, Texas Medical Center, Houston TX, United States of America; [4]MCP Hahnemann University, Cardiac Catheterization Laboratory, Philadelphia PA, United States of America; [5]Freedman Memorial Cardiology Ass., Alexandria, United States of America; [6]M.F. Miller Statistical Services, Langhorne, United States of America; [7]Datascope Corp., Fairfield, United States of America*

Patients treated with IABP represent a selected high risk subset. We used multivariate logistic regression to analyse the prospectively collected data in the international Benchmark registry. The major predictors of in-hospital mortality for 21102 patients treated with IABP in 243 institutions between 1997 and 2001 were assessed, and are listed in the table. 13801 patients underwent cardiac surgery (mortality 18.9%), 5155 percutaneous coronary intervention (mortality 18.6%) and 2146 were treated medically (mortality 32.9%).

Odds ratio for major mortality predictors (95% CI)

	surgery	PCI	Medical
age > 75	1.5 (1.4-1.7)	2.2 (1.8-2.6)	2.0 (1.6-2.6)
previous CABG	1.8 (1.6-2-6)	0.8 (0.6-1.0)	1.0 (0.7-1.3)
cardiogenic shock	2.8 (2.5-3.1)	2.7 (2.3-3.1)	2.6 (2.2-3.1)
periph vasc. disease	1.5 (1.3-1.7)	1.4 (1.1-1.8)	1.3 (0.9-1.8)
unstable angina	0.4 (0.4-0.5)	0.5 (0.3-0.6)	0.5 (0.4-0.6)
LVEF < 30%	1.2 (1.0-1.3)	1.5 (1.2-1.9)	1.6 (1.2-2.2)
3 vessel disease	0.7 (0.6-0.8)	1.6 (1.4-1.9)	1.1 (0.9-1.4)
wean from bypass	1.6 (1.5-1.8)	-	-
preoperative IABP	0.5 (0.5-0.6)	-	-
IABP later than 5 days after admission	1.6 (1.4-1.7)	1.3 (1.0-1.8)	1.7 (1.2-2.3)
non-US institution	1.2 (1.0-1.3)	1.6 (1.3-2.1)	1.9 (1.4-2.6)

The model had a concordance of 74.9%, 78.6%, and 74.3% respectively for the three treatment categories.

Hospital mortality in patients treated with IABP was markedly higher when no intervention was performed. Several baseline clinical characteristics, as well as IABP timing relative to hospital admission and surgical intervention were identified as in-hospital mortality predictors. For some of these, there were major differences according to the mode of therapy that was chosen.

P3641 Superior outcome of ambulatory care versus hospitalization in patients on mechanical circulatory support

T. Drews, M. Jurmann, Y. Weng, M. Pasic, C. Wendelmuth, R. Hetzer. *Deutsches Herzzentrum Berlin, Abt. für Herz- und Thoraxchirurgie, Berlin, Germany*

Anticipating the increased necessity of long-term mechanical circulatory support (MCS), a policy to discharge patients home was introduced at our institution in 1996. This concept was followed for patients with intact psychological, social and family situation after full peripheral organ restitution. The study compares the results of these outpatients with MCS to those of a group of patients remaining hospitalized for non-medical reasons.

We report our 10-year experience with 108 patients on MCS, who were supported for more than 3 months. Group A consisted of 38 patients (25 Novacor, 13 Berlin Heart), with assist implantation from 1996 to 2001. They had a mean support time of 454 days (range 100-1074 days) and spent 326 days (range 20-769 days) at home. Group B consisted of 70 patients (24 Novacor, 46 Berlin Heart), with assist implantation between 1991 and 2000. They had a mean support time of 234 days (range 95-795 days) and were not discharged from hospital for psychological, social and familial or non-medical reasons. Complications, hospital readmissions, causes of death including infections and thromboembolic and bleeding events were recorded.

In group A total mortality was 16% (6/38). Two patients died from cerebral embolism, one from cerebral hemorrhage, two from systemic infection and one from multiorgan failure.

Thirty-two patients (84%) required 95 readmissions to the hospital (cerebral embolism (n=9), bleeding (n=1), wound infections (n=23), coagulation disorder (n=13), for heart transplantation (n=5) and non-cardiac causes (n=44)). There were no deaths related to device failure and only four patients had to be readmitted due to a minor MCS problem.

In Group B the mortality was higher at 43% (30/70; p=0.004 vs. Group A). This was largely attributed to the higher rate of infections (n=14; p=0.04 vs. Group A). Other causes of death were cerebral embolism (n=5), cerebral hemorrhage (n=7), and multiorgan failure (n=4).

In our experience ambulatory care of MCS patients proved advantageous in terms of mortality and incidence of infections. Ambulatory care has proven to be a safe therapeutic concept ensuring increased mobility and quality of life for patients on MCS and a reduction of the cost of treatment.

P3642 First use of the Orqis™ Medical Cancion™ Cardiac Recovery System (CRS) for heart falure therapy

A. Wasler[1], B. Radovancevic[2], M. Tripolt[1], F. Fruhwald[3], M. Schweiger[1], W. Klein[3], K.H. Tscheliessnigg[1]. *[1]University of Graz - LKH, Div.of Transplantation, Graz, Austria; [2]Texas Heart Institute, Houston, United States of America; [3]University of Graz, Dep. of Cardiology, Graz, Austria*

A new concept of mechanical unloading the heart has been invented to effectively decrease LVEDP, LVEDD, PCWP. A pilot clinical trial has been initiated in Austria. We report from the first clinical use of the Orqis™ Medical Cancion™ CRS

Methods: The CRS is connected to circulation via a graft cannula anastomosed to the left axillary artery and a percutaneous cannula placed into the left common femoral artery. Using a centrifugal pump, flow is initiated from the femoral to the axillary artery.

Results: A sixty-four year-old patient with chronic congestive heart failure, renal insufficiency, awaiting heart transplantation was admitted due to worsening symptoms. He was placed on dobutamine 16 μ/kg/min without obvious signs of improvement. Cardiac catheterization showed PCWP of 28 mmHg, CI 1.5 l/min/m^2. He had signs of worsening renal function with a BUN of 50 and a creatinine of 1.9 mg/dL. CRS was implanted and the patient was supported for 3 days. The system was electively explanted. There was a dramatic decrease in PCWP, LVDD and creatinine, as well as an increase in CI and EF, with maintaining low flows of 1.3-1.9 l/min.

		baseline	8h	24h	72h	24h post expl.	35 days post explant
PCWP	mmHg	28	22	10	9	7	7
CI	L/min/m^2	1,5	3,2	2	2,7	2,4	1,83
ABPm	mmHg	65	69	66	67	62	67
BUN	mg/dl	50	-	29	30	48	47
Cr	mg/dl	1,9	-	1,1	1,1	1,1	0,9
EF	%	25	35	n/a	n/a	n/a	30
LVEDD	cm	6,78	6,16	n/a	n/a	n/a	6,6

Conclusion: In this first patient the Orqis™ Medical Cancion™ CRS seems to be an effective system to quickly improve hemodynamics. Due to it's advantages such as easy and fast application of mechanical circulatory support this system may become an excellent short-term alternative for high-dose inotrop therapy. Additionally, it's application may delay applications of more invasive forms of mechanical circulatory support.

P3643 Ventricular tachyarrhythmias in patients with ventricular assist devices as prognostic indicator for survival

B.K. Kantharia[1], F. Padder[2], F. Samuels[2], T. Padder[2], S. Kutalek[2], E. Holmes[3], J. Entwistle[3], L. Samuels[3]. [1]Division of Cardia Electrophysiology, Department of Cardiology, Philadelphia, United States of America; [2]MCP Hahnemann University, Cardiology, Philadelphia, PA, United States of America; [3]MC P- Hahnemann University Hospital, Division of Cardiac Surgery, Philadelphia, United States of America

Background: Ventricular tachyarrhythmias (VT) are associated with ventricular assist devices (VAD). The presence of VT has important implications in management and prognosis. This report is aimed to describe the association between VT and VADs and clinical outcome.
Methods: A study comprising of review of records of patients (pts) with VADs, for the presence of VT, indication for VAD support, and outcome was performed. Three commercially available VADs: Novacor (Worldheart, Inc., Ottawa, Ontario), Heartmate (Thoratec Corp., Pleasonton, CA), and BVS 5000 (Abiomed, Inc., Danvers, MA) were used. The indication for Novacor and Heartmate insertion was a bridge to transplantation in pts with chronic heart failure and that for BVS 5000 insertion was acute refractory cardiogenic shock. The pts with Novacor and Heartmate devices were included in Group A and those with BVS devices in Group B.
Results: A total of 98 pts underwent VAD insertion between 1993 and 2001. Group A (n = 43), included 27 pts with Novacor, and 16 pts with Heartmate VADs and Group B included 55 pts with BVS VADs. In this cohort, 88 (90%) pts had VT, 66 (75%) with non-sustained VT and 22 (25%) with sustained VT. In Group A, preexisting VT was present in 22 (51%) pts, all treated with anti-arrhythmics and/or ICDs, and 10 pts developed VT following LVAD insertion, requiring anti-arrhythmics in all and ICD implantation in 3 pts. In Group B, 44 pts (80%) had VT, all requiring anti-arrhythmics and none received ICD. Of the 22 pts with sustained VT, 15 pts (68%) (5 in Group A and 10 in Group B), required insertion of a right ventricular assist device (RVAD). None of these pts survived. Eighty percent of pts in Group A compared to only 40% in Group B were discharged home following either native cardiac recovery or transplantation.
Conclusions: (1) VT is present in the majority of patients who require LVAD implantation. (2) Following LVAD implantation, the presence of sustained VT needing RVAD support is associated with a poor prognosis. (3) Prognosis of patients with acute refractory cardiogenic shock is very poor despite LVAD support.

P3644 Clenbuterol structural, functional and molecular changes in a large animal model: relevance to usage of left ventricular assist devices

J.K.F. Hon[1], P. Steendijk[2], P. Morrison[1], N. Latif[3], M. Koban[1], M. Kemp[4], E. Birks[3], M.H. Yacoub[1]. [1]National Heart and Lung Institute, Cardiothoracic Surgery, London, United Kingdom; [2]Leiden University Medical Centre, Leiden, Netherlands; [3]Harefield Hospital, Cardiothoracic Surgery Dept., Harefield, United Kingdom; [4]Royal Brompton Hospital, Chemical Pathology, London, United Kingdom

Background: - Chronic hemodynamic off-loading with left ventricular assist devices (LVAD) is associated with regression of pathological hypertrophy. We have previously shown that clenbuterol (Clen), a beta2-adrenoceptor agonist stimulates 'physiological' myocardial hypertrophy in rodents and are exploring its potential as a novel strategy to maximize the efficacy of LVAD as a bridge to recovery. This study aims at evaluating the functional, morphological and molecular features of clen induced myocardial growth in a large animal model.
Methods: - 14 sheep were randomly assigned to treatment with either saline (n=7) or clen (n=7) for 6 weeks. Right ventricular (RV) pressure-volume loops were obtained before and after treatment, using micromanometer-conductance catheters. RV tissues were harvested at final assessment for: 1) Morphometric analysis of fibrous tissue. 2) Quantification of sarcoplasmic reticulum Ca^{2+}-ATPase 2A (SERCA 2A), phospholamban (PLB), sodium/calcium exchanger (NCX) and apoptotic markers by Western Blot. 3) MMP-2 and -9 activities by gelatin zymography. Serum samples were collected at final assessment for measurement of matrix metalloproteinase-1 (MMP-1), tissue inhibitor of metalloproteinases-1 (TIMP-1) and MMP-1/TIMP-1 complex.
Results: - RV wall thickness and heart weight were significantly greater in the clen treated animals. Systolic function was higher in the clen treated animals associated with a reduction in fibrous tissue in the myocardium. However, there was no significant difference in the myocardial protein expression of SERCA 2A, PLB, NCX, Bcl-2 family of proteins and caspases 3, 8 and 9. The MMP-2 and -9 activities and serum levels of free MMP-1 and TIMP-1 were also not different between the two groups.
Conclusion: - Clen produces 'physiological' cardiac growth. This supports its usage to maximize the efficacy of LVAD as a bridge to recovery.

P3645 S100A1: a marker for successful transformation of circulatory assist skeletal muscle ventricles (SMV's) for the failing heart

P. Most[1], N.W. Guldner[2], P. Ehlermann[1], P. Klapproth[2], H.H. Sievers[2], H.A. Katus[1], A. Remppis[1]. [1]University of Luebeck, Internal Medicine II, Luebeck; [2]Clinic for Cardiac Surgery, University of Lübeck, Lübeck, Germany

Background: Biomechanical circulatory assist devices like autologous skeletal muscle ventricles (SMV's) have been considered as an attractive alternative treatment of chronic heart failure. Despite the profound loss of mechanical performance that occurs after exlusive electrical conditioning, recent advances in adaptation of SMV's to hemodynamic load by systemic pharmacological and dynamic-training interventions dramatically enhanced their mechanical performance (Biomechanical Hearts (2001), Guldner et al., Circulation 104). As Ca^{2+} cycling governs contraction we sought to explorate the molecular alterations underlying succssesful skeletal muscle transformation in SMV's by investigating the putative shift in the expression pattern of proteins that are involved in intracellular Ca^{2+} handling and contraction.
Methods/Results: In adult goats, SMV's were constructed as biomechanical hearts (BMH) from latissimus dorsi (M.lat.dorsi.) to pump volume against systemic load in intact circulation. Dynamic adaptation of SMV's was supported by combined dynamic training under electrical stimulation and systemic clenbuterol administration (50 μg/d). Samples of M. lat. dorsi from six goats were taken both prior to SMV construction (day 0) and at termination of experiments while samples from the contralateral M.lat.dorsi served as temporal controls. Western-Blot experiments from homogenates were carried out to investigate the expression levels of S100A1, SERCA2, SERCA1, PLB, cardiac and skeletal muscle actin. The most prominent shift in protein expression from day 0 to SMV and contralateral control at termination was found for the non-fatigue muscle specific Ca^{+} binding protein S100A1 (+29.5±7.1-fold, $P<0.01$, n=6) beside upregulation of SERCA2a (+5.2±1.3-fold, $P<0.01$, n=6), PLB (+2.7±0.9-fold, $P<0.03$, n=6) and cardiac-actin. In contrast, SERCA1 (-8.5±2.4-fold, $P<0.05$, n=6)and skeletal muscle actin was found to be significantly downregulated in SMV's compared to control.
Conclusion: Our results suggest that advanced dynamic and pharmacological training of fast skeletal muscle (Typ II) to BMH is based on the transdifferentiation into non-fatigue skeletal muscle (Typ I) as indicated by the shift in Ca^{2+} sensing and Ca^{2+} cycling proteins. Among these alterations most prominent changes occurred in S100A1 protein expression that might be therefore considered as an interesting marker for successful BMH generation.

P3646 Third generation of mechanical cardiac assist systems as long-term supporting devices for patients with heart failure

J. Mueller[1], Y. Weng[1], P. Nuesser[2], P. Goettel[2], A. Arndt[2], A. Kilic[2], H. Buchholz[2], R. Hetzer[1]. [1]Deutsches Herzentrum Berlin, Cardiac Surgery Dept., Berlin, Germany; [2]Berlin Heart AG, Berlin, Germany

Although there has been progress in the technique of pulsatile implantable ventricular cardiac assist devices (VAD) within the last 15 years they are still bulky (> 600 ml) and heavy (> 600 g) and therefore carry an inherent risk for complications. Pulsatile axial flow pumps of the latest generation are small (< 100 ml) and light (< 200 g). In an industrial joint venture an axial flow pump (INCOR) for long-term application (years) was developed. Due to magnetic levitation of the spinning rotor this device has no mechanical friction and therefore no wear at all (1), changes of the rotational speed of the rotor within one cardiac cycle create a pulsatility that is comparable to the physiological pulsating flow of the native heart (2), and the flow of the pump automatically adapts to the patient's need (3).
The VAD was evaluated in 14 calves to test hemolysis and thrombogenicity in short- and long-term observation. Five of the animals died within 12 hours after placement due to persistent ductus Botalli which was not anticipated and therefore overlooked in the first animals. One animal died due to slip-off of the outflow cannula which was only insufficiently connected to the pump. Six animals were euthanized after 40 days of support due to the requirements of the European approval authorities. One animal was euthanized after 150 days of support and one is still on the device (> 200 days). Clinically, no signs which could have been related to thromboembolic events were observed. Mean flow and power consumption were constant over the whole observation period. Plasma free hemoglobin was slightly elevated for a period of 1 week after operation, as was LDH. Both parameters normalized thereafter and remained constant. Fibrin degradation products did not show any increase. Creatinine and urea were normal at the time of placement and remained in the normal range. At explantation no thrombus deposit inside the cannulas or the pump was found. However, at the inflow site of one pump some fibrin deposits were seen which were related to poor polishing of the titanium surface. Additionally, in one of the calves' kidneys signs of a thromboembolic event could be seen. No further biological abnormalities could be detected during this pre-clinical trial. With regard to the pump, no pump stop or malfunction of the pump could be observed. The overall test results of this axial-flow blood pump are very encouraging. They have to be confirmed in a clinical trial which will start in March 2002.

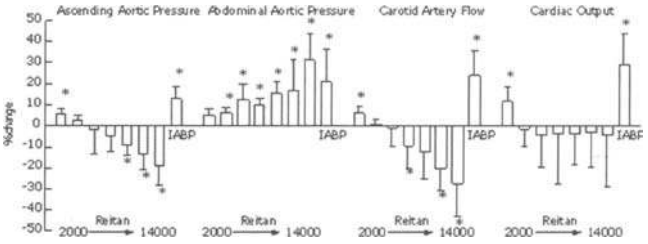
P3647 Comparison of IABP and the new Jomed Reitan catheter pump in acute mitral regurgitation

A.L.A.J. Dekker[1], K.D. Reesink[1], F.H. van der Veen[1], G.V.A. van Ommen[2], G.G. Geskes[1], A.C.M. Soemers[1], J.G. Maessen[1]. [1]*Academic Hospital Maastricht, Dept. of Cardiothoracic Surgery, Maastricht, Netherlands;* [2]*Academic Hospital Maastricht, Dept. of Cardiology, Maastricht, Netherlands*

Background The Jomed Reitan Catheter Pump (RCP) is a new, minimal invasive, propeller based intra aortic device, designed to reduce left ventricular afterload. In this study the RCP was tested, placed in the high descending aorta, and compared to IABP in an acute mitral regurgitation (MR) animal model.

Methods In nine calves acute MR was created by placing a steel wire cage in the mitral valve. The RCP was tested at 2000 to 14000 rpm and compared to 1:1 IABP support. Cardiac output, coronary blood flow, carotid artery flow, ascending and abdominal aortic pressure, left atrial pressure and LV pressure-volume loops were recorded.

Results The RCP caused a large reduction in afterload (-28%, p<.001) at 14000 rpm. In the mean time, preload decreased (-20%, p<.001) and cardiac output remained the same. PV-loops shifted leftward and reduced in size, suggesting acute LV remodeling and a reduction in stroke work. The RCP redistributed blood from the upper to the lower body as seen by a reduction in carotid artery flow (-28%, p=.002) and an increase in mean abdominal aortic pressure (+32%, p<.001) (see Figure). The IABP increased cardiac output (+30%, p=.005), carotid flow and aortic pressure (see figure).



Mean perc. change in hemodynamics.

Conclusions The RCP is a very powerful afterload reducing device. In this acute MR animal model, it favored blood flow distally from the device and remodeled the left ventricle, but left out positive effects on cardiac output. Further research activities are planned to test the RCP in other aortic positions and types of heart failure, such as ischemic failure.

P3648 First prolonged use of the Thoratec heart mate II left ventricular assist device as a bridge to recovery

M.H. Yacoub[1], E. Birks[1], P.D. Tansley[1], C.T. Bowles[1], N.R. Banner[2], A. Khaghani[1], A.G. Mitchell[2]. [1]*Harefield Hospital, Cardiothoracic Surgery Dept., Harefield, United Kingdom;* [2]*Royal Brompton and Harefield Hospital, Department of Cardiology, London, United Kingdom*

The Heart mate II is an impellar pump capable of providing full circulatory support and virtually complete unloading of the left ventricle (LV) with flows of up to 10 L/min, making it possibly an ideal tool for bridge to recovery. However, to date, experience with prolonged use of the device, its effect on the heart and target organs, effect of lack of pulsatility and the type of antithrombotic therapy has been unknown. We describe our experience with the use of the device in a 41 year old man with a 4 month history of rapidly deteriorating heart failure due to idiopathic dilated cardiomyopathy. At the time of implantation the patient had a cardiac index of 1.7 L/min/m^2, PCWP of 33mmHg, with deteriorating renal and hepatic function. The device was placed behind the left costal margin without opening the peritoneum. The patient was weaned off CP bypass without difficulty. In the post-operative period the device maintained an output of 4-7L with the mean RPMs varying from 9-11000. Arterial pressure was 70mmHg with a flat trace. Kidney function improved immediately. Antiplatelet and antithrombotic therapy, which included aspirin and low molecular weight heparin, were started on the 2nd day, long term Warfarin was not used. There were no thromboembolic complications during the 160 days on the device. Initially, the pump was run in the automatic mode, which produced flows in excess of 7L and was occasionally associated with collapse of the left ventricle and multiple ventricular ectopics and runs of ventricular tachycardia. This responded to running the pump in the fixed mode. The patient was treated by additional pharmacologic therapy to induce reverse remodelling, followed by physiologic hypertrophy as part of the Harefield recovery protocol. The criteria for explantation were met significantly earlier than in patients receiving the Heart Mate I device. Following explantation, the patient made a smooth recovery and is being followed up, with evidence of maintained LV recovery to date. It is concluded that the Heart Mate II is a promising clinical tool, particularly for recovery.

THERAPEUTIC INTERVENTIONS FOR HEART FAILURE

P3649 Possible role of nitric oxide (NO) in preserving pulmonary diffusion capacity for carbon oxide (DLco) in heart failure (HF) patients

D. Andreini, M. Bussotti, A. Magini, A. Moraschi, P.G. Agostoni. *Centro Cardiologico Monzino, FPCR, MILANO, Italy*

Diffusion capacity of alveolar-capillary membrane (clinically expressed as diffusion for carbon monoxide) is impaired in HF patients. During exercise, DLCO can improve, through an increase of capillary volume (Vc), that is blood volume participating to lung gases exchange. Previous observations show that also membrane diffusion (Dm), the other subcomponent of DLCO, can increase during effort. We hypothesized involvement of NO in vasodilatation of pulmonary capillaries (determining increase of Vc), but also in increasing permeability of alveolar-capillary membrane to gases (determining increase of Dm).

For this aim, we evaluated 20 patients affected by heart failure (19 males; age: 62.7 ± 9.2 years; ejection fraction: 33.8 ± 8.3%; NYHA class: 1.7 ± 0.7; Minnesota score: 27.5 ± 20.4), in stable clinical conditions. They underwent to respiratory function tests, maximal cardiopulmonary test and measurement, at rest and during submaximal constant workload exercise, of DLCO and exhaled NO. These results were compared with data of 10 normal subjects (10 males, age: 61.8 ± 6.7; Minnesota score: 5.6 ± 6.0). In HF patients DLCO (impaired at rest, 74.9 ± 17.6% of predicted value) significantly increases during effort, as Vc does. Baseline value of Vc and its increase during effort correlate with exercise induced increase of DLCO. NO values, both at rest and during effort, do not correlate with DLCO and its subcomponents changes, nor with peak VO2.

However a correlation (r = 0.379; p = 0.003) was found between NO and DLCO, when all values (controls and patients at rest and during effort) were considered. A similar correlation was also found between NO and DM values (r = 0.375; p = 0.004).

	HF Patients Rest	HF patients Exercise	Controls Rest	Controls Exercise
DLCO	20.0 ± 4.4	21.9 ± 4.9*	26.1 ± 4.4	27.6 ± 4.3*
Vc	92.0 ± 41.3	109.6 ± 41.0*	104.7 ± 26.6	113.0 ± 19.5
DM	31.5 ± 11.1	31.2 ± 9.1	39.9 ± 6.9	41.7 ± 10.0
NO	10.9 ± 5.5	10.4 ± 4.8	15.7 ± 5.6	13.3 ± 4.6*

* = p < 0.05

These data can support the hypothesis of an active role of NO in preserving DLCO and its physiological increase during effort.

P3650 Serum magnesium concentration tends to increase slightly in response to dosages of the loop diuretic torasemide that are used in heart failure

A.J. Reyes[1], W.P. Leary[2], R.D. Espinas[3]. [1]*Institute of Cardiovascular Theory, Montevideo, Uruguay;* [2]*University College, Dept. of Pharmacology and Therapeutics, Cork, Ireland;* [3]*Institute of Cardiovascular Theory, Montevideo, Uruguay*

Background: In the nephron, most filtered magnesium (Mg) is reabsorbed in the proximal tubule (PT) and in the loop of Henle (LH). Loop diuretics block reabsorptions in the LH and, with the exception of torasemide (T), also interfere with reabsorptions in the PT. Furosemide (Fur) increases magnesiuresis and usually reduces serum Mg concentration (SMg) in patients with heart failure (HF) and unimpaired renal function. The objective of this study was to evaluate formally the response of SMg to T.
Methods: Sixteen healthy subjects (age range: 19-26) in a metabolic unit took oral doses of placebo (Pla) and of T 2.5, 5 and 10 mg, at 08.00 hours once daily (od), during four separate single-treatment periods of 7 days each. The design was crossover, individually randomised and double-blind. Data are presented as mean ± SD.
Results: Just before and 1.5, 6 and 24 h after administration of Pla on day 1, SMg was 0.78 ± 0.04, 0.78 ± 0.05, 0.79 ± 0.04 and 0.80 ± 0.05 mmol/L; corresponding day-7 values, which did not differ from day-1 values (paired t test), were 0.77 ± 0.05, 0.78 ± 0.05, 0.79 ± 0.06 and 0.79 ± 0.06 mmol/L. Just before and 1.5, 6 and 24 h after dosing with 2.5 mg T on day 1, SMg was 0.77 ± 0.04, 0.78 ± 0.05, 0.79 ± 0.05 and 0.79 ± 0.04 mmol/L, and it was 0.80 ± 0.05, 0.78 ± 0.04, 0.79 ± 0.06 and 0.79 ± 0.04 mmol/L on day 7; corresponding day-7 and day-1 mean values did not differ. SMg was 0.78 ± 0.04, 0.77 ± 0.04, 0.75 ± 0.04 and 0.81 ± 0.05 mmol/L just before and 1.5, 6 and 24 h after dosing with 5 mg T on day 1; on day 7 it was 0.80 ± 0.03 ($p < 0.05$ vs. day 1), 0.77 ± 0.05, 0.80 ± 0.06 ($p < 0.01$ vs. day 1) and 0.82 ± 0.06 mmol/L. Just before and 1.5, 6 and 24 h after dosing with 10 mg T on day 1, SMg was 0.78 ± 0.06, 0.77 ± 0.06, 0.76 ± 0.05 and 0.81 ± 0.04 mmol/L; corresponding day-7 values were 0.82 ± 0.06 ($p < 0.01$ vs. day 1), 0.78 ± 0.05, 0.80 ± 0.05 ($p < 0.01$ vs. day 1) and 0.82 ± 0.05 mmol/L. At 08.00 hours on day 7, SMg was higher during treatment with T 10 mg than with Pla (ANOVA for repeated measures: $p < 0.01$; Dunnett's test: $p < 0.01$).
Conclusions: The small rises in SMg in response to T 5 and 10 mg od are consistent with a previous finding in patients with HF. In a similar study in healthy subjects, SMg fell after one week of treatment with 40 mg Fur od. All loop diuretics tend to elevate calciuresis and thus raise parathyroid hormone (PTH), which increases SMg. This rise in PTH could explain the small increase in SMg caused by T, given that T blocks Mg reabsorption in the LH but not in the PT. These results may well be of therapeutic importance.

P3651 Effects of the α1-adrenoceptor antagonist doxazosin on the cardiac index in patients with chronic congestive heart failure

A. G. Kieback[1], O. Rödiger[1], H. Jaenecke[1], A. Grohmann[1], G. Baumann[1], K.-D. Wernecke[2], S.B. Felix[3]. [1]*Charité, Humboldt-Universität Berlin, Klinik für Innere Medizin, Berlin, Germany;* [2]*Institut für medizinische Biometrie, Charité, Humboldt-Universität Berlin, Berlin, Germany;* [3]*Ernst-Moritz-Arndt-Univers. Greifswald, Klinik für Innere Medizin, Greifswald, Germany*

Background Nonselective alpha-adrenoceptor antagonists have not demonstrated significant beneficial effects in chronic heart failure. We examined the effects of the selective alpha1-adrenoceptor antagonist doxazosin on the cardiac index in patients with chronic congestive heart failure.
Methods Our double-blind, randomized trial was conducted on 30 patients with chronic congestive heart failure (NYHA III-IV), with cardiac index < 2.5 l/min x m^2, and/or with pulmonary capillary wedge pressure > 16 mmHg. We treated 15 patients with doxazosin and 15 with placebos, adjuvant to standard oral therapy, which included a minimum of an ACE inhibitor and a diuretic. Hemodynamic measurements were performed on days 1 and 2, and after 12 weeks on study medication. On day 1, patients were treated with 4 mg doxazosin versus placebo. On day 2 and the following 12 weeks, the patients were treated with 4 mg or 8 mg doxazosin/day (the latter, if 4 mg/day did not induce significant hemodynamic changes) versus placebo. Statistical analysis was performed using non-parametric rank variance analysis for longitudinal data. Differences between independent and dependent groups were determined by the Mann-Whitney U-test and the Wilcoxon test, respectively. Dichotomous variables were analyzed by the exact chi-square test.
Results Six patients were treated with 4 mg doxazosin/day, 9 patients with 8 mg doxazosin/day, and 15 with placebo. Baseline values for the cardiac index failed to disclose significant differences between patient groups and between the days of study. The maximum value for the cardiac index was 3.5 l/min x m^2 in the 4 mg doxazosin group, 2.6 l/min x m^2 in the 8 mg doxazosin group, and 2.6 l/min x m^2 in the placebo group. The increase in cardiac index compared to baseline was significantly higher in the 4 mg doxazosin group than in the placebo group ($p = 0.046$). Between the 8 mg doxazosin group and the placebo patients there was no significant difference ($p = 0.695$).
Conclusion Oral application of doxazosin supplementary to previous medication resulted in significant increase in cardiac index only in a minority of patients. Sixty percent of those receiving doxazosin were non-responders.

P3652 C-reactive protein predicts improved systolic performance in patients with idiopathic dilated cardiomyopathy treated with pentoxifylline

K. Sliwa[1], A. Woodiwiss[2], F. Zhanje[3], R. Motara[3], C. Libhaber[3], G. Norton[2], D. Skudicky[3], P. Sareli[3]. [1]*Baragwanth Hospital, Cardiology, Johannesburg, South Africa;* [2]*University of the Witwatersrand, Physiology Dept., Johannesburg, South Africa;* [3]*Baragwanath Hospital, Cardiology Dept., Johannesburg, South Africa*

Background: The acute phase protein C-reactive protein (CRP) was found to be elevated in acute cardiac decompensation and is associated with adverse prognosis in patients with idiopathic dilated cardiomyopathy (IDC). It is not known whether elevation of this inflammatory mediator at baseline can predict the response to Pentoxifylline (PTX; a drug known to modulate cytokines as TNF-alpha, IL-6, IL-10 and Fas/Apo-1).
Methods: In the present study, we combined the results of two prospective, randomised, double blind placebo-controlled trials in patients with IDC. In the 1st study, patients in the placebo arm were treated with diuretics, digoxin and ACE-inhibitors, and in the 2nd study carvedilol was added to this placebo therapy. The treatment arm in both studies received PTX 400 mg TDS in addition to the respective placebo therapy. Patients were treated for 6 months. Cardiac dimensions and function was determined by echocardiography and from radionuclide studies. TNF-alpha plasma concentrations were determined at baseline and after treatment. CRP was measured at baseline.
Results: There were no differences in baseline characteristics between the 45 patients in the treatment group and the 43 patients in the placebo arm. Thirteen patients died (9 in the placebo group, p=0.058 between groups). The PTX treated patients had a significant increase in ejection fraction (22.2±9% to 33.1±15%, $p<0.0001$) and a significant decline in the TNF-alpha plasma levels (7.5±5.6 pg/ml to 2.1±1.5 pg/ml) wheras no significant changes occurred in the placebo group.
Fifteen of the PTX treated patients improved their ejection fraction by more than 10 absolute units. These patients had a significantly higher CRP at baseline (14.2±6.2 mg/l) compared to the patients that did not improve on PTX (n=26; 7.2±4.5 mg/l;$p<0.0004$). There was a significant association between CRP>10 mg/l and TNF-alpha >5 pg/ml ($p<0.0005$).
Multiregression analysis showed that CRP >10 mg/l is an independent predictor of the ejection fraction after 6 months of therapy with PTX (r=0.30;p=0.039).
Conclusion: In patients with IDC, baseline levels of CRP may identify a group of patients with a better response to treatment with pentoxifylline.

P3653 Short-term haemodynamic effects of levosimendan versus prostaglandin E1 in refractory, decompensated chronic heart failure patients

R. Berger, M. Huelsmann, A. Bojic, R. Pacher. *University of Vienna, General Hospital, Dpt of Cardiology, Vienna, Austria*

Background: We compared the hemodynamic effect of 24 hours infusion of the balanced vasodilator prostaglandin E1 (PGE1) with the inodilator levosimendan in refractory, decompensated chronic heart failure patients.
Methods: 17 patients (LVEF <25%) in NYHA class IV despite optimized therapy with high dose RAAS antagonists (100%), beta-blockade (82%) and furosemide (mean dose 74±49 mg/day) were randomized to low dose 24 hours PGE1-infusion (low dose: 2,5 ng/kg/min.; n=8) or levosimendan (10 minutes bolus: 12 µg/kg/min. followed by 0,1 µg/kg/min.; n=9). Hemodynamic evaluation with right heart catheterization was performed at baseline and after 24 hours.
Results: At baseline, mean values of heart rate (69±13/min.), RR mean (73±14 mmHg), CVD (10±6 mmHg), PAP mean (35±9 mmHg), PCWP (24±6 mmHg), CI (1,7±0,2 l/min.m^2), SVR (1527±406 dyn.sec/cm5) and PVR (267±131 dyn.sec/cm5) were comparable in both groups. After 24 hours, patients with levosimendan showed a significant decrease of PAP mean (from 37±9 to 32±6; p=0.03) and PCWP (from 25±6 to 21±6; p=0.05) and a significant increase of CI (from 1,7±0,3 to 2,2±0,6; p=0.0005) resulting in a significant decrease of SVR (from 1374±354 to 1071±287; p=0.03). Patients treated with PGE1 showed a significant decrease of PAP mean (from 33±9 to 30±8; p=0.03) and PCWP (from 22±5 to 18±4; p=0.02).
Conclusion: 24 hours infusion with both drugs resulted in a comparable, significant decrease of PAP mean and PCWP. Only levosimendan significantly increases CI resulting in a significant decrease of SVR.

P3654 Short-term effects of levosimendan versus prostaglandin E1 on haemodynamics and BNP plasma levels in patients with chronic heart failure

R. Berger[1], M. Huelsmann[1], A. Bojic[2], R. Pacher[1]. [1]*University of Vienna, General Hospital, Dpt of Cardiology, Vienna, Austria;* [2]*Ludwig Boltzmann Institute, Cardiovascular Research, Vienna, Austria*

Background: The balanced vasodilator prostaglandin E1 (PGE1) as well as the calcium sensitizer levosimendan are used for treatment of patients with refractory, decompensated chronic heart failure. We compared the effects of a 24 hours infusion with levosimendan and PGE1 on hemodynamics and BNP plasma levels in these patients. **Methods:** 24 patients (LVEF<25%) in NYHA class IV despite optimised therapy with RAAS antagonists (100%), beta-blockers (83%) and furosemide (72 ± 50 mg/day) were randomised to a 24 hours infusion with levosimendan (10 minutes bolus with 12 μg/kg/min followed by 0.1 μg/kg/min) or with low-dose (2.5 ng/kg/min) PGE1. Evaluation of hemodynamics with right heart catheterisation and of BNP plasma levels were performed at baseline and after 24 and 48 hours. **Results:** At baseline, mean values of heart rate (68±12/min), RRmean (73±12 mmHg), CVP (10±6 mmHg), PAPmean (36±9 mmHg), PCP (23±5 mmHg), CI (1.8±0.3l/min m^2), SVR (1458±384 dyn sec/cm^5), PVR (285±140 dyn sec/cm^5) and BNP levels (740±612 pg/ml) were comparable between groups. After 24 hours, patients with levosimendan (n=14) showed a significant decrease of RRmean (from 70±7 to 66±9; p=0.04), PAPmean (from 37±9 to 33±7; p=0.003) and PCP (from 24±5 to 20±5; p=0.008) and a significant increase of CI (from 1.8±0.4 to 2.2±0.6; p=0.004) resulting in a significant decrease of SVR (from 1364±331 to 1076±269; p=0.01). BNP levels decreased from 833±739 to 569±469 (p=0.01). Patients treated with PGE1 (n=10) showed a significant decrease of CVP (from 8±4 to 6±3; p=0.02), PAPmean (34±8 to 30±7; p=0.02) and PCP (from 22±4 to 18±4; p=0.003). **Conclusion:** 24 hours infusion with both drugs resulted in a comparable, significant decrease of PAPmean and PCP. Only levosimendan significantly increased CI (resulting in a significant decrease of SVR) and significantly decreased BNP plasma levels.

P3655 The impact of intermittent intravenous dobutamine therapy on endothelial function in patients with severe chronic heart failure

M. Shechter, M.S. Feinberg, S. Matetzky, D. Freimark. *Sheba Medical Center, The Heart Institute, Tel Hashomer, Israel*

Background: Intermittent intravenous (i.v.) dobutamine therapy is used to treat decompensated end-stage heart failure patients. However, its use has not been adequately documented in controlled trials and its prognostic effects are not well delineated. Chronic heart failure (CHF) is associated with abnormal endothelium-dependent vasodilation. The impact of short-term i.v. dobutamine on flow-mediated dilation (FMD) has not yet been assessed. **Methods:** We prospectively assessed intermittent i.v. dobutamine therapy (up to dose 5 mcg/kg/min), endothelium-dependent brachial artery FMD and endothelium-independent nitroglycerin-mediated vasodilation (NTG) using high resolution (16 MHz) ultrasound in 15 consecutive severe CHF male patients (New York Heart association class III-IV) (mean age 57±11 years, mean left ventricular ejection fraction 22±8%), at baseline and after 3-4 months. Cardiac index (CI), stroke index (SI), and systemic vascular resistance (SVR) were assessed non-invasively by bio-impedance technique, prior to and post i.v. dobutamine therapy. **Results:** (see table). All patients had ischemic cardiomyopathy. 61% of severe CHF patients received aspirin, long-acting nitrates, and beta blockers, 83% angiotensine converting-enzyme inhibitors, 5% calcium blockers, 56% spirinolactone, 44% statins, digoxin, and coumadin, and 33% multivitamins.

	%FMD	%NTG	SVR (dyne sec/cm^2)	CI (l/min/m^2)	SI (ml/m^2)
Baseline	1.1±5.3	7.5±8.8	2172±1133	1.9±0.6	27.2±12.4
Post therapy	7.7±4.6	7.6±5.5	1797±926	2.4±0.6	33.5±11.7
p-value	0.001	0.979	0.05	0.016	0.024

Values are expressed as mean±SD; %FMD, %NTG=%change from baseline in brachial artery diameter caused by FMD and NTG, respectively.

Conclusion: Severe CHF patients suffer from impaired endothelium-dependent and -independent vasodilation, suggesting the presence of both endothelial and smooth muscle dysfunction. Short-term intermittent i.v. dobutamine therapy, however, can significantly improve vascular endothelial function, perhaps demonstrating an additional mechanism whereby SVR, CI and SI are improved in severe CHF patients treated by i.v. dobutamine.

P3656 Gradual reactivation over time of vascular tissue angiotensin I to angiotensin II conversion despite angiotensin-converting enzyme inhibition therapy in chronic heart failure

C A J. Farquharson, A.D. Struthers. *Department of Clinical Pharmacology, Dundee, United Kingdom*

Background: Plasma angiotensin II does not remain fully suppressed during chronic ACEI therapy in chronic heart failure (CHF). However, evidence suggests that the plasma renin angiotensin system (RAS) might be dissociated from the vascular tissue RAS. We therefore set out to characterise for the first time in vivo in man the time course of vascular RAS reactivation during chronic ACEI therapy.
Methods: Vascular AI/AII conversion was studied in CHF patients taking chronic lisinopril therapy. In a cross sectional study, 37 patients with NYHA Class I-III CHF were studied to see whether there were differences in vascular AI/AII conversion according to NYHA Class. A second longitudinal study followed 28 patients with NYHA I-II CHF serially over 18 months to see whether vascular ACE inhibition was progressively lost with time despite ACEI therapy. A third study took patients with the least vascular ACE inhibition observed in the first study to see whether increasing the dose of lisinopril in a double-blind cross-over fashion affected subsequent vascular ACE inhibition.
Results: In the cross sectional study, vascular ACE inhibition was significantly reduced in NYHA Class III compared with Class I/II ($p<0.05$), suggesting that tissue inhibition is more difficult to achieve with standard doses of ACEI in more severe CHF. In the longitudinal study, vascular ACE inhibition was significantly reduced at 18 months as compared with baseline ($p<0.001$), suggesting reactivation of vascular ACE in CHF despite initially achieving satisfactory ACE inhibition. In the third study, tissue ACE inhibition could once again be restored by increasing the ACEI dose compared with baseline ($p<0.001$), suggesting that this reactivation of vascular AI/AII conversion is at least partly ACE-dependent. In all studies, neither plasma angiotensin II levels, plasma aldosterone or plasma angiotensin II/I ratios bore any correlation with vascular responses, consistent with dissocation between plasma and tissue-bound ACE systems.
Conclusions: Vascular AI/AII conversion reactivates over time during chronic ACEI therapy. This occurs over time even if the CHF disease process is apparently clinically stable. It also occurs as the CHF disease process progresses. Even if vascular AI/AII conversion has reactivated, it can be suppressed by increasing the dose of the ACE inhibitor. There is no correlation whatever between any plasma RAS markers and vascular tissue AI/AII conversion.

P3657 What is the relation between drug therapy and survival in real world heart failure patients?

R. Yuval[1], I. Levin[1], D.A. Halon[1], E. Goldhammer[2], E. Abinader[2], B.S. Lewis[1]. [1]*Lady Davis Carmel Medical Center, Cardiology, Haifa, Israel;* [2]*Bnai Zion Medical Center, Cardiology, Haifa, Israel*

Background and Aims: Evidence from randomized clinical trials forms the basis for heart failure (HF) treatment guidelines but trial data are collected in carefully selected pts who meet strict inclusion/exclusion criteria. We examined drug therapy and 12 mth survival in a real world HF population. **Patients and Methods:** Drug therapy was recorded during index admission in 362 consecutive pts hospitalized for HF or suspected HF (drug treatment compatible with HF/LV dysfunction) and enrolled on discharge into the European Heart Failure survey. Survival status was ascertained for all pts by telephone interview and/or governmental records. **Results:** Drug therapy included digoxin in 97 (27.6%) pts, diuretics in 325 (92.6%), ACE-inhibitors in 234 (66.7%), angiotensin receptor blockers in 21 (6.0%) and beta blockers in 142 (40.5%). In addition, nitrates were given to 186 (53.0%) pts, calcium antagonists to 96 (27.4%), anti-thrombotic drugs (aspirin/heparin/warfarin) to 283 (80.6%) and anti-arrhythmics to 67 (19.1%) pts. At one year, 90/362 (25%) of the pts had died. Mortality was lower by 36% in pts receiving ACE-inhibitor (24.8% vs 38.5%, p=0.008), by 42% with beta blocker (20.4% vs 35.4%, p=0.002) and by 32% with anti-thrombotic therapy (26.9% vs 39.7%, p=0.037). There was no difference in mortality in pts receiving diuretics (29.8% vs 23.1%, NS), nitroglycerin (26.3% vs 32.7%, NS) and anti-arrhythmic drugs (28.4% vs 29.6%, NS). **Conclusions:** In a consecutive population of pts hospitalized for HF: 1. 12 mth mortality was lower in pts treated with ACE-inhibitors (-36%), beta blockers (-42%) and anti-thrombotic drugs (-32%). 2. Use of digoxin, diuretics and calcium antagonists had no relation to 12 mth mortality. 3. The findings were in keeping with results of major clinical trials and strongly support applicability of treatment guidelines to the real world HF population.

Abstract P3657 – Table: Drug therapy and 12 mth survival

	Digoxin		Diuretic		ACE-inhibitor		Beta blocker		Ca antagonist	
	yes	no	yes	no	yes	no	yes	no	yes	no
dead	29 (29.9%)	74 (29.1%)	97 (29.8%)	6 (23.1%)	58 (24.8%)	45 (38.5%)	29 (20.4%)	74 (35.4%)	28 (29.2%)	75 (29.4%)
alive	68 (70.1%)	180 (70.9%)	228 (70.2%)	20 (76.9%)	176 (75.2%)	72 (61.5%)	113 (79.6%)	135 (64.6%)	68 (70.8%)	180 (70.6%)
p value	0.88		0.46		0.008		0.002		0.96	

12 mth survival was higher in pts receiving ACE-inhibitor and beta blocker

P3658 Continuous positive airway pressure by "helmet" in acute pulmonary oedema. Report of 60 cases

S. Tresoldi[1], S. Maggiolini[2], A. Bozzano[2], G. Vitale[3], A. Pesenti[3], R. Fumagalli[4]. [1]*Ospedale di Desio, Div. Cardiologia-UTIC, Desio, Italy;* [2]*Ospedale San Gerardo, UO Cardiologia, Monza, Italy;* [3]*Ospedale San Gerardo, Istituto di Anestesia e Rianimazione, Monza, Italy;* [4]*Ospedali Riuniti, Dip. di Anestesia e Rianimazione, Bergamo, Italy*

Background: Acute cardiogenic pulmonary edema (ACPE) is a frequent cause of respiratory failure. Positive pressure ventilation had been shown to be more effective than conventional pharmacologic treatment by several studies in the literature. Its use was associated with the reduction of number of orotracheal intubations and costs. The aim of our study is to show the efficacy, safety and feasibility of an alternative cPAP (continuous positive airway pressure) system in patients with cardiogenic pulmonary edema admitted to a Coronary Care Unit (CCU).
Methods: Retrospective analysis of clinical reports of 60 consecutive patients with ACPE treated with helmet cPAP admitted in CCU during 10 mounths in 2001. The helmet c-PAP (Plain Hood & Neckseal SEA-LONG Medical System Inc. Horsham, UK) is a non-invasive system with the shape of a cylinder with a PVC transparent upper part and a latex lower one which fits around the patient's neck. It is equiped with an inspiratory limb connected to a flow meter and expiratory valve that allows the maintenance of a positive pressure.
Results: Non-invasive cPAP improved blood pressure (BP), heart rate (HR), rate-pressure product and blood gas parameters. The average values of HR have decreased from 105±29 mmHg to 94±25 in one hour ($p<0.001$) and to 83±16 after 9hrs ($p<0.001$); systolic blood pressure from 148±39 to 127±21 in 1h ($p<0.001$); diastolic blood pressure from 83±23 to 72±12 in 1h ($p<0.001$). In the time interval of 1 hour PaO2 improved from 66±25 mmHg to 220±115 ($p<0.001$), pCO2 from 46±16 mmHg to 39±6 mmHg after 9hrs ($p<0.001$), arterial saturation of O2 from 86%±10% to 98%±2 in 1hour ($p<0.001$), the PaO2/FiO2 ratio from 118±67 to 241±119 ($p<0.001$), arterial pH from 7.27±0.1 to 7.34±0.09 in 1 hour ($p<0.001$) and to 7.42±0.07 after 9hrs ($p<0.001$). 12% of patients died during c-PAP treatment. The 7.1% of the patients were intubated and ventilated. The records analyzed revealed intolerance of the method in only 1 patient after one hour of treatment. No complications were observed.
Conclusions: "Helmet" cPAP is an effective tool for ACPE treatment and is easily applicable. It rapidly improves oxygenation and is associated with improvement of hemodynamic parameters.
Comments: Although helmet cPAP is used in ACPE treatment in many hospitals in Italy, the studies in literature suppporting the use of cPAP in ACPE are all made with the tight fitting mask. There aren't in literature studies describing "helmet" efficacy and applicability. Our work is the first official documentation.

STROKE

P3659 Efficacy and problems in transcatheter closure of patent foramen ovale in patients with cryptogenic cerebrovascular events

J.I. Stein[1], A. Beitzke[1], A. Gamillscheg[1], H. Schuchlenz[2], M. Beitzke[1], P. Zartner[1]. [1]*Universitäts-Kinderklinik, Pädiatrische Kardiologie, Graz, Austria;* [2]*LKH-Uniklinikum, Kardiologie,II.Med.Abteilung, Graz, Austria*

The role of the patent foramen ovale (PFO) in patients with cryptogenic cerebrovascular events is well documented. By transesophageal echocardiography (TEE)incidence of a PFO with right to left shunting, its size and shape as well as additional atrial septal aneurysm formation in those patients can be defined. Transcatheter closure being the widely used alternative treatment to drug therapy or surgery also has its problems.
In 228 adult patients (aged 18 to 71 years) with a history of at least one cryptogenic cerebrovascular event (64% stroke, 46% TIA or PRIND)TEE proved a PFO and transcatheter closure was performed. During the procedure TEE was used in the majority of patients to define the shape of the PFO and atrial septum and detect other abnormalities or additional defects. TEE findings and balloonsizing determined the type and size of the device used. For anticoagulation heparine was given for 24 h around the procedure, antiplatelet therapy for the following 6 months. We successfully implanted 109 Amplatzer PFO occluders (APFO),76 Cardioseal(CS) and 36 CS-Starflex (CSStf) devices. The vast majority of the APFO were 25 mm devices. In the CS/CSStf group more than 2/3 were 23mm and 28mm. In large ASA or PFO >10mm 33 or 40mm devices were used.
There were early complications like device embolization due to inappropriate size of the device (CS 2) and early release.Devices could be removed from the femoral groin. Undetected perforation of the roof of the left atrium with the guide wire lead to cardiac tamponade and surgery 6 hours after successfull implantation of a device.In five patients significant venous hematoma occurred. As late complications there was 1 LA-perforation by the leftatrial disc of a APFO with the need of urgent surgery. Late arrhythmias(atrial flutter, fibrillation)with shortterm therapy occurred in 5%. Residual leaks and/or an additional lesion detected on TEE after 6 months were trivial in 3, 4 others have got a second device.
These different devices we report are the mainly used for closing a PFO.Problems may occur with the larger sized CS/CSSTf used in long tunnel-like PFOs with late dislocation after immediate correct positioning, or infolding of the device into the tunnel and incomplete contact with the septum. APFO-devices are more bulky and we had 1 late perforation. Transcatheter closure of a PFO is effective in terms of closure rate, is preferable to longtime anticoagulation or other drug therapy, and its recurrance rate of neurological events is low.

P3660 Percutaneous closure of patent foramen ovale in young adults with cerebral infarction – Results with the CardioSeal Starflex Occluder

B. Hornig, C. Ceconi, S. Jategaonkar, H. Rasthofer, G.P. Meyer, H. Drexler. *Medizinische Hochschule, Abt. Kardiologie und Angiologie, Hannover, Germany*

Background: Prevalence of patent foramen ovale (PFO) with detectable right-to-left shunt is high in young adults with TIA/cerebral infarction and is associated with increased risk for recurrent paradoxical thrombembolism. Percutaneous closure represents a promising therapeutic concept since it avoids surgical closure or life-long anticoagulation with coumadin. So far, however, published data included different occluder systems, different indications (PFO with small/large shunt; ASD II) and different regimens of anticoagulation after the procedure within the same study.
Methods and Results: Accordingly, in the present study 51 young adults (27 men; age: 43±2 years) with >1 TIA/stroke documented by CCT or MRI were included. All had PFO with large right to left shunt (Valsalva: >50% of left atrium filled with contrast during TEE) and/or PFO with atrial septum aneurysm, since it has recently been demonstrated that particularly these conditions are associated with increased risk of recurrent stroke. Other sources of embolism were excluded. Implantation of the CardioSeal Starflex Occluder was performed under local anaesthesia, fluoroscopic and TEE guidance (procedure including diagnostic right and left heart catheterization: time 52±2 min, contrast medium 45±2 ml, fluoroscopy time 5.4±0.5 min). PFO-closure was successfull in 50 patients (98.0%). All patients were subsequently treated for 6 months with Phenprocoumon (INR 2.5) to inhibit plasmatic coagulation and Aspirin (100mg/d) to inhibit thrombocyte aggregation. Follow-up included contrast-enriched TEE with Valsalva manoeuvre after 6 months and a health questionnaire every 6 months. After 6 months PFO was completely occluded in 92% of the patients, in 3 cases a residual shunt (small) was detected. None of the patients had local thrombus formation on the occluder system. The mean follow-up with the health questionnaire is 15.4±6.6 months (range 6 to 28 months) and revealed recurrent neurological symptoms in 4 patients with completely occluded PFO. In 2 of these cases symptoms were associated with migraine and in the other 2 cases a cerebral infarction was excluded by NMR. All other patients (92%) were free of recurrent neurological events. Six patients developed supraventricular arrhythmias which needed no treatment (n=4) or were successfuly treated with b-blockers (n=2).
Conclusion: Percutaneous closure of patent foramen ovale with the CardioSeal Starflex Occluder represents a safe and effective therapy for appropriately selected young adults to prevent recurrent cerebral ischemic events.

P3661 The impact of physical activity on stroke mortality, in elderly individuals: forty-years follow-up of the Corfu cohort; Seven Countries study

C. Chrysohoou, C. Pitsavos, D. Panagiotakos, J. Skoumas, A. Dontas, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, University of Athens, Attica, Greece*

Background: Stroke is one of the leading causes of death, universally. This analysis aims at describing the effects of physical activity on the stroke mortality, based on 40-years (1961-2001) prospective evaluation of the Corfu cohort, from the Seven Countries Study. **Methods:** The population studied in this analysis consisted of rural men enrolled at 1961 (n=529, 49.7±5.7 years old) in Corfu. Among several factors the effect of moderate or vigorous physical exercise was evaluated with stroke mortality as the end-point. Cox proportional hazards models were applied in order to evaluate the investigated parameters. A major limitation of the study was our inability to segregate thrombotic from hemorrhagic strokes. **Results:** Among 529 cardiovascular disease-free men at entry, 65 (12.3%) died because of cerebrovascular disease. The cumulative survival at the end of the follow-up was 76%. Mean age at death for stroke was 75 ± 9 years old. At baseline, 167 (32%) reported sedentary life, 197 (36%) moderated exercise and the rest of them 165 (31%) reported vigorous physical activity. Compared to subjects reported sedentary life at baseline, those reported moderate physical exercise had 42% (hazard ratio = 0.58, $p < 0.01$) lower risk of fatal stroke evens, while those reported vigorous exercise had 35% (hazard ratio = 0.65, $p < 0.05$) lower risk, after adjusting for arterial blood pressure, smoking habits and body mass index. **Conclusions:** In these elderly men 40-years incidence of cerebrovascular disease seems to be strongly associated with the presence of physical activity, at baseline. The effect of physical activity on stroke mortality, was independent from arterial blood pressure levels, body mass and smoking habits.

P3662 Carotid angioplasty: initial experience with the flow reversal technique for prevention of embolic complications

H. Sievert[1], K. Rabe[2], W. Pfeil[2], C. Rubel[2], D. Scherer[2], H. Lißmann-Jensen[2], K-F. Beykirch[3], R. Theis[3]. [1]*Frankfurt, Germany;* [2]*Cardiovascular Center Bethanien, Frankfurt, Germany;* [3]*Bethanien Hospital, Neurology Dept., Frankfurt, Germany*

Background: Complications of carotid angioplasty usually occur due to embolization of arteriosclerotic debris. Reversal of blood flow in the internal carotid artery during angioplasty and stenting has been suggested to prevent this. **Patients:** Carotid angioplasty and stenting under flow reversal was attempted in 34 patients (age 68 ± 9). 16 patients had a previous ipsilateral TIA and or stroke. Diameter stenosis ranged from 60 to 99,9% (79 ± 10), the length of the lesion ranged from 1 to 24,6 mm. At least 4 lesions contained fresh thrombus. Two patients had a contralateral stenosis of > 50% and one patient had a contralateral occlusion. **Methods:** Reversal of blood flow in the internal carotid artery was achieved by occlusion of both the common and the external carotid artery during the procedure using the ArteriaO device. During the procedure the blood flowing back into the guiding catheter was re-transfused into the femoral vein via a filter. Conventional wires and balloons where used. A Wall-Stent was implanted in 24 patients. 7 patients received a Precise-Stent, 2 patients a Smart-Stent and 1 patient a Tetra-Stent. **Results:** The device could easily be introduced into the common carotid artery. Balloon occlusion of the common carotid artery as well as the external carotid artery was achieved in all patients. The occlusion time ranged between 4 and 37 min (15 ± 8) and was tolerated reasonable in all patients except one, in whom the balloon had to be deflated repeatedly during the procedure. Two patients experienced transient neurological symptoms during balloon occlusion without need for interruption of the procedure. In all patients angiographic success was achieved without immediate complications. In one patient a TIA occurred several hours later. Macroscopic debris was found in the filter in 32/34 patients. **Conclusions:** Flow reversal in the carotid artery for protection of embolism during carotid angioplasty is feasible in the majority of patients. Atherosclerotic debris is kept back efficiently. If the balloon occlusion is not tolerated, the procedure can be completed by deflating the balloon intermittently. As in any other embolic protection device, late ischemic events can not be avoided.

P3663 Galantamine is effective for at least 12 months in patients with vascular dementia and Alzheimer's diesase with cerebrovascular disease

T. Erkinjuntti[1], A. Kurz[2], S. Lilienfeld[3], S. Schwalen[4]. [1]*Helsinki Univ. Hospital, Memory Research Unit, Helsinki, Finland;* [2]*TU München, Dept. of Psychiatry and Psychothe, Munich, Germany;* [3]*R.W. Johnson Pharmaceutical Research, Medical Affairs, Raritan, USA;* [4]*Janssen-Cilag GmbH, Medical Development, Neuss, Germany*

Background: Large artery disease, small vessel disease, cardiac embolic phenomena and hemodynamic mechanisms are all frequent etiologies associated with cerebrovascular disease (CVD) and subsequent dementia. Various cardiovascular risk factors such as hypertension, atherosclerosis, diabetes mellitus and hyperlipidemia are also thought to contribute. To date, the treatment of dementia related to CVD has focused on primary prevention of some of these risk factors. However, galantamine (Reminyl®), a cholinergic dementia treatment with a novel dual mode of action, has recently shown broad, significant benefits for up to 6 months in patients with vascular dementia (VaD) and Alzheimer's disease (AD) with CVD. Galantamine is the first cholinergic agent to demonstrate such efficacy in these patient groups. Here we report further data on the long-term (12-month) maintenance of cognitive function from a 6-month open-label extension to the initial 6-month double-blind study.
Methods: Patients with VaD or AD+CVD who had completed a 6-month, randomized, double-blind trial with galantamine 24 mg/day or placebo were eligible to enter a 6-month, open-label extension study. All patients in the open-label study received galantamine 24 mg/day up to Month 12, irrespective of whether they had received placebo or galantamine during the double-blind phase. Cognitive function was measured at baseline and at Months 6, 7.5 and 12 (endpoint) using the 11-item Alzheimer's Disease Assessment Scale - cognitive subscale (ADAS-cog/11).
Results: Overall, 459 patients received open-label treatment with galantamine; 195 (42%) had probable VaD. 73% of placebo/galantamine and 86% of galantamine/galantamine patients completed 6 months of open-label treatment. At the end of 6 months of double-blind treatment, ADAS-cog/11 scores had significantly improved over baseline in the galantamine group ($p < 0.001$). After a further 6 months of galantamine (12-months' follow-up), ADAS-cog/11 scores were still better than baseline (-0.9 ± 0.45), but not significantly so. Placebo patients had deteriorated significantly during the double-blind phase, but their ADAS-cog/11 scores returned to baseline after 6 months of open-label galantamine (-0.3 ± 0.68).
Conclusion: The maintenance of cognitive function at baseline levels for at least 12 months represents an important clinical benefit in patients with probable VaD or AD+CVD. This 12-month, open-label extension study with galantamine represents the first robust evidence for such efficacy with a cholinergic agent in these patient groups.

P3664 The – 174 g/c polymorphism of the il-6 gene promoter is associated with multi-infarct dementia in an Italian population

A. Flex[1], R. Pola[1], E. Gaetani[1], P. Papaleo[2], A.S. Proia[2], G. Straface[2], A. Santoliquido[2], P. Pola[2]. [1]*Lab. of Vascular Biology and Genetics,* [2]*Internal Medicine, A. Gemelli University Hospital, Rome, Italy*

Introduction: Multi-Infarct Dementia (MID) is a pathology whose incidence has greatly increased over the last decades. Recently, attention has been paid to the role of inflammatory processes in the progression of cerebrovascular diseases. Several observations hint at the role of inflammatory mechanisms in the development, maturation and destabilization of atherosclerotic plaque. Pro-inflammatory cytokines have been localized into the atherosclerotic vessel wall, and there is evidence that this profile shifts the endothelium towards a prothrombotic state. In addition, an increment of pro-inflammatory mediators, such as TNF-alpha, IL-6, and IL-8, has been observed in ischemic cerebral areas. These data are consistent with the observation that elevated levels of IL-6 in plasma increase the risk of future myocardial infarction in an apparently healthy population. A common genetic polymorphism has been reported in the promoter region of the IL-6 gene. This polymorphism is functionally important, since it influences the transcription rate of the gene. Two different alleles of the IL-6 gene can be identified (G and C allele), resulting in three possible genotypes, GG, GC, and CC. Recently, this polymorphism has been associated with intima-media thickness and abdominal aortic aneurysms.
Methods: the IL-6 G/C gene polymorphism was analyzed in 122 patients with MID and 134 age- and sex-matched controls. All subjects were Caucasians from central and southern Italy.
Results: The distribution of IL-6 genotypes in MID patients was 63 GG, 47 GC, 12 CC, and differed significantly from that observed in the 134 control subjects: 29 GG, 58 GC, 47 CC. The GG genotype was significantly more common in patients with MID than in the control group ($P<0.0001$), while the CC genotype was significantly more frequent in control subjects ($P<0.0001$). The GC genotype was not significantly different between the 2 groups ($P=0.432$). The allele distribution was significantly different between the two groups, as well ($P<0.0001$). A linear regression analysis demonstrated that GG genotype is an independent risk factor for MID: Odds ratio for the GG genotype was 9.1 (3.1-26.1), $P<0.0001$.
Conclusions: In this study, we provide evidence that the -174 G/C polymorphism of the IL-6 gene promoter is a risk factor for MID in an Italian population. Although further studies are needed, our data support the hypothesis that IL-6 is important in the pathophysiology of cerebrovascular disorders and suggest a role for anti-inflammatory therapy in these diseases.

LEFT VENTRICLE AFTER INFARCTION: REMODELLING, PERFUSION, FUNCTION

P3665 Correlation of pacing "Stress" NOGA with angiography for the detection of myocardium ischaemia

E.C. Perin[1], H.F. Dohmann[2], A.L.S. Sousa[1], G. Silva[3], C.T. Mesquita[2], C.S. Gonzales[2], R.C.V. Branco[2], H.J. Dohmann[2]. *[1]Texas Heart Institute, Cardiology, Houston, United States of America; [2]Hospital Pro-Cardiaco, Cardiology, Rio de Janeiro, Brazil; [3]texas heart institute, cardiology, houston, United States of America*

Introduction: Electromechanical maps (EMM)have been shown to accurately detect chronic severe myocardial ischemia (hybernating myocardium).Linear Local shortening(LLS) function is utilized to assess myocardial contractility.The present study investigates if a "stress" mode of EMM can enhance the detection of myocardial ischemia when compared to the "gold standard" coronary angiography.
Methods: In 22 patients with proven myocardial ischemia by SPECT, coronary angiography was performed as well as rest and paced (85% MPHR) EMM. EMM were divided into five segments according to the regional distribution of the main epicardial coronary arteries(LAD:(1)Anterior-basal,(2)Mid-anterior,(3)apical; RCA:(4)Inferior; LCX:(5)Lateral). Of a total of 110 myocardial 87 were submitted to analysis. Twenty three were excluded because of the presence of scar or resting ischemia. Coronary lesions were measured using QCA and segments were divided in two groups:a)Group I: supplied by a vessel with <50% stenosis(n=44). b)Group II >= 50% stenosis(n=43). LLS(%)values (mean±SD) were obtained for both groups at rest and stress. An LLS "stress" index (LLS stress/LLS rest - 1) reflecting the mechanical response of each group to stress was calculated. A T-test was used to compare indexes. A $p<0.05$ was considered significant.
Results (see table): Using a LLS "stress" index of -0.40 as a threshold for diagnosis of myocardial ischemia EMM showed a specificity of 69.1% and sensitivity of 68.2%.

LLS at rest and with pacing

	Stenosis <50%	Stenosis >= 50%	P value
Rest LLS (%)	14.60 ± 7.40	13.60 ± 5.41	NS
Paced LLS (%)	12.6 ± 6.27	6.52 ± 4.63	<0.001
LLS Index	-0.04 ± 0.68	-0.49 ± 0.37	<0.001

LLS= linear local shortening

Conclusion: Pacing "stress" EMM is capable of detecting myocardial ischemia in non-hybernating and non-scarred myocardial segments.Its low sensitivity and specificity might limit it's use in clinical practice though future studies with larger sample sizes are needed to further address this matter.

P3666 Contrast echocardiography and its relationship with the intensity of the inflammatory response in the acute phase of myocardial infarction

J. Monge[1], J. Cortez[2], H. Custódio[1], L. Bronze[1], M. Vieira[1], J. Azevedo[1], A. Aleixo[1], M.G. Morais[2]. *[1]Hospital São Francisco Xavier, Echocardiographic Laboratory, Lisbon, Portugal; [2]Faculdade de Ciências Médicas-UNL, Biochemistry Department, Lisbon, Portugal*

Myocardial ischemia, necrosis and rupture of the coronary microcirculation are directly related with the intensity of the inflammatory process that occurs during an acute myocardial infarction (AMI). Purpose: The aim of this study was to evaluate the relationship between the intensity of AMI inflammatory response and the extension of the left ventricular (LV) myocardial contrast enhancement (MCE) distribution. Methods: We studied a group of 26 patients with clinical, EKG and laboratorial AMI diagnosis. Between day 1 and 3 post AMI we calculated the mean (Mn) and maximal (Max) values of several laboratorial parameters, such as the C-reactive protein (CRP-U/L), troponin I (TI-U/L) and mioglobin (MG-U/L) levels, and CD11b, CD43, and its CD11b/CD43 ratio, cell adhesion molecule ligands to circulating monocytes (M). The MCE study was performed using intermittent imaging acquisition, 1:4 cardiac cycles, PCI software (Acuson, Mountain View, CI, USA), Doppler angio mode, after intravenous injection of MCE Levovist® (Schering AG, Germany) 4g/300 mg/ml, following the transthoracic echocardiographic ASE model of 16 LV myocardial segments. Computerized ultrasound densitometry was applied and its Max and Mn LV segmental myocardial wall intensity (UI-dB) values were calculated. The individual (Ind) and Mn LV segmental values of UI (dB) and its percentage (UI%-%) variation post MCE administration were used as quantitation parameters of LV MCE intra-myocardial distribution and change. LV wall segments wre divided in two groups according to the AMI related coronary artery. Results: For AMI related LV segments, an inverse correlation was observed between CRP Max and Mn values and the Mn and Ind values of UI (r=-0.37 and r=-0.42; p=0.03) and %UI (r=-0.44 and r=-0.46; p=0.02). Significant correlations were also obtained between CD11b/CD43 ratio and the UI Mn value (r=-0.47; p=0.01) and %UI (r=-0.45; p=0.02) of LV MCE study. No significant correlation was found for the LV mycardial wall segments not related with the AMI coronary artery lesion. Conclusion: In our population, the intensity of the inflammatory cell response to AMI is directly related with the reduction of the intra-myocardial distribution of MCE in the coronary involved segments during the first days post acute coronary event.

P3667 Serial echocardiographic assessment of the left ventricle function after the direct PTCA; a one-year follow-up

L. Nechvatal, O. Hlinomaz, L. Groch, I. Hornacek, J. Sitar, M. Orban, E. Petrikovits. *St. Anna University Hospital, cardiology, Brno, Czech Republic*

Acute myocardial infarction (AMI) causes remodeling of the left ventricle (LV).
Aim of the study: Echocardiographic follow-up of the late LV remodeling in patients with acute myocardial infarction, who were treated with the direct percutaneous transluminal coronary angioplasty (PTCA). The patients were followed up from the discharge from the hospital for 12 months.
Methods: 61 patients with acute myocardial infarction treated with direct PTCA were included in the study. 47 were men and 14 women with average age 60 ± 10 years. Complete closure of the infarction-related coronary artery (TIMI flow 0) prior to the direct PTCA performance was diagnosed in 84% of the cases. Full patency of the artery (TIMI III) after the direct PTCA performance was diagnosed in 93% of the cases. An echocardiographic examination was performed on the 6th to 8th day after direct PTCA, at the end of the 1st month and after 6 and 12 months. We used a 16-segment model of the left ventricle. The ventricular wall motion was scored using a 4-grade scale (1 = normokinesis, 2 = hypokinesis, 3 = akinesis, 4 = dyskinesis). Ejection fraction (EF) was calculated by Simpson's method.
Results: The EF value increased significantly at the end of the first month in comparison with the examination performed on the 6th to 8th day after the direct PTCA increase from 46 ± 8% to 49 ± 8%, p = 0.005). The changes in EF after 6 months (EF = 50 ± 9%) and after 1 year (EF = 49 ± 7%) were not statistically significant.
The wall motion score index (WMSI) showed a statistically significant improvement after 1 month (1.64 ± 0.34 in the first examination, 1.53 ± 0.30 after 1 month, p = 0.004). The WMSI after 6 months (1.50 ± 0.32) and after 1 year (1.54 ± 0.28) did not show further statistically significant development. End-diastolic diameter (EDD)in the first examination on the 6th to 8th day after the direct PTCA was 49 ± 6mm. EDD did not change after one month, increased insignificantly to 50 ± 7 mm after 6 months and increased significantly to 51 ± 5mm after one year ($p < 0.05$).
Conclusion: The ejection fraction and the ventricular wall motion showed significant improvement in the period between one week and one month after the direct PTCA. The LV end-diastolic diameter showed only a small increase during the whole one-year follow-up. These results confirm the beneficial effects of achieving the infarct-related artery patency with direct PTCA on the LV remodeling after the AMI.

P3668 A mitral pattern of impaired relaxation and the presence of infarct-zone viability identify patients without left ventricular remodelling

A. Sestili[1], C. Coletta[2], M. Renzi[2], N. Aspromonte[2], V. Ceci[2]. [1]*Rome, Italy;* [2]*Santo Spirito Hospital, Cardiology Dept., Rome, Italy*

Acute myocardial infarction (AMI) is followed by a complex and interrelated sequence of events termed postinfarction left ventricular remodelling (LVR) which lead to heart failure and increased mortality. However LVR does not always occur, consequently some patients (pts) can not develop such an unfavourable eventuality. The aim of this study was to examine a group of pts with first AMI to evaluate if echocardiography parameters, at rest and during dobutamine stimulation, would be able to predict the absence of LVR.

Methods: 70 pts. with a first uncomplicated AMI (M=61, F=9), underwent complete 2-dimensional and Doppler echocardiographic examinations at predischarge and 6 months after the index infarction. End-diastolic left ventricular volume index (EDVI, mL/m^2) and end-systolic left ventricular volume index (ESVI, mL/m^2) were calculated by modified biplane Simpson's rule. From Doppler spectra of 3 consecutive cardiac cycles, averages values were calculated for the following diastolic variables: peak flow velocity of E (E) and A wave (A),peak E/A wave velocity ratio (E/A), deceleration time of early filling (Edt). Echo-dobutamine stress test to identify infarct-zone viability was performed at incremental doses (5 to 20 μg/Kg/min) in 3 min-steps. Infarct-zone viability was defined as any contractile improvement in > 2 left ventricular (LV) dysfunctioning segments during dobutamine stimulation, using standard 16-segments model of the LV and a 1-4 scoring system. Finally on the basis of LV dimension at 6 months, pts were divided in two subsets: those without (27 pts, Group 1) and those with (43 pts, Group 2) LV dilatation.

Results: Clinical characteristics and LV volume indexes (EDVI: 60 ± 12 Group 1 vs 65 ± 16 mL/m^2 Group 2, p = ns; ESVI: 34 ± 11 Group 1 vs 37 ± 11 mL/m^2 Group 2, p = ns, respectively) were similar in both groups at baseline. Group 2 had significantly greater end diastolic (77 ± 17 vs 57 ± 13 mL/m^2, p<0,0001) and end systolic (43 ± 13 vs 29 ± 9 mL/m^2, p<0,0001) volumes at 6 months than did patients in Group 1. Viable myocardium was found in 13 pts. of the Group 2 and in 17 pts.of the Group 1 (19% vs 62%, p<0,01), moreover Group 1 exhibited a mitral pattern of impaired relaxation, Group 2 a normal or rather pseudonormalized mitral pattern (E/A: 0,9 ± 0,3 vs 1,23 ± 0,4, p< 0,0001).

Conclusions: These data suggest that the presence of a residual infarct-zone viability and a mitral pattern of impaired relaxation discriminate patients who maintain left ventricular geometry from those who develop progressive LV dilatation after a first AMI.

P3669 Regional curvature and wall-motion abnormalities in anterior postinfarction cardiomyopathy with functional mitral regurgitation

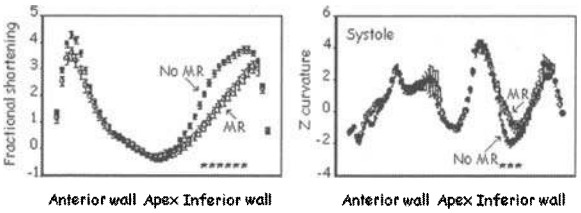
A. Toso[1], G. Barletta[1], M. Sabatier[2], V. Dor[2], M. Di Donato[3]. [1]*Careggi Hospital, Malattie Cardiovascolari, Firenze, Italy;* [2]*Centre Cardiothoracique de Monaco, Monaco, France;* [3]*University of Florence, Clinica Medica e Cardiologia, Florence, Italy*

Several mechanisms were proposed for ischemic mitral regurgitation (IMR), including global left ventricular (LV) dysfunction, geometric distortion by LV dilatation, or regional segmental wall motion abnormalities. However, ventricular shape in IMR has not been fully elucidated.

LV shape in IMR has not been fully elucidated. The relationship between LV shape (eccentricity index -EI- and regional curvature analysis) and IMR was evaluated in 221 consecutive patients with anterior post-infarction scar submitted to diagnostic heart catheterization; 174 patients (60±9yrs) did not have and 47 (61±9yrs) had angiographic grade 2 MR or more.

In patients with IMR hemodynamics were significantly worse (EDVI 242±73 vs. 190±70 ml/m^2; ESVI 174±73 vs. 120±57 ml/m^2; EF 30±13 vs. 38±13%); cardiac index was lower and mean pulmonary artery pressure significantly higher (p 0.0001).

Patients with IMR had a greater extent of severe (> 2SD) asynergy (58±21 vs 52±16%, p = 0.001) and a reduced systolic EI (0.769±0.01 vs 0.809±0.01 p = 0.002). Systolic curvature and fractional shortening are shown in Fig. 1. Shortening is lower and curvature is flattened at inferior regions (stars indicate significance)



Patients with IMR have greater systolic sphericity and worse hemodynamics. Inferior curvature and wall motion abnormalities are strictly related and characterize patients with MR. Systolic shape abnormalities are independent of volumes. Regional inferior flattening and reduced shortening could be considered as a further mechanism of IMR.

P3670 Long-term changes in systolic and diastolic function and serum markers of collagen synthesis in patients with post-infarction left ventricular remodelling

G. Cerisano[1], L. Bolognese[1], A. Migliorini[1], R. Valenti[1], E. Taddeucci[1], M. Tommasi[2], S. Raspanti[2], D. Antoniucci[1]. [1]*Careggi Hospital, Division of Cardiology, Florence, Italy;* [2]*Dep. Clinical Physiopathology, Nuclear Medicine Unit, Florence, Italy*

Background: Left ventricular (LV) remodeling after AMI is thought as a progressive phenomenon leading to heart failure. The occurrence of such a transition and its time course vary greatly and most of the informations stem from studies on thrombolyzed patients (pts). However, long-term serial changes in systolic and diastolic function, as well as in serum markers of collagen synthesis, have been poorly investigated among pts successfully reperfused by primary PTCA. OBJECTIVE: To assess serial late changes in echo LV geometry and function, and in serum values of procollagen type I and III in asymptomatic pts with and without post-infarction LV remodelling. METHOD: 48 consecutive pts with AMI treated with primary PTCA, 14 pts (group 1) with and 34 (group 2) without early (6 months) LV remodeling (change in LV end-diastolic volume from baseline to 6 months > 20%), underwent the following examinations: 1) coronary angiography at 6 month, 2) echo-Doppler assessment of systolic function (LV end-diastolic volume - LVEDV, LV end-systolic volume- LVESV, LV ejection fraction- LVEF, LV eccentricity and mass index) and diastolic function (E and A wave peak; E/A ratio, isovolumetric relaxation time - IVR, deceleration time of early LV transmitral flow - DT), and 3) serum measurements of procollagen type I and III (as an indirect marker of collagen shyntesis) at 2,5 and 5 years of follow-up. RESULTS: Baseline anagraphic and clinical characteristics, and 6-month angiographic results were similar in two groups. Six month LV systolic geometry/function, but no diastolic function were significantly worse in group 1 that in group 2 (LVEDV: 101 ± 31 ml vs 63 ± 22 ml, p < 0.001; LVESV: 68± 28 ml vs 35 ± 20 ml, p < 0.005; LVEF: 36% ± 10 vs 49% ± 14, p < 0.005). From 6 month to 5 years, LV volumes, LVEF and eccentricity indexes shown a slight and non significant improvement in both groups. On the contrary, LV mass (101 g/m^2 ± 31 vs 81 g/m^2 ± 24, p < 0.03), Doppler indexes of reduced LV compliance (DT: 169 ± 56 msec vs 201 ± 32 msec, p < 0.03), and changes in serum procollagen type 1 (60 ± 64 vs -1,6 ± 59, p < 0.008) were significantly increased in group 1 compared with the group 2. CONCLUSION: Among pts reperfused with primary PTCA systolic function and geometry remain stable both in pts with and without early (6-month) LV remodeling. However pts with 6-month LV remodeling show peculiar adverse long-term changes in LV mass, diastolic function, and plasma markers of collagen synthesis. Large-scale studies are needed to assess if these changes will translate in a worse prognosis.

P3671 Beneficial effect of preinfarction angina on ventricular remodelling after mechanical reperfusion for acute myocardial infarction

A.N. Neskovic[1], L. Bolognese[2], N. Carrabba[2], G. Cerisano[2], P. Buonamici[2], G.M. Santoro[2], D. Antoniucci[2]. [1]*Dedinje Cardiovascular Institute, Cardiovascular Research Center, Belgrade, Yugoslavia;* [2]*Careggi Hospital, Division of Cardiology, Florence, Italy*

Background: The effects of preinfarction angina (PA) on infarct size, postinfarction left ventricular (LV) function and clinical outcome, particularly in pts with myocardial infarction (MI) treated with mechanical reperfusion, has not been fully clarified. Thus, we sought to determine the relationship between PA (within 7 days before MI) and myocardial damage, LV functional recovery and 6-month LV remodeling in a large series of patients (pts) with acute myocardial infarction (MI) treated with primary PTCA.
Methods: We serially evaluated 317 consecutive pts who underwent successful primary PTCA for acute MI (TIMI 3 flow in the infarct-related artery and residual stenosis <30%) by 2-dimensional echocardiography (within first 72 hours, and at 1 and 6 months following MI). LV volumes (determined by Simpson's biplane formula), ejection fraction (EF), and infarct zone wall motion score index (IZ-WMSI) were calculated for each study. Coronary angiography was repeated at 6 months in all pts.
Results: PA was detected in 112/317 (35%) pts. Baseline echocardiographic and clinical data as well as the therapy during follow-up period were similar in pts with and without PA. Peri- and postprocedural angiographic data (extent of coronary artery disease, collateral circulation, time to restored TIMI 3 flow, and late restenosis and reocclusion rates at 6 months) were also similar for the groups with and without PA. Peak creatine phosphokinase level was lower in pts with than without PA (2395±1818 vs. 3025±2269 IU, p=0.013). According to ANOVA, pts with PA did not change LV end-diastolic volumes (from 122±37 to 123±39 ml, p=NS) and slightly decreased end-systolic volumes during the follow-up period (from 70±29 to 64±36 ml, p=NS). In pts without PA, LV end-diastolic volumes increased from 1 month on (from 125±40 to 133±48 ml, p=0.009), and were significantly larger as compared to pts with PA at 6 months (133±48 vs. 124±39 ml, p=0.013). EF improved in both groups during follow-up (from 44±9 to 51±13%, p=0.0002, and from 43±10 to 50±12%, p=0.0002, in pts with and without PA, respectively) as well as IZ-WMSI (from 2.3±0.4 to 1.7±0.7, p=0.0001, and from 2.3±0.5 to 1.8±0.6, p=0.0002, in pts with and without PA, respectively).
Conclusions: PA may limit myocardial damage in pts treated with successful primary PTCA. It appears that PA may have inhibiting effect on LV remodeling during 6 months following acute MI.

P3672 Left ventricular remodelling after primary coronary angioplasty in patients treated with abciximab or intracoronary adenosine

A.S. Petronio, M. De Carlo, U. Limbruno, G. Amoroso, A. Micheli, C. Palagi, R. Dell'Anna, M. Mariani. *U.O. Cardiologia Universitaria, Dipartimento CardioToracico, Pisa, Italy*

Background: Coronary stent implantation during primary coronary angioplasty for acute myocardial infarction (AMI) has been shown to result in lower rates of recurrent ischemia and subsequent target vessel revascularization. Recent trials have described preserved left ventricular (LV) function and improved outcome with the combined use of abciximab and stent implantation, via protection from distal microembolization. Similarly, intracoronary adenosine bolus administration during primary angioplasty has been reported to reduce the incidence of no reflow. Objective: To evaluate the efficacy of standard abciximab treatment vs. intracoronary adenosine administration in preventing LV remodelling after AMI.
Methods: 65 patients (57 men and 8 women; mean age 57±11 years) presenting with a first AMI (<6 hours from symptom onset) and treated with primary PTCA with coronary stenting were randomized to abciximab treatment (0.25 mcg/kg bolus plus 12 hours infusion; ABCX, n=25), intracoronary adenosine (4 mg after balloon inflation; ADO, n=24), or conventional therapy (CONTROL, n=25). Patients with cardiogenic shock were excluded. The study end points included angiographic results (final corrected Thrombolysis In Myocardial Infarction [TIMI] frame count and a composite end point of slow and no-reflow or distal embolization), and 6-month echocardiographic results (% change in LV ejection fraction [LVEF], end diastolic volume [LVEDV], end systolic volume [LVESV], and wall motion score index [WMSI] compared with hospital admission).
Results: Baseline clinical, angiographic, and echocardiographic characteristics were similar in the 3 groups. A final TIMI grade 3 flow was achieved in 95% of patients, without significant differences in mean final corrected TIMI frame count among the 3 Groups (21±6 vs. 28±20% ADO vs. 25±10% CONTROL; p>0.2). A slow flow or no-reflow was observed in 2 ADO patients. At 6-month follow-up, ABCX patients showed a lower increase in LVEDV (1±10% vs. 10±16% ADO vs. 3±18% CONTROL; p=0.01) and a higher increase in WMSI (19±18% vs. 10±14% ADO vs. 9±16% CONTROL; p=0.04).
Conclusion: In patients undergoing primary angioplasty with coronary stenting for AMI, the use of abciximab, but not of intracoronary adenosine, results in a significant reduction of LV remodelling at 6 months, probably via protection from microvascular injury.

P3673 Beyond TIMI-3 flow and myocardial blush: myocardial perfusion assessed by MPI immediately after primary percutaneous coronary intervention predicts final infarct size

A. Kaltoft[1], M. Bottcher[2], N.P.R. Sand[2], M. Rehling[1], F. Zjilstra[3], T.T. Nielsen[2]. [1]*Skejby Universityhospital, Dept. of nuclearmedicine, Aarhus N, Denmark;* [2]*Skejby University Hospital, Cardiology Dept., Aarhus, Denmark;* [3]*Hospital De Weezenlanden, Cardiology Dept., Zwolle, Netherlands*

Background: Impaired tissue perfusion, despite normalized epicardial flow (TIMI 3), is a predictor of adverse outcome in patients with acute myocardial infarction. Techniques enabling identification of such patients are required to evaluate possible treatment regimes to enhance perfusion. Corrected TIMI frame count (CTFC) and myocardial blush grade (MBG) have been suggested as indicators of successful reperfusion. We investigated the association between CTFC, MBG and an acute perfusion scan (MPI), and these parameters' ability to predict the final infarct size.
Methods: Sixty-one patients (59±6 years) treated with primary PCI (pPCI) achieving TIMI 3 flow in the infarct related artery (IRA) were included. MPI (99mSestamibi SPECT) defect size, CTFC and MBG were estimated immediately after successful pPCI. MPI was analyzed blinded to clinical and angiographic data, and perfusion defects were quantified and reported in percents of the left ventricle. The final angiography was analyzed at an independent angiographic core laboratory. MBG was scored as grade 3=normal, 2=reduced, and 0/1=absent or minimal. Final infarct size was assessed by MPI 3 months after treatment. Peak LDH was used as an alternative and independent assessment of infarct size. Correlations were tested by Spearman's Rho (Rho).
Results: IRA was LAD, CX and RCA in 41, 5 and 54% respectively. Median time from pain to reperfusion was 235 [95-751] minutes. MBG was 3, 2, 0/1 in 37, 16, and 8 patients respectively. Mean CTFC was 25±13 frames. The mean acute perfusion defect was 29%±15% [0-61%]. The acute perfusion defect correlated to MBG (Rho=0.37, p=0.003), but not to CTFC (Rho=0.12, p=0.40). Mean final infarct size was 14%±11% [0-45%] and mean peak LDH was 1782±1046 U/l. There was a good correlation between these measures (Rho=0.8, p<0.001). CTFC and MBG were not correlated to final infarct size either by MPI or peak LDH (Rho=0.11-0.24, p=0.09-0.50). The acute perfusion defect was a very strong predictor of final infarct size using either methods (LDH: Rho=0.77, p<0.001, MPI: Rho=0.88, p<0.001).
Conclusion: In the clinical setting acute MPI can serve as a useful tool for early identification of patients, who despite epicardial TIMI 3 flow have inadequate tissue level perfusion. MPI performed immediately after pPCI accurately predicts final infarct size and thereby enables possible interventions to enhance tissue level perfusion.

P3674 Coincidental fluctuation of circulating amyloid beta 42 and tissue inhibitor of metalloproteinases 1 after a severe acute myocardial infarction

E.V. Economou, C.E. Pitsavos, A. Masourou, A. Zervoudaki, K.I. Kapetanios, M.G. Toutouza, C.I. Stefanadis, P.K. Toutouzas. *Hippokration Hosp., Univ. Athens, Department of Cardiology, Athens, Greece*

Background: Amorphous, non-filamentous deposition of circulating vasoconstrictive amyloid beta ending at 42 amino acid (Abeta42) has been recently described in peripheral blood vessels and non-neural tissues and could cause oxidative stress-mediated local cellular toxicity. Elevation of circulating Abeta42 and altered vascular and smooth muscle cell basement membrane protein metabolism (BMPM) are both considered as requriments for peripheral Abeta42 deposition. Aim of the present study was to delineate whether a severe acute myocardial infarction (AMI) possibly provide conditions associated with altered BMPM that might provoke deposition of circulating Abeta42.
Methods: In 21 patients (pts) with first attack of AMI, large infarct size, ejection fraction <45%, no evidence of any later thrombotic occlussion or extension of myocardial necrosis, serum levels of Abeta42 and tissue inhibitor of metalloproteinases 1 (TIMP-1), previously described as an estimate of AMI-induced extracellular matrix remodeling, were determined on hospital admission [mean latency from the onset of chest pain: 2±1 hours (h)] before thrombolysis (0h) and after 3h, 6h, 9h, 12h, 18h, 24h, 36h, 48h, 72h, 4 days (d), 5d, 7d, 15d and 30d and compared to corresponding values of 20 age- and sex-matched healthy controls (HS).
Results: At 0h, Abeta42 levels were higher in comparison to those of HS (26.7±1.1 vs 1.3±0.3 pg/mL, p=0.001). After that, a gradual drop of Abeta42 levels to their lowest values at 6h (18.2±7.8 pg/mL) was followed by a progressive elevation of them to their highest values at 30d (35.9±6.4 pg/mL), (in both cases $p<0.05$ in comparison to the respective levels at 0h). In addition, TIMP-1 levels at 0h were lower than those of HS (582±74 vs 710±24 ng/mL, $p<0.04$). After that, they increased sharply at 6h (763±46 ng/mL), peaked at 36h (780±40 ng/mL) (in both cases $p<0.001$ in comparison to the respective levels at 0h) and then declined to normal values, reaching them on 5d (672±37 ng/mL). Negative correlations between Abeta42 and TIMP-1 levels were detected at 24h (r=-0,71, p=0,03 and at 48h (r=-0,82, p=0,0001) after the onset of chest pain.
Conclusions: Severe AMI induces coincidentally elevation in circulating Abeta42 and alterations in BMPM during the first 5 days from the onset of chest pain. This may enhance the potential of Abeta42 peripheral deposition, especially at 24h and 48h after the onset of chest pain, that could cause oxidative stress-mediated local damage and reduce local blood flow, further increasing oxidative stress and upregulating Abeta42 peripheral production.

P3675 Left ventricular function, myocyte injury markers, inflammatory status and MRI-determined no-reflow in post-myocardial infarction patients

L. Jesel[1], P. Germain[1], C.H. Jahn[2], P. Ohlmann[1], P.M. Coulbois[2], P. Bareiss[1], G. Roul[1]. *[1]CHU Hautepierre, Cardiology, Strasbourg cedex, France; [2]Hôpitaux Universitaires de Strasbourg, Radiology Department, Strasbourg, France*

Aim: The extent of microvascular obstruction during acute coronary occlusion referred to as the no-reflow phenomenon could determine the magnitude of myocardial damage and thus patient (pts)prognosis after myocardial infarction (MI). Areas of no-reflow at the infarct core were assessed in order to determinate the factors that could predict the amount of no-reflow. Methods: Using contrast-enhanced MRI (5-7 slices, 10mm thick encompassing the whole left ventricle), no-reflow was defined as early hypoenhancement (2 to 3 minutes after iv gadolinium) in post-MI patients. The contrast defect was scored from 0 (no hypoenhancement) to 3 (strong hypoenhancement). Results: 50 patients (mean age 56±11 yrs; 78% men) with documented acute MI underwent coronary angiography and contrast-enhanced MRI (6±2 days after MI) and were evaluated with biochemical parameters. No-reflow (score 1 to 3) was observed in 88% of the pts. Major no-reflow phenomenon (score 2-3) was found in 54% of the group. No-reflow intensity was positively related to peak CPK (rho=0.44; $p<0.003$), peak Troponin I (rho = 0.43; $p<0.003$) and negatively to LVEF (rho = -0.44; $p<0.02$). Low TIMI grade (<3) was well predictive of the extent of no-reflow: 79% of these pts had a no-reflow score > 1. However TIMI 3 grade was a weak predictor of the absence of no-reflow. The TIMI grade was also barely related to LVEF (rho = 0.30; $p<0.04$). Cardiovascular risk factors were not predictive of no-reflow occurrence. Baseline inflammation status assessed by plasma C-reactive protein and leukocytes were significantly related to the extent of no-reflow (rho = 0.43 and rho = 0.44; $p<0.003$), and inversely to the LVEF (rho = - 0.30; $p<0.04$). Leukocytes and peak Troponin I were also significantly correlated (rho = 0.44; $p<0.002$). Conclusion: MRI-detected no-reflow, is confirmed as a determinant of post-MI LVEF and moreover appears related to the inflammatory status at the admission. This later aspect already pointed out in experimental studies deserves further investigations in the clinical setting.

P3676 The effect of percutaneous myocardial revascularization on myocardial perfusion, glucose metabolism and ischaemia

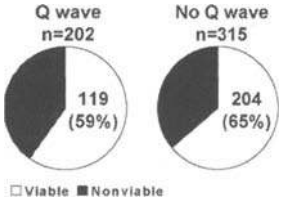
F.B. Sozzi[1], D. Poldermans[1], W. van der Giessen[1], P.W. Serruys[1], J.R.T.C. Roelandt[1], J.J. Bax[1], D. Ardissino[2], P. Smits[1]. *[1]Thoraxcentre, Erasmus Medical Centre, Rotterdam, Netherlands; [2]Cardiology Dept, Parma, Italy*

Background: Percutaneous myocardial revascularization (PMR) has emerged as an alternative treatment for patients with severe angina non-amenable for coronary revascularization. We studied the effect of PMR on myocardial perfusion and glucose utilization.
Methods: 18 consecutive patients (mean age 59 ± 10 years, 17 males) underwent PMR. Prior and six months postPMR left ventricular ejection fraction (LVEF) using radionuclide ventriculography, dobutamine stress echocardiography (DSE) and single-photon emission computed tomography (SPECT) with 99m-technetium-tetrofosmin (perfusion) and 18-F-fluorodeoxyglucose (glucose utilization) were performed. Both DSE and SPECT tests were scored semiquantitatively using a 16-segment model and respectively a 5- and 4-point score.
Results: PriorPMR 132/288 (46%) segments showed an ischemic response during DSE of which 90 (68%) were eligible for treatment. Canadian Cardiovascular Society Score for angina decreased from 3.4 to 2.4 ($p<0.01$) at six months. PostPMR LEVF was unchanged, 47 ± 7% vs. 49 ± 7% ($p = 0.1$). PMR-treated segments compared to non treated ischemic segments showed: (1) an increased wall motion score at rest, 2.11 to 3.00 ($p<0.01$) vs. 2.05 to 2.10 ($p = 0.1$); (2) a reduced myocardial perfusion, 14 (14%) treated segments compared to 1 (3%) non-treated segments ($p = 0.02$); and (3) a reduced glucose utilization, 18 (20%) treated segments compared to 1 (3%) of non-treated segments ($p<0.01$).
Conclusions: Conversion of ischemic myocardium to infarcted myocardium was observed after PMR in a significant number of treated ischemic segments, which may explain the reduction of angina.

P3677 Assessment of residual myocardial viability in regions with chronic electrocardiographic Q-wave infarction

A.F.L. Schinkel, J.J. Bax, E.C. Vourvouri, M.A. Bountioukos, F.B. Sozzi, A. Elhendy, J.R.T.C. Roelandt, D. Poldermans. *Erasmus Medical Center Rotterdam, Cardiology Dept., Rotterdam, Netherlands*

Background: Q waves on the ECG are often considered to be reflective of irreversibly scarred myocardium, as a result of antecedent transmural myocardial infarction. However, there are some indications that residual viable tissue may be present in Q wave infarcted regions. It is important to know how many Q wave regions contain viable tissue, since patients may benefit from revascularization in terms of improvement of function and long-term survival.
Methods: Patients (n=150) with chronic electrocardiographic Q wave infarction, heart failure symptoms and chronic coronary artery disease underwent dobutamine-atropine stress echocardiography (DSE) to assess myocardial viability. Residual viability in regions with Q wave infarction was considered present when the end-diastolic wall thickness (EDWT) was >6 mm and the response during dobutamine infusion indicated viable tissue.
Results: Baseline echocardiography revealed 517 dysfunctional myocardial regions, 202 of the dysfunctional regions were related to Q waves on the ECG, the other 315 dysfunctional regions were not. EDWT was <6 mm in 13 regions with a Q wave on the ECG, with only 1 region exhibiting viable tissue during DSE. EWT was >6 mm in 189 regions with a Q wave with 118 (62%) having viable tissue on dobutamine stress echocardiography. In 6 dysfunctional regions without a Q wave EDWT was =6 mm with all being nonviable on DSE; of the 309 regions without a Q wave and EDWT >6 mm, 204 (66%) exhibited viability on DSE.



Viability in infarcted regions.

Conclusion: 59% of dysfunctional regions related to chronic Q waves exhibit viability on dobutamine stress echocardiography. EDWT <6 mm virtually excludes viability; regions with EDWT >6 mm need additional testing to detect/exclude viability.

P3678 Response to dobutamine in function, myocardial perfusion, and fatty acid metabolism for predicting the reversible infarct-related myocardium

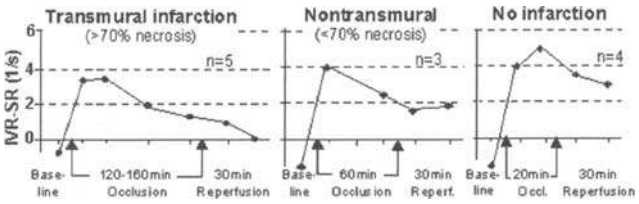
Y. Akutsu[1], H. Nishimura[1], H. Li[1], T. Huang[1], H. Kayano[1], H. Yamanaka[1], A. Shinozuka[2], T. Katagiri[1]. *[1]Showa University School of Medicine, Third Department of Internal Medicine, Tokyo, Japan; [2]Showa University School of Medicine, Department of Radiology, Tokyo, Japan*

Background: Although low-dose dobutamine stress echocardiography (LDDS), assessment of myocardial perfusion, and activity of fatty acid metabolism using nuclear procedure predict the reversible dysfunction myocardium after myocardial infarction (MI) respectively, the relative merit among these 3 parameters has not been evaluated at a time in acute phase. The aim of this study was to investigate the significance of each parameter and these relative merit.
Methods: We studied 45 patients (60.7 ± 10.4 yrs.) who underwent successful revascularization within 24 hour after the onset of MI (5.4 hours from 1 to 24 hours) and who were confirmed no restenosis by coronary arteriography after 1 year. Thallium-201/I-123 beta-methyl-branched fatty acid (BMIPP) dual-isotope SPECT was performed with LDDS (5 to 10 mg/kg/min) within 1 week after MI (4.8 ± 1.7 days). Final functional improvement was evaluated on echocardiography at 1 year. Segmental wall motion was scored on 3 grades as normal, hypokinesis, akinesis or dyskinesis. An abnormality with SPECT images in each tracer was quantitatively scored as ranged from 0 to 4. Viability was defined in each, LDDS; a score change more than 1 grade, thallium-201; the change to % uptake during dobutamine stress from that by redistribution images or score 0 (normal), thallium-201/BMIPP; a mismatch of 2 tracers during dobutamine stress or score 0 of either tracer.
Results: In 93 dyssynergic infarct-related segments within 1 week after revascularization, viability was detected in 46 segments by LDDS (49.5%), in 44 segments by thallium-201 (47.3%), and 44 segments by thallium-201/BMIPP (47.3%). The sensitivity, specificity and accuracy for predicting the functional improvement by LDDS (81.3%, 68.3%, and 72%) were higher than that by thallium-201 (62.5%, 60.7% and 61.3%) or by a mismatch of thallium-201/BMIPP (62.5%, 60.7% and 61.3%). The sensitivity and accuracy by LDDS were increased in the segments in which viability was detected by only thallium-201 (44 segments) or by thallium-201/BMIPP (44 segments) (85%, 66.7% and 75%, or 90%, 62.5% and 75% in order). In 35 segments in which viability was detected by 2 methods using SPECT imaging, these by LDDS were increased remarkably (93.9%, 63.2% and 77.1% in order).
Conclusions: The positive response to adrenergic stimulation with low-dose dobutamine in wall motion predict the functional recovery of MI more accurately than that in 2 methods with SPECT imaging, but the more accurate prediction was filled by the recovery of oxidative metabolism and cell menbrane integrity in stunning myocardium.

P3679 High myocardial strain rate during isovolumic relaxation phase identifies viable myocardium after reperfusion in acute myocardial ischaemia

C. Pislaru[1], C.J. Bruce[2], P.C. Anagnostopoulos[2], J.I. Jackson[3], J.B. Seward[2], M. Belohlavek[2], J.F. Greenleaf[1]. *[1]Mayo Clinic and Foundation, Physiology and Biophysics, Rochester MN, United States of America; [2]Mayo Clinic, Cardiovascular Disease, Rochester, United States of America; [3]Acuson, Mountain View CA, United States of America*

Postsystolic thickening (PST) is a marker of ischemia and, potentially, of viability. PST can be detected by abnormally high intramyocardial strain rates (SR) during the isovolumic relaxation phase (IVR). We tested whether IVR-SR correlates with the content of viable myocardium after acute myocardial ischemia.
Methods: Twelve open-chest pigs were subjected to LAD occlusion (20-160 min) followed by reperfusion (30 min). Tissue Doppler velocities (>150 frames/sec) of the anterior LV wall were collected from within the LV cavity using an 8.5 MHz intracardiac ultrasound catheter. Radial strain rates and systolic strain were obtained from ischemic and normal adjacent myocardium. Transmural extent of necrosis (TEN) was quantified from TTC-stained cardiac specimens. Alignment of ultrasound and cardiac specimen data was assured by placing, at baseline, 2 epicardial echogenic markers on the interrogated wall.
Results: Systolic strain was severely reduced during ischemia and reperfusion as compared with baseline (-5±3%, 3±2%, and 38±6%, respectively). IVR-SR consistently increased during ischemia, and persisted high in walls with viable myocardium (Figure). In animals with a transmural infarct, IVR-SR progressively decreased during the occlusion period and at reperfusion (figure). End-diastolic wall thickness, as measured using gray-scale M-mode, increased 30 min following reperfusion in proportion to TEN (r=0.75, p<0.0001). IVR-SR at reperfusion was inversely related to both TEN (r=-0.82, p<0.0001) and change in end-diastolic wall thickness (r=-0.79, p<0.0001).



Conclusions: In reperfused myocardial infarcts with severely reduced systolic strain, presence of PST identifies viable elastic myocardium while its absence reflects a stiff transmurally infarcted myocardial wall.

P3680 The PURSUIT risk score correlates with ejection fraction and angiographic findings in non-ST elevation acute myocardial infarction

E.S. Brilakis[1], R.S. Wright[2], S.L. Kopecky[2], G.S. Reeder[2], C.S. Rihal[2], B.J. Gersh[2], B.A. Williams[2], I.P. Clements[2]. *[1]Mayo Clinic, Division of Cardiovascular Diseases, Rochester, United States of America; [2]Mayo Clinic, Division of Cardiovascular Diseases, Rochester, United States of America*

Background: In patients with non-ST elevation acute myocardial infarction (NSTEMI), a higher PURSUIT risk score is associated with higher mortality. We tried to determine if the PURSUIT risk score also correlates with predischarge ejection fraction (EF) and with angiographic severity of coronary artery disease (CAD).
Methods: The PURSUIT risk score was calculated for 337 consecutive Olmsted County, Minnesota, patients with NSTEMI admitted to the coronary care unit of our institution between 1988 and 1998. After excluding patients with prior coronary bypass surgery (n=42), 219 patients (65%) had coronary angiography within 30-days from admission. A predischarge EF measurement was available on 246 patients (73%).
Results: Mean age was 70 ± 13 years, and 37% of the patients were women. Mean predischarge EF was 52 ± 16%. Patients with higher PURSUIT risk score had lower EF (p<0.001, Kruskal-Wallis test, Table). Three-vessel (>=70% stenosis in all 3 coronary arteries), or left main (>=50% stenosis) CAD was present in 66 of 219 (30%) patients who underwent coronary angiography. The mean ± SD CAGE 50 score (number of CASS (Coronary Artery Surgery Study) segments with >=50% stenosis) was 4.3 ± 2.6. A higher PURSUIT risk score was associated with greater likelihood of 3-vessel or left main CAD (p<0.001, chi-square test), a higher CAGE 50 score (p<0.001, Kruskal-Wallis test), and higher 30-day mortality (p<0.001, chi-square test) (table).
Conclusions: The PURSUIT risk score correlates not only with mortality but also with predischarge ejection fraction and with angiographic severity of CAD in nonselected, community-based patients with NSTEMI. Early coronary angiography should be considered for NSTEMI patients with a high PURSUIT risk score that are candidates for revascularization, since they are very likely to have 3-vessel or left main CAD.

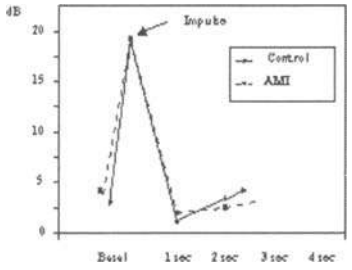
Abstract P3680 – Table

	PURSUIT risk score						P
	0-4	5-8	9-12	13-16	17-20	>20	
EF (%), mean (SD)	59 (12)	57 (13)	54 (15)	45 (12)	38 (16)	33 (5)	<0.001
3-vessel or left main disease, n (%)	3/34 (9%)	10/66 (15%)	17/63 (27%)	23/37 (62%)	9/15 (60%)	4/4 (100%)	<0.001
CAGE 50 score, mean (SD)	2.9 (1.9)	3.7 (2.3)	4.4 (2.4)	5.4 (2.7)	5.8 (2.4)	7.3 (2.2)	<0.001
30-day mortality, n (%)	0/39 (0%)	1/85 (1%)	9/108 (8%)	9/60 (15%)	5/31 (16%)	6/14 (43%)	<0.001

P3681 Myocardial perfusion in real-time using power modulation. An in-vivo evidence for a microcirculatory damage after acute myocardial infarction

J. Zamorano, R. Moreno, V. Serra, C. Almería, J.L. Rodrigo, E. De Marco, C. Alburquerque, L. Sánchez-Harguindey. *Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain*

Recently, myocardial contrast echocardiography (MCE) have shown to be capable to evaluate the myocardial microvasculature status by measuring flow reserve during the administration of vasodilator stimuli. The objective of this study was to evaluate the usefulness of MCE in detecting the microvasculature abnormalities that occur after acute myocardial infarction (AMI) by using real-time MCE at baseline without the necessity of vasodilator stimuli.
We studied 89 myocardial segments in 16 patients (11 with recent AMI and 5 control subjetcts with normal coronary arteries angiographically demonstrated). The Power-Modulation technique (Agilent 5500 equipment) was used. This technique combines low (0.1) and high (1.7 for 5 frames) mechanical index. A quantification system (Quanticom, Echotech, Germany) was used. The velocity of contrast refilling was calculated with the following formula: (Ip - I1 sec)/tp - 1, where Ip is the peak refilling videointensity, I1 sec the intensity 1 sec after the high-mechanical index impulse to the time of peak videointensity
Myocardial segments in AMI patients showed a significantly reduced contrast refilling velocity in comparison with control subjects (1.41±2.16 vs 2.69±2.48, $p<0.05$) (see figure).



MCE in AMI vs control subjects.

Conclusion: This low-index, real-time MCE tecnique allows an in vivo demonstration of the abnormalities that occur in the myocardial microvasculature of patients with AMI, with the administration of i.v. contrast agents and without the necessity of vasodilator stimuli.

P3682 Left ventricular segmental motion and perfusion myocardial contrast echocardiography analysis in the acute phase of coronary ischaemic syndromes

H. Custódio, A. Cândido, J. Galvão, L. Bronze, J. Fernandes, J. Azevedo, I. Arroja, A. Aleixo. *Hospital São Francisco Xavier, Echocardiographic Laboratory, Lisbon, Portugal*

Doppler echocardiography with the administration of new myocardial contrast enhancement agents (MCE) has been applied in a large number of cardiac pathologies including the evaluation of left ventricular (VE) myocardial perfusion post acute coronary syndromes (ACS). MCE clinical impact has not yet been established in ACS. Our aim was to assess the clinical utility of the initial MCE study (day 1) in ACS patients (pts). We evaluated 54 pts with ACS clinical and laboratorial diagnosis, mean age 62±13 yrs (44-72 yrs), 56% male, submitted to B-mode echocardiogrphy, second harmonic (2H) and MCE imaging, destruction technique, PCI software, Doppler "power angio", MCE agent Levovist® 4g/300mg/ml. 2H MCE studies were performed <24 hours post CCU admission. 2H MCE studies were analysed in 3 apical LV views, transferred to a cine-loop digital memory, 0.8 mechanical index, delta 2 function, endocardial contour 3 level, 1:4 cycles synchronization and optimisation of the B-mode imaging. 864 LV myocardial wall segments were analysed according to the ASE classical model. We assessed the LV regional wall motion abnormalities (normal-0, hypo-1, aqui-2 e disquinesia-3, aneurysm-4) and calculated the wall motion index (WMI) by 2H MCE. In the same We established the LV segmental MCE perfusion pattern (normal-2, heterogeneous-1 and absent-0) and calculated the MCE perfusion index (MCEI). Pts were submitted to coronary angiography to assess the extension and degree of coronary artery disease severity (single- vs. multivessel). Type 2 MCE pattern was found in 59,1%, type 1 in 23,3% and type 0 in 17,5% of the LV myocardial wall segments. LV MCEI registered an inverse correlation with the WMI (r=-0.44; $p<0.01$). Single vessel disease was detected in 23,1% and multivessel in 76,9% of pts.
MCE is a noninvasive technique with the potential to identiphy the extension and degree of severity of the LV myocardial microcirculation involvement in the acute phase of ACS.

MCE Results

P3683 Right ventricular function in patients with left ventricular infarction

K. Kitikidou, H. Karvounis, C. Papadopoulos, D. Adamidis, A. Kiotsekoglou, A. Mitakidou, G. Parharidis, G. Louridas. *AHEPA Hospital, Aristotle University, 1st Dept. of Cardiology, Thessaloniki, Greece*

Introduction: Patients with acute myocardial infarction (AMI) may develop right-side signs and symptoms. We evaluated right ventricular (RV) function in patients (pts) with a left ventricular (LV) AMI and no RV involvement.
Methods: We studied RV function using Doppler Echocardiography in 22 pts (mean age 56±4) with LV-AMI and no ECG signs of RV involvement. Seven pts had anterior AMI, five pts lateral AMI and ten pts inferior AMI. Echo-Doppler examination was performed on admission and two months after the acute event. All pts were thrombolysed, had an uncomplicated course and stayed only on medical treatment until the second study. We evaluated RV (diastolic) function from the transtricuspid and transpulmonary velocity curves and measured the E wave, the A wave, decceleration time of the E wave, isovolumic relaxation time, E/A ratio and the myocardial performance index (TEI index) of the RV. Twenty two age and sex matched normal individuals comprised our control group. Statistical analysis was performed using t-test and statistical significance was defined as a p value <0.05.
Results: There were no statistical differences concerning the location of the AMI. The table reviews all relevant data.

RV indices	Controls (n=22)	Patients on admission (n=22)	p	Controls (n=22)	Patients at 2 months (n=22)	p
E wave (m/sec)	0.581±0.13	0.380±0.25	<0.001	0.581±0.13	0.498±0.18	NS
A wave (m/sec)	0.440±0.04	0.320±0.27	<0.001	0.440±0.04	0.364±0.22	NS
E/A	1.35±0.11	1.16±0.24	NS	1.35±0.11	1.35±0.19	NS
DT (sec)	0.124±0.011	0.237±0.12	<0.001	0.124±0.011	0.168±0.14	NS
IVRT (sec)	0.031±0.025	0.048±0.07	<0.001	0.031±0.025	0.034±0.038	NS
MPI	0.264±0.14	0.364±0.18	<0.001	0.264±0.14	0.278±0.18	NS

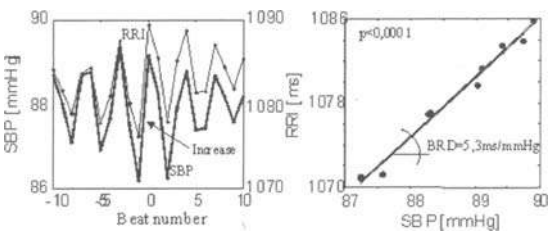
RV indices in pts with a LV-AMI versus controls on admission and two months after the acute event.

Conclusions: Patients with LV-AMI and no RV involvement on the surface ECG, exhibit impairment of RV systolic and diastolic function as assessed by the MPI and RV indices. There is spontaneous improvement of these indices after two months towards normal values.

P3684 New method for quantification of the baroreflex in post infarction patients

G. Schmidt[1], A. Bauer[2], R. Schneider[1], P. Barthel[2]. [1]*Technische Universität, I. Medizinische Klinik, München, Germany;* [2]*Deutsches Herzzentrum München, Munich, Germany*

Objective: To demonstrate a new method for quantification of the baroreflex.
Methods: In 69 post-MI patients, simultaneous 30 minutes recordings of ECG and arterial blood pressure (Portapres®) were derived. The new method selects systolic arterial blood pressure (SBP) waves which are higher than the preceding SPB wave and calculates the mean fluctuations of RR intervals (RRI) and of SBP before and after the SBP increase. The slope of the regression line of the first ten values of RRI and SBP after the increase of SBP is used as measure of baroreflex dynamicity (BRD).
Results: The fluctuations in RRI are closely coupled to the fluctuations in SBP (Figure 1). Accordingly, there was a close correlation of RRI and SBP (Figure 2). BRD was highly correlated with Heart Rate Turbulence Slope (r=0,69, $p<0,0001$, not shown).



Conclusion: The new method allows a non-invasive quantification of the baroreflex function.

P3685 Functional recovery of akinetic segments post acute myocardial infarction. The role of myocardial contrast echocardiography

H. Custódio[1], V. Azevedo[1], A. Anão[1], C. André[1], M. Vieira[1], I. Arroja[2], J. Azevedo[2], A. Aleixo[1]. [1]Hospital de São Francisco Xavier, UNICARD, Lisbon, Portugal; [2]Hospital São Francisco Xavier, Echocardiographic Laboratory, Lisbon, Portugal

Myocardial contrast echocardiography (MCE) is a new imaging technique that can perform a non invasive analysis of the coronary microcirculation during acute myocardial ischemia and infarction (AMI). Purpose: To assess the MCE distribution post AMI on the potential recovery of LV myocardial wall segments with abnormal wall motion (AWMS). Methods: We evaluated a sample population of 54 pts submitted to MCE study <24 h post AMI, using a Sequoia C256 (Acuson, CL, USA) ultrasound equipment, intermitent imaging, 1:4 cycles acquisition, destructive method, PCI software, Doppler angio mode, delta function 2, edge function 2, 3V2c 4 MHz probe, 0.8 mechanical index, after Levovist® 4g-300 mg/ml (Schering AG, Germany) intravenous injection. A pair of MCE images, corresponding to the destruction and perfusion phases were compared. Hypokinetic and akinetic LV myocardial wall segments with >6 mm thickness were identified and the MCE pattern evaluated (normal-2; patchy-1; absent-0). AWMS of the LV myocardium included both hypokinetic and akinetic LV myocardial wall segments. LV wall segments with <6 mm thickness were not included in this MCE study. Several LV parameters were analysed, such as the number of AWMS per pt, the total number of LV myocardial wall segments with MCE pattern 0 (P0), 1 (P1) and 2 (P2) per pt, the number of MCE pattern 0, 1 and 2 per pt among AWMS, the LV end-diastolic (LVDV-ml) and endsystolic (LVSV-ml) volumes and its derived LV percent ejection fraction (LV%EF-%). The recovery of LV segmental function and LV%EF were analysed at >6 months follow-up. The LV%EF variation (LV%EF Var-%) was also calculated as this variable difference between <24 hours and 6 month studies. Results: 92% (48/52)pts were evaluated at >6 months follow-up. Significant direct correlations were obtained between LV%EF and the total number of P2/pt (r=0.55; p=0.01) and P2 AWMS/pt (r=0.63; p<0.01). Significant inverse correlations were obtained between LV%EF and the total number of P0 and P1/pt (r=-0.44 and -0.47; p=0.04-0.03) and P0 and P1 AWMS/pt (r=-0.51 and -0.56; p=0.01 and <0.01). The LV%EF at >6 months period and LV%EF Var were related mainly with the number of P1/pt (r=0.66 and 0.70; p<0.01) and P1 AWMS/pt (r=0.68 and 0.72; p<0.01). Conclusions: The recovery of left ventricular segmental wall motion and global function post AMI was related with the presence of a particular pattern of myocardial contrast echocardiography. The functional recovery of the LV myocardium post AMI can be already assessed by myocardial contrast echocardiography at an early phase of the acute coronary event.

ANTITHROMBOTIC/THROMBOLYTIC AGENTS

P3686 Recombinant P-selectin glycoprotein ligand-Ig enhances the thrombolytic effect of alteplase, reteplase, and streptokinase in a canine model

A. Kumar[1], M.P. Villani[2], G.D. Shaw[1], R.G. Schaub[1]. [1]Wyeth Genetics Institute, Inflammation Biology, Cambridge, United States of America; [2]DaVinci Biomedical Research Products, South Lancaster, United States of America

Platelet-leukocyte interactions, mediated by P-selectin on platelets and its high affinity ligand P-selectin Glycoprotein Ligand-1 (PSGL-1) on leukocytes, lead to tissue factor release and fibrin generation and hence are important in thrombus stabilization and amplification. We have previously demonstrated that P-selectin antagonism using rPSGL-Ig, a recombinant soluble form of PSGL-1, in conjunction with alteplase, significantly accelerated thrombolysis and prevented reocclusion in a porcine model. In this study, the efficacy of rPSGL-Ig in enhancing the thrombolytic effect of alteplase (tPA), reteplase (rPA) and streptokinase (SK) was studied in a canine model of thrombolysis. Occlusive thrombus formation was induced by placing a copper coil in the left internal iliac artery of 12-15 kg mongrel dogs under fluoroscopic guidance. All animals received aspirin (2 mg/kg IV) prior to coil placement and heparin (70 U/kg bolus+15 U/kg/hr infusion) immediately upon coil occlusion. After 15 min, thrombolytic therapy was initiated using tPA (1.5 mg/kg IV, 8% as an initial bolus, remaining infused over 90 min), rPA (2 IV bolus injections of 0.17 U/kg 30 min apart) or SK (23,000 U/kg IV infused over 60 min). Ten minutes after initiation of the thrombolytic, animals received a single IV bolus of either vehicle (n=6, 10, 7 for tPA, rPA and SK respectively) or rPSGL-Ig at 500 μg/kg (n=6, 7, 7 for tPA, rPA and SK respectively). Blood flow through the artery was monitored by angiography every 10 min for 3 hr and was graded on a scale 0-3. In control animals, thrombolysis was achieved in 55±7.6 (mean±SEM), 60±10.4, and 50±4.9 min with tPA, rPA and SK respectively. rPSGL-Ig reduced time to lysis with the three lytics by 55% (p=0.002), 55% (p=0.02), and 46% (p=0.004) respectively. rPSGL-Ig also increased the post-lysis percent time with near normal (score 2 or 3) blood flow from 38.1±8.5%, 38.5±10.2% and 35.1±11% to 74.3±14.1% (p=0.03), 88.4±11.6 (p=0.006) and 64.1±15.9% (p=0.16) in the tPA, rPA and SK groups respectively. Further, no increases in bleeding times (measured on the inner lip) and bleeding from incision sites was noted in rPSGL-Ig-treated vs control animals. These data demonstrate that P-selectin blockade with rPSGL-Ig modulates platelet-, leukocyte-mediated thromboinflammatory events, and enhances the thrombolytic effect of the thrombolytic agents tPA, rPA, and SK without increasing bleeding complications.

P3687 Superior clinical efficacy of clopidogrel compared to ticlopidine after successful coronary stenting: a meta-analysis of published studies

G. Casella[1], F. Ottani[2], A. Capecchi[3], P. Sangiorgio[3], P.C. Pavesi[3], D. Bracchetti[3]. [1]Cardiology Ospedale Maggiore, Bologna, Italy; [2]Ospedale San Bortolo, Cardiology, Vicenza, Italy; [3]Ospedale Maggiore, Cardiology, Bologna, Italy

Background: Combination therapy with aspirin plus ticlopidine has become the reference antithrombotic therapy after coronary stenting. However despite its effectiveness, ticlopidine has a significant incidence of severe side effects. Thus, clopidogrel, a ticlopidine analogous with an excellent safety profile, has been introduced in clinical practice. To date only few underpowered studies comparing the clinical efficacy of clopidogrel and aspirin versus standard combination therapy after coronary stenting have been performed and odds ratios (OR) vary substantially between them. Thus, the present investigation refines these values by means of a formal meta-analysis.
Methods: Ten studies were considered suitable for analysis. OR were calculated for 30-days follow-up in patients who had undergone successful coronary stenting. Primary end points were a composite of death and non-fatal myocardial infarction (MI) as well as a composite of major adverse side effects as considered in every single study. Secondary end points were a composite of major adverse cardiac events (MACE), according to single study definition, and individual cardiac events as well.
Results: A total of 11688 patients were included. At 30 days, the OR for death and non-fatal MI was 0,63 (95% CI, 0.47-0.85; p=0.003) in favor of patients treated with clopidogrel and aspirin. There was also a trend toward less MACE (p=0.1), less mortality (p=0.2) and less non-fatal MI (p=0.12) for patients treated with clopidogrel. Furthermore, OR for major adverse side effects was 0,53 (95% CI, 0.42-0.66, p<0.00001) in favor of patients treated with clopidogrel and aspirin. However, when the analysis was limited to the randomized trials, clopidogrel plus aspirin demonstrated less impressive advantage over standard therapy except for a better safety profile (OR 0.46, 95% CI 0.32-0.66; p=0.00002).
Conclusions: According to 30-day death and nonfatal MI rates, the present meta-analysis demonstrates that clopidogrel has a superior clinical efficacy compared to ticlopidine in patients who had undergone successful coronary stenting. In addition a significantly better safety profile than ticlopidine was reported, confirming on a larger scale the findings of the randomized comparative trials.

P3688 Enoxaparin in unstable angina patients who would have been excluded from randomized pivotal trials

J.Ph. Collet[1], G. Montalescot[2], E. Fine[2], J.L. Golmard[3], R. Choussat[2], A. Ankri[4], R. Dumaine[2], D. Thomas[2]. *[1]Hôpital Pitié-Salpétrière, Cardiology, Paris, France; [2]Pitié-Salpétrière, Cardiology, Paris, France; [3]Pitié-Salpétrière, Department of Biostatistics, Paris, France; [4]Pitié-Salpétrière, Department of Haemostasis, Paris, France*

Background: Following ESSENCE and TIMI 11B trials, a large population with UA/NSTEMI is being treated with enoxaparin. However, many of these patients receiving enoxaparin would not have been eligible for these trials. The present study tried to identify and to describe this group of patients and examined the therapeutic options and the 1 month outcomes.
Methods and Results: In our center, all patients with UA/NSTEMI are anticoagulated with subcutaneous enoxaparin and followed-up for 1 month. Among 515 consecutive patients, we identified 174 patients ("EP" group for excluded patients)who would have not been eligible for ESSENCE or TIMI 11B according to 7 major exclusion criteria, including heart failure (n=82), chronic renal failure (creatinine clearance <30 mL/min, n=62), left bundle branch block (n=35), a recent history of stroke (n=20), recent surgery (n=19), cancer (n=20) and acute anemia (n=5). This "EP" group was older, had a higher female/male ratio, had more frequently a past-history of MI or a diagnosis of non-Q MI on admission in comparison patients without any of the exclusion criteria ("NEP" group). Coronary revascularization and the use of GP IIb/IIIa inhibitors were less frequent in the "EP" group than in the "NEP" group (24.7% vs 34.9%, $p<0.01$, and 4.6% vs 11.1%, $p<0.01$, respectively). The distribution of the anti-Xa activity was similar in both groups. Although the "EP" group were at higher risk of bleedings than the "NEP" group, the rates of bleedings (major and minor) at 30 days were similar in both groups (2.3%vs 2.9%, respectively, p=NS). After multivariate analysis, the use of GP IIb/IIIa inhibitors and hypertension were the only independent predictors of bleeding found in the whole population. Compared with the "NEP" group, the group of "EP" had also a higher risk profile for further ischemic events. Indeed, this group had a 4-fold increase rate of death or MI at 30 days (15.5% vs 4.1% for "EP" vs "NEP", respectively, $p<0.01$). After multivariate analysis, the independent predictors of death or MI at 30 days were NSTEMI on admission, creatinine clearance and heart failure.
Conclusion: Patients who do not fit the enrolment criteria of ESSENCE/TIMI 11B are at higher risk of both bleedings and ischemic events. In these patients, enoxaparin with dose-adjustment to creatinine clearance provides adequate anti-Xa levels and no excess of bleeding. However, these patients remain at high risk of recurrent ischemic events. Renal and heart failures were two strong predictors of poor outcome besides a positive troponin test on admission.

P3689 Inhibition of ADP-induced platelet-leukocyte conjugate formation by clopidogrel and AR-C69931MX

R.F. Storey, H.M. Judge, R.G. Wilcox, S. Heptinstall. *University Hospital, Cardiovascular Medicine, Nottingham, United Kingdom*

Background: Platelet-leukocyte interactions are recognised to have pro-inflammatory effects, which may be important in the pathophysiology of ischaemic heart disease. Clopidogrel and the novel intravenous antithrombotic agent AR-C69931MX act at the level of the platelet P2Y12 receptor, which is known to amplify platelet activation, aggregation and other responses including expression of P-selectin, which is the dominant mediator of platelet-leukocyte conjugate formation via interaction with PSGL-1 on leukocytes.
Methods: ADP-induced platelet-monocyte and platelet-neutrophil conjugate formation, as well as P-selectin expression, were studied using hirudin-anticoagulated whole blood and flow cytometry with fluorescent-labelled antibody techniques (anti-CD14-RPE and anti-CD42a-FITC to identify platelet-leukocyte conjugates). Platelet aggregation was measured using whole blood single-platelet counting. We studied the effects of 10 days administration of clopidogrel 75 mg od, aspirin 75 mg od or their combination in 12 healthy volunteers with 2 weeks washout period between phases. The effects of clopidogrel (300 mg loading dose and 75 mg od) in 8 patients undergoing intracoronary stent implantation were assessed with blood sampling prior to and 4-7 days after clopidogrel, with addition of AR-C69931MX 100 nM in vitro before and after clopidogrel administration.
Results: In the healthy volunteer study, ADP (30 μM) induced significant aggregation, P-selectin expression, platelet-monocyte and platelet-neutrophil conjugate formation that were all inhibited by clopidogrel ($p<0.01$ all parameters) but not by aspirin e.g. platelet-monocyte % conjugates 89.1 ± 1.8 before treatment, 59.3 ± 5.2 clopidogrel, 89.6 ± 2.3 aspirin, 53.0 ± 5.2 clopidogrel + aspirin. The same inhibitory effects of clopidogrel were seen in the patient study. AR-C69931MX yielded greater inhibition of aggregation and P-selectin expression ($p<0.05$) than clopidogrel. AR-C69931MX significantly added to the inhibitory effect of clopidogrel on platelet-monocyte conjugate formation (platelet-monocyte % conjugates: before clopidogrel 96.3 ± 0.6, before + AR-C69931MX 63.5 ± 7.0, clopidogrel 80.3 ± 5.1, clopidogrel + AR-C69931MX 61.2 ± 7.2, $p<0.01$).
Conclusions: Inhibition of platelet-leukocyte conjugate formation, via inhibition of platelet P-selectin expression, by clopidogrel and AR-C69931MX may confer therapeutic anti-inflammatory effects in the management of patients with ischaemic heart disease. The greater effects of AR-C69931MX compared to clopidogrel support further clinical trials of this agent.

P3690 The EARLY platelet substudy

P.A. Gurbel[1], M. Roe[1], R.D. Bahr[2], W. Gibler[1], A. Malinin[1], E.M. Ohman[3], V.L. Serebruany[1]. *[1]Sinai Hospital, Baltimore, United States of America; [2]ST. Agnes Hospital, Baltimore, MD, United States of America; [3]University of North Carolina, Chapel Hill, NC, United States of America*

Background: Receptors other than GPIIb/IIIa may mediate leukocyte-platelet-endothelial interactions that obstruct the microvasculature in acute coronary syndromes (ACS) and cause microinfarcts. The effect of eptifibatide on these receptors was investigated in a substudy of the EARLY trial.
Methods: Patients received early(in the Emergency Department, n=27) or late (12-24 hours, n=28) eptifibatide. Ten platelet receptors by flow cytometry and platelet aggregation were measured serially at baseline, and at 3,6,12 and 24 hours after randomization.
Results: Demographics were similar, except that late patients were older. No significant differences were seen in either group for CD 31, CD 63, CD 107a, CD107b, CD 41 (GPIIb/IIIa expression), CD 62p or platelet-leukocyte aggregate formation. PAC-1 (GPIIb/IIIa activity), CD 51/61 (vitronectin receptor)and CD 42b (GPIb)were inhibited by eptifibatide ($p<.05$). See table.

Early data

	ADP (%)		PAC-1 (MFI)	
	Early	Late	Early	Late
B-L	72± 20	80±12	5.8±9	5.5±1.2
3H	7±9*	58±21+	2.2±4*	4.9±2.1+
6H	4±9*	63 ±23+	2.4±1.1*	4.4±1.6+
12H	8±17*	66±26+	2.6±1.1*	3.7±7
24H	30±33*	9±16+*	2.3±4*	3.1±1.4*
	CD 51/61 (MFI)		CD42b (MFI)	
	Early	Late	Early	Late
B-L	11.9±4.4	11.5±5.5	207±60	126±70+
3H	5.9±3.2*	10.8±3.1+	121±40*	140±93
6H	5.6±2.3*	12.4±3.3+	135±73*	117±59
12H	6.1±2.9*	12.9±3.0+	129±62*	155±42
24H	6.0±2.3*	6.2±2.3*	135±82*	107±59

ADP= aggregation by 10u mol ADP, MFI= mean fluorescence intensity, *$p<.05$ vs. baseline, + $p<.05$ between groups, B-L= baseline

Conclusion: 1) In the Emergency Department, early eptifibatide therpay rapidly and profoundly inhibits platelet aggregation. 2) The drug effect on platelet receptors appears limited not only to a reduction in GPIIb/IIIa activity, but also to CD 51/61 and CD 42b inhibition.

P3691 Evidence of platelet aspirin resistance acquisition after a long-term treatment

F.M. Pulcinelli, P. Pignatelli, A. Celestini, F. Violi, P.P. Gazzaniga. *University "La Sapienza", Experimentale Medicine and Pathology, Rome, Italy*

Acetylsalicylic acid is the most commonly used antiplatelet drug in the prevention of atherothrombotic diseases. While the clinical efficacy of aspirin in acute coronary syndrome has been well established, chronic use of aspirin may be not efficacious in preventing cardiovascular events. Here we report for the first time that aspirin resistance is a phenomenon that can appear after a prolonged treatment with this drug. In 150 patients with atherothrombosis maximal percentage and the lag phase of Platelet Aggregation induced by collagen (2 microg/ml) and ADP (2 microM) was performed before and after 2, 6, 12, and 24 months of aspirin treatment were evaluated.
The lag-phase was unmodified in 21% of the patients at 2 and 6 months, in 36% at 12 months and 60% at 24 months compared to the baseline values.
Maximal aggregation was unmodified in 19% of the patients at 2 months, in 23% at 6 months, in 35% at 12 months and 51% at 24 months compared to the baseline values. ADP aggregation was unmodified in 27% of the patients at 2 months in 29% at 6 months, in 34% at 12 months and 53% at 24 months compared to the baseline values. In all patients the response to arachidonic acid was absent during aspirin treatment.
Treatment with ticlopidine (250 mg/die) did not show any change of platelet aggregation during two years of follow-up.
Taken together these data suggest that there are two types of aspirin resistance, one occurring early after aspirin ingestion, another later at least after 6 months of aspirin ingestion. These findings suggest the existence of multiple mechanisms causing aspirin resistance. In conclusion, we showed that prolonged aspirin treatment is associated with progressive restoring of platelet function. Identification of aspirin resistance may be useful to tailor individual therapy in patients with atherothrombosis.

P3692 R-PA and abciximab, r-PA, TNK-tPA and streptokinase: fibrinolytic and haemostatic alterations in myocardial infarction

S. Szabo[1], D. Etzel[2], T. Walter[2], R. Ehlers[2], S. Kazmaier[2], U. Helber[2], H.M. Hoffmeister[1]. [1]*Städtisches Klinikum Solingen, Medizinische Klinik II, Solingen, Germany;* [2]*Medizinische Klinik, Abteilung III, 72076 Tübingen, Germany*

In order to reduce undesirable side-effects, newer thrombolytics should have a high fibrin-specificity. We investigated the effects of the regimen with half dose reteplase (r-PA) & the GpIIb/IIIa antagonist abciximab compared with full dose r-PA, tenecteplase (TNK-tPA) and streptokinase on systemic plasmin and coagulation activation markers (plasmin antiplasmin complexes (PAP), thrombin antithrombin-III (TAT)). 20 (pts.) with acute myocardial infarction had r-PA & abciximab, 18 pts. had r-PA, 10 pts. were given TNK-tPA and 26 pts. received streptokinase; control group: 75 healthy persons.

Streptokinase	13.0±3.7*	49.8±16.8*	49.9±17.0*	23.9±7.1*

*: p<0.05 vs. controls; #: p<0.05 vs. r-PA, ¶: p<0.05 vs. TNK-tPA

The TNK-tPA group had the highest, the streptokinase group the lowest in vivo fibrin-specificity. R-PA & abciximab caused a lower systemic procoagulatory state vs. r-PA alone, however, these effects were more marked compared with TNK-tPA.

P3693 Thrombolytic therapy prior to coronary thrombectomy using the rescue PT catheter in acute myocardial infarction

C. Kuehne, A. Bollmann, D. Husser, R. Fischer, H.U. Klein, J. Molling. *University Hospital, Cardiology, Magdeburg, Germany*

Background: Pharmacological thrombolytic therapy is an established method in the management of acute myocardial infarction with ST-segment elevation. There are, however, no reports showing the safety and efficacy of this approach in conjunction with direct, catheter-based coronary thrombus removal.
Methods and Results: In 42 consecutive pts (mean age 56±9 years, 33 male, 9 female) with acute ST-segment elevation myocardial infarction the Rescue percutaneous thrombectomy (RPT) system (Boston Scientific) was applied to remove fresh (< 12 hours) coronary thrombus. Among those pts, 14 were treated with thrombolytic agents (1.5-2 mio IE streptokinase n=6, 10 U reteplase n=8) prior to the intervention (L+). Their clinical characteristics including age, gender, "door-to-needle"-time and target vessel were similar to the remaining 28 pts without thrombolytic pretreatment (L-). Initial TIMI > 0 flow was observed in 8/14 L+ pts (57%), as opposed to 6/28 L- pts (21%, p=.021). This resulted in a shorter X-ray (12±7 vs 19±8 min, p=.025) and also a trend towards shorter total procedure duration (60±30 vs 77±43 min, p=.145) in L+ pts. After thrombosuction TIMI 2 or 3 flow was present in 8/28 (28%) and 19/28 L- pts (68%), and in 3/14 (21%) and 9/14 L+ pts (64%), respectively (p=ns). There were no procedure related complications in both groups. L+ pts had a shorter hospital stay (3.7±2.7 days) than L- pts (6.7±6.5 days, p=.044).
Conclusions: Thrombolytic therapy prior to catheter-based coronary thrombus removal appears to be safe and effective. A larger prospective, randomized trial assessing this approach seems warranted.

P3694 Safety and efficacy of a new Streptokinase regimen (0.75 MU/10 min) in combination with Enoxaparin in acute myocardial infarction

G. Tatu-Chitoiu, C. Teodorescu, M. Guran, P. Capraru, M. Dan, O. Istratescu-Wolkowski, D. Constantinescu, M. Dorobantu. *Spitalul de Urgenta, Card. Dept., Bucharest, Romania*

Background: Recent data suggested a similar efficacy of the combination between the standard Streptokinase (SK) regimen (1.5 m.u./60 min.) and Heparin (H) with the one between the Standard SK and Enoxaparin (Enox) in patients (pts) with acute myocardial infarction (AMI).
Objective: Safety and efficacy of a new SK regimen (0.75 M.U. infused in 10 min.) in combination with Enox has been compared to the one of the classical combination Standard SK and H.
Methods: A group of 302 pts admitted within the first 6 hours after the onset of the chest pain revealing AMI was divided in two subgroups according to the SK regimen. In subgroup A (147 pts.) a dose of 0.75 MU was infused in 10 min. The first bolus was followed after 50 min. by a new dose of 0.75 MU/10 min. only if no bed-side signs of coronary reperfusion (CR) have been detected These pts. also received Enox i.v. 40 mg. either before or immediately after the end of the first SK bolus and 1 mg/kg every 12 hours for the next 48-96 hours. In subgroup B (155 pts.) the classical SK regimen was used. In these pts. an infusion of 1000 iu/hour of H started immediately after the SK administration and lasted for the next 48-96 hours. All pts. received aspirin. Three noninvasive CR criteria have been used: 1.Rapid cessation of the chest pain. 2.Rapid decreasing of the sum of the ST segment elevations by more than 50% from the initial value. 3.Rapid increasing of the CK and CK-MB with a peak within the first 12 hrs.
Results: The ratio of the CR was 75.5% in subgroup A, significantly higher that the one of 61.9% registered in subgroup B (p=0.016). The in-hospital mortality was 7.48% in subgroup A and 12.25% in subgroup B. Neither stroke nor other major haemoragical events were registered in both subgroups. Symptomatic hypotension was more frequent in patients belonging to the A subgroup (34.6%) as compared to the B subgroup (23.8%)(p>0.05). However hypotension proved to be transient and well controlled in all patients.
Conclusions: Combination between SK 0.75 MU/10 min. plus Enox is safe and leads toward a significant higher ratio of CR and a lower in-hospital mortality as compared to the classical SK regimen plus H.

P3695 Early posthrombolysis lesion pattern, coronary flow and myocardial perfusion in ST elevated infarcted patients: results from the GRACIA trial

F. Fernández-Avilés[1], J.J. Alonso[1], J.M. Duran[1], O. Sanz[1], R.A. Hernandez[2], A. Merchan[3], J.M. Gutierrez[4], A. Bethencourt[5] on behalf of GRACIA group. [1]*University Hospital of Valladolid, Institute of Heart Science (ICICOR), Valladolid, Spain;* [2]*H. Clinico San Carlos, Madrid, Spain;* [3]*H. Infanta Cristina, Badajoz, Spain;* [4]*H. Arquitecto Marcide, El Ferrol, Spain;* [5]*H. Son Dureta, Palma de Mallorca, Spain*

Objective: We analysed basal angiographic data of infarcted and thrombolysed patients included in the interventional arm of the GRACIA trial. Purposes of this subanalysis were: 1) To assess coronary flow and myocardial blush following TIMI classification; 2) to assess the angiographic characteristics of the culprit lesion within 6 to 24 hours after trhombolysis with rt-PA and; 3) to investigate clinical predictors of effective flow after thrombolysis.
Methods: The GRACIA trial included 500 pts randomly assigned to angiography and intervention within 6-24 hours of thrombolysis, or conservative posthrombolysis ischemia-guided approach. We studied the angiographic data from the 250 interventional patients (age: 60±12 years, 87% female), which were obtained 17±6 hours (range 6 to 24 hours) after thrombolysis. Infarction were located in the inferior wall in 57% of patients. The delay between onset of symptoms and thrombolysis was 3.0±1.8 hours. Angiographic evaluation was carried out by an independent core laboratory.
Results: Location of the culprit lesion was: left descending artery: 38%; right coronary artery: 47%; circumflex: 15%; left main: 0.4%. At the time of angiography only 11% of arteries had TIMI 0-I flow and the remaining 89% of patients had TIMI flow III (73%) or II (17%). The blush score was grade 0 in the majority of the arteries (81%), grade 1 in 2 arteries (1%), grade 2 in 3 arteries (1%) and 3 grade in the remaining 17% of arteries. Diameter stenosis of the culprit lesions was 83±18%. Complex morphology was found in 38% culprit lesions. Only 20% of culprit lesions had angiographic evidence of thrombus. Multivariate analysis (logistic regression) of clinical variables showed two independent predictors of operative flow (TIMI II or III): a) the infarct location in the inferior wall (OR: 1.6 CI 95%: 1.01-2.49, p=0.04), and b) the presence of multivessel disease (OR 0.63, CI 95% 0.41-0.98, p= 0.04).
Conclusions: 1) Most pts with AMI had a good myocardial perfusion and effective coronary flow in the angiography performed 6 to 24 hours after thrombolysis; 2) The probability TIMI flow II or III is 60% higher in patients with inferior AMI; 3) the probability of effective flow is 40% lower in pts with multivessel disease.

P3696 Transcutaneous ultrasound enhances coronary thrombolysis. The first human pilot study

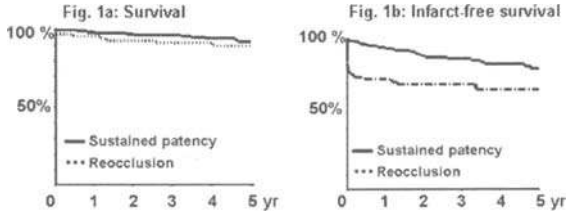
M.G. Cohen[1], E. Tuero[2], J. Bluguermann[3], R. Kevorkian[4], R.J. Siegel[5], M.P. Hudson[6], D. Weaver[6], L.R. Grinfeld[1]. [1]*Hospital Italiano de Buenos Aires, Buenos Aires, Argentina;* [2]*Instituto Cardiovascular de Rosario, Rosario, Argentina;* [3]*Policlinico Bancario, Hemodinamia, Buenos Aires, Argentina;* [4]*Hospital Santojanni, Buenos Aires, Argentina;* [5]*Cedars-Sinai Hospital, Los Angeles, United States of America;* [6]*Henry Ford Hospital, Detroit, United States of America*

Background: Thrombolysis efficacy is limited by moderate patency rates and increased bleeding risk. Animal studies using the combination of transcutaneous low frequency ultrasound and thrombolysis have shown improved patency over thrombolysis alone.
Objective: To assess the safety and feasibility of noninvasive, transcutaneous low frequency ultrasound (Timi3 Systems, Inc, Santa Clara, CA) as adjunctive treatment to thrombolytic therapy for patients with acute myocardial infarction (MI).
Methods: Patients presenting with ST elevation MI within 6 hours of symptom onset, without contraindications for thrombolytic therapy, were enrolled in the study. Patients were treated with reteplase (n=15) or tenecteplase (n=10) and 60 minutes of low-frequency transcutaneous ultrasound applied on the midsternal area within 8±12 min after initiation of fibrinolysis. The primary efficacy endpoint was TIMI grade flow at 90 minutes in the infarct related artery (IRA). All patients were followed for 30 days.
Results: Of the 25 patients enrolled between December 2000 and August 2001, 24 were treated with 60 min of ultrasound. Mean age was 57±10 years; prior MI was present in 4 (16%) patients. Symptom onset to fibrinolytic administration was 193±82 min. The IRA was the LAD in 9 (36%) patients, the LCx in 1 (4%) patient, and the RCA in 15 (60%) with a mean residual stenosis of 92%. At 91±14 minutes, TIMI grade 3 flow was present in 16 (64%) patients, TIMI grade 2 in 5 (20%). None of the patients had TIMI grade 0. ST segment deviation resolution at 90 min after ultrasound in combination with thrombolysis was greater than 50% in 67% of patients. Post-angiography PCI was performed in 13 patients. There were no strokes, reinfarctions or deaths at 30-day follow-up. No major adverse events were associated with adjunctive transcutaneous ultrasound therapy.
Conclusion: Transcutaneous ultrasound therapy and standard thrombolysis are feasible and safe in MI patients. A randomized clinical trial is under way to further assess the efficacy of this novel, non-invasive, non-pharmacologic approach to augmenting thrombolytic therapy.

P3697 Impact of reocclusion on 5-year survival and reinfarction following fibrinolytic therapy: long-term follow-up of the APRICOT-1 trial

M.A. Brouwer[1], P.C. Kievit[1], G. Veen[2], A. Meijer[3], F.W.A. Verheugt[1]. [1]*University Medical Center, Heartcenter, Department of Cardiology, Nijmegen, Netherlands;* [2]*Free University Medical Center, Department of Cardiology, Amsterdam, Netherlands;* [3]*Catharina Hospital, Department of Cardiology, Eindhoven, Netherlands*

Background: In the first three months after successful fibrinolytic therapy, reocclusion has been shown to occur in about 30% of patients. Whereas reocclusion within a week after demonstrated patency has been associated with a twofold increased risk of mortality, the prognostic impact of reocclusion after the acute phase remains to be determined.
Methods: In the APRICOT-1 trial 248 patients < 71 years had fibrinolysis for acute myocardial infarction within 4 hours of symptom onset and a patent infarct artery at angiography < 48 hours. Follow-up angiography and ventriculography was scheduled at three months. Death and reinfarction were recorded using medical charts, telephone contact with the general physician and information from municipal registries.
Results: Reocclusion was observed in 71 patients (29%). Left ventricular ejection fraction increased from 51±10% to 55±11% in patients with sustained patency ($p < 0.01$); in patients with reocclusion the change in ejection fraction was -1.0±1.8% (p=ns). Mean clinical follow-up was 4.3±1.2 years. At five years, survival was 90% for patients with reocclusion compared to 92% for patients with a patent artery at follow-up angiography (fig.1a, p=ns). Death and reinfarction rates were 34% and 20%, respectively (fig.1b, $p < 0.01$).
Conclusion: After demonstrated coronary patency following fibrinolysis for acute ST-elevation myocardial infarction, patients who survived the first 48 hours had an excellent 5-year prognosis. Although reocclusion was associated with a higher risk for reinfarction and impaired left ventricular contractile recovery, the potential adverse impact on long-term survival could not be demonstrated.



P3698 Platelet-monocyte-endothelium interactions: aspects of r-PA versus r-PA and abciximab in acute myocardial infarction

S. Szabo[1], D. Etzel[2], T. Walter[2], R. Ehlers[2], S. Kazmaier[2], U. Helber[2], H.M. Hoffmeister[1]. [1]*Städtisches Klinikum Solingen, Medizinische Klinik II, Solingen, Germany;* [2]*Medizinische Klinik, Abteilung III, 72076 Tübingen, Germany*

Alterations of the fibrinolytic/haemostatic system as well as the involvement of platelets, leukocytes and endothelial cells have been described in acute myocardial infarction. Newer regimen with a thrombolytic and a GpIIb/IIIa antagonist additionally influence these systems.
We investigated the effects of a new combined regimen with $\frac{1}{2}$ dose reteplase (r-PA) and the GpIIb/IIIa antagonist abciximab versus full dose r-PA on CD40, CD40 ligand (CD40L) and CD42b on monocytes in a substudy of GUSTO V; controls: 28 healthy persons.

	0h	90min.	3h	12h	16h
CD40 (monocytes, %); controls 68±2.7					
R-PA	72±4.2	74±3.5	72±4.3	71±4.0	81±2.6
R-PA/abcix.	69±3.4	63±4.1	62±4.2*	74±4.1	73±3.6
CD40L (monocytes, %); controls 5.7±1.2					
R-PA	6.3±2.0	5.6±2.0	4.7±1.9	4.0±2.0	3.9±2.2
R-PA/abcix.	8.8±2.4	7.5±1.5	4.1±0.8#	6.7±2.0	6.1±2.0
CD42b (monocytes, %); controls 44.2±4.8					
R-PA	39.5±7.8	32.6±7.3	25.5±6.1	28.0±9.0	29.3±8.5
R-PA/abcix.	38.0±6.4	34.0±6.5	25.4±4.6¶	39.5±7.7	35.0±6.6

decrease 0h/3h: *: p=0.078, #: p=0.025, ¶: p=0.005

The r-PA/abciximab group showed a marked decrease of CD40-, CD40L- and CD42b-positive monocytes in contrast to the r-PA group. This could be an indicator for more benefical effects of the combined regimen on platelet-induced monocyte activation, platelet-monocyte-endothelial adhesion and on CD40/CD40L associated procoagulatory, proinflammatory and proadhesive effects by monocytes.

P3699 A comparison of efficacy and safety between three streptokinase regimens and front loaded Alteplase in patients with acute myocardial infarction

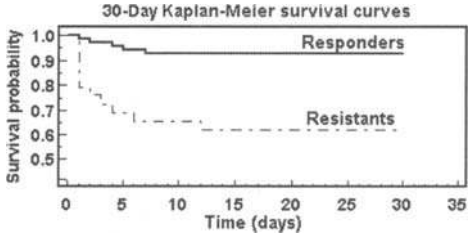
G. Tatu-Chitoiu, C. Teodorescu, M. Dan, M. Guran, P. Capraru, O. Istratescu-Wolkowski, M. Dorobantu. *Spitalul de Urgenta, Card. Dept., Bucharest, Romania*

Objective: In a prospective study we compared the safety and efficacy of the front loaded Alteplase (tPA) regimen (100 mg./90 min) to the one of three Streptokinase (SK) regimens: 1. Infusion of 1.5 M.U./60 min (the SK1.5/60 regimen). 2. Infusion of 1.5 MU/20 min (the SK1.5/20 regimen). 3. Bolus of 0.75 M.U./10 min followed by a new bolus of 0.75 M.U./10 min. after 50-60 min. only if no bed side signs of coronary reperfusion (CR) have been detected (the SK 0.75/10 regimen).
Methods: A group of 440 patients (pts.) admitted within the first 6 hours after the onset of the chest pain revealing acute myocardial infarction (AMI) have been divided in 4 subgroups according to the thrombolytic regimen used: the tPA subgroup (82 pts.); the SK1.5/60 subgroup (121 pts.); the SK 1.5/20 min. subgroup (125 pts) and the SK 0.75 MU/10 min. subgroup (112 pts.). All pts also received heparin (1000 i.u./hour, 48-72 hours) and aspirin.. Three noninvasive CR criteria have been used: 1.Rapid cessation of the chest pain. 2.Rapid decreasing of the ST segment elevation by more than 50% from the initial value. 3.Rapid increasing of the CK and CK-MB with a peak within the first 12 hrs. The incidence of haemorrhagic events, the ratio of CR, and the in hospital mortality were evaluated.
Results: The ratios of the CR were 74.39% in the tPA subgroup, 75.2% in the SK1.5/20 and 75.0% in the SK0.75/10 sbgroup. These ratios proved to be practically equal each other but all were significant higher that the one of 59.5% registered in the SK1.5/60 min. subgroup. (p=0.031, 0.009 and 0.012, respectively). The in hospital mortality was 7.3% in the tPA subgroup, 7.2% in the SK1.5/20, 8.03% in the SK0.75/10 and 12.39% in the SK1.5/60. No significance difference has been registered among the 4 subgroups. One patient in the tPA subgroup and 1 patient in the SK1.5/60 subgroup had signs of ischemic stroke. The incidence of the major haemorrhagic events were 2.4% in the tPA subgroup, 3.3% in the 1.5/60, 3.2% in the SK1.5/20 and 2.6% in the SK0.75/10 (non-significant differences)
Conclusions: Our data suggest that two accelerated SK regimens (SK1.5/20 and 0.75/10) are equally efficient and safe as compared to the front loaded tPA regimen. The classical SK1.5/60 regimen seems to be the weakest one among the three SK regimens tested in this study.

P3700 A lytic test for determination of resistance to streptokinase predicts 30-day survival in patients treated with streptokinase for acute myocardial infarction

K. Al-Shawafi[1], J. Francart[2], A. Robert[2], A. de Meester[3], B. Pirenne[4], J. Col[1]. [1]Saint Luc University Hospital, Cardiology, Brussels, Belgium; [2]Université Catholique de Louvain, Public Health, Brussels, Belgium; [3]Hôpital de Jolimont, Cardiology, Jolimont, Belgium; [4]Hôpital Saint Pierre, Intensive Medicine, Ottignies, Belgium

Background: Streptokinase (SK) remains world-widely used because of its low cost. The survival benefit obtained with SK is not optimal in AMI patients with prior exposure to streptococcal antigen by infection or previous SK treatment. The high anti-SK antibody titers in these patients are neutralizing SK, hamper the thrombolytic response and probably clinical efficacy. The prevalence of SK resistance in candidates for thrombolytic treatment is 9-28% depending on the region. Identification of patients who are potentially resistant to SK before therapy would contribute to prompt selection of an alternative reperfusion strategy. A recent thrombolytic assessment system (TAS) furnished a lytic test for rapid screening for SK resistance.
Objective: To evaluate the predictive value of this lytic test, applied to patients with AMI before treatment with a standard dose of SK, on 30-day survival.
Methods: Hundred consecutive AMI patients were screened with the TAS SK resistance test before the administration of SK, test results were blinded. Each patient, whom was discharged alive, was contacted by telephone to ascertain vital status at 30 days.
Results: There were 71 patients screened as responders and 29 as resistants. Final follow-up was 99%. 30-day survival rate was in favor of responders (94.4%) over resistants (61.9%, p<0.001). The resistants group was older (p=0.004). Age adjusment was done using Cox's regression analysis, survival rate remained in favor of responders (p=0.027); hazard ratio: 3.94 (95% CI 1.17 - 13.27).



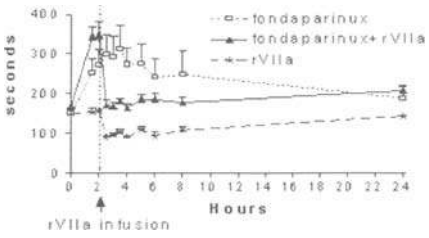
Survival curves.

Conclusion: The 30-day results showed a worse outcome for patients screened to be resistants, and demonstrate that pre-therapeutic determination of resistance to streptokinase can significantly contribute to a better management of patients with AMI.

P3701 Neutralization of the anticoagulant effect of fondaparinux by recombinant activated factor VII in healthy male volunteers

N. Bijsterveld[1], A. Moons[1], B. van Aken[2], R. van Amsterdam[2], H. de Greef[2], R. Peters[1], H. Büller[3], M. Levi[3]. [1]AMC, Cardiology, Amsterdam, Netherlands; [2]Organon, Oss, Netherlands; [3]AMC, Vascular Medicine, Amsterdam, Netherlands

Background: Fondaparinux sodium (Arixtra®), a synthetic selective factor Xa inhibitor, has proved beneficial for treatment of thrombotic disorders. In the context of the use of every anticoagulant drug, bleeding may occur. Therefore we tested the efficacy of recombinant activated factor VII (rVIIa, NovoSeven®) in neutralizing the anticoagulant effect induced by a high dose of fondaparinux in healthy volunteers.
Methods: The study was a randomized, placebo-controlled, three-parallel group trial. Male volunteers were to receive a single subcutaneous administration of either fondaparinux (10 mg) followed by an intravenous bolus injection of rVIIa (90 μg/kg, n=8); or fondaparinux followed by an intravenous bolus injection of placebo (n=4); or placebo followed by rVIIa (n=4). Placebo rVIIa and rVIIa were given in a double-blind fashion two hours after fondaparinux or placebo.
Results: Administration of rVIIa after pretreatment with fondaparinux prevented the decrease in thrombin generation marker prothrombin fragment 1.2 (F1+2) as observed after fondaparinux administration. These in vivo data were supported by the results of two ex vivo thrombin generation tests. The injection with rVIIa, after the treatment with fondaparinux, resulted in a rapid and marked thrombin generation, reflected by the reduction of the time to fibrin polymerization in the thrombin generation assay (figure) and by the induction of endogenous thrombin potential (ETP).
Conclusion: In this trial the inhibition of thrombin generation induced by fondaparinux was rapidly and significantly counteracted by rFVIIa. The overall results suggest that rVIIa is an effective and safe candidate as an antidote for fondaparinux.



Thrombin generation time

P3702 Angiographic and clinical outcomes after coronary artery stenting with glycoprotein IIb/IIIa inhibitors – Is the gender gap closing?

I. Iakovou[1], G. Dangas[2], F. Kuepper[1], Y. Kobayashi[1], D.T. Ashby[1], J.W. Moses[2], M.B. Leon[2], R. Mehran[2]. [1]Cardiovascular Research Foundation, New York, NY, United States of America; [2]Lenox Hill Hospital, Interventional Cardiology, New York, NY, United States of America

Background: Women undergoing percutaneous coronary interventions (PCI) are generally considered at higher early risk compared to men. However, it is unknown whether this risk profile persists also when glycoprotein (GP) IIb/IIIa inhibitors are used during coronary artery stenting.
Methods: We identified 1215 concecutive patients who received GP IIb/IIIa inhibitors during 1852 coronary artery stent implantation procedures. Of these, 322 (26.5%) were women (488 procedures).
Results: Women had similar rates of in-hospital myocardial infarction (MI) (0.9% vs. 0.56, p=0.48) and target vessel revascularization (TVR) (0% vs. 0.22%, p=0.72) compared to men. There were no procedural or in-hospital deaths. No statistically significant differences were observed in bleeding and major vascular complications. One-month major adverse cardiac event (MACE) rate was also similar in both women and men (4.0% vs. 3.3%, p=0.5).

Procedural and in-hospital complications

	Female	Male	P value
Procedures	488	1364	
Angiographic success	488 (100%)	1354 (99.26%)	0.06
Acute stent thrombosis	1 (0.2%)	10 (0.7%)	0.20
Subacute thrombosis	5 (1%)	11 (0.8%)	0.65
Procedural MI	3 (0.93%)	5 (0.56%)	0.48
Q-wave MI	2 (0.62%)	1 (0.11%)	0.11
Non-Q-wave MI	1 (0.31%)	4 (0.44%)	0.10
Procedural CABG	0 (0%)	2 (0.22%)	0.72
Bleeding complications	0 (0%)	3 (0.33%)	0.29
Vascular complications	4 (1.2%)	6 (0.67%)	0.33

Conclusions: In-hospital and one-month outcomes of women undergoing PCI with GPIIb/IIIa inhibitors are similar to those of men.

P3703 Is the clopidogrel effect by patients treated with statins diminished? A flow cytometric evaluation of a possible interaction

B. Günesdogan, H. Neubauer, A. Mügge. *Ruhr-University-Bochum - St. Josef KH, Med. Klinik II - Cardiology, Bochum, Germany*

The thrombocyte function inhibitor clopidogrel is transduced by the cytochrom P450 3A4 into his active metabolite. The same isotype is also responsible for the metabolization of most statins like atorvastatin. We try to answer the question if the clopidogrel linked effect in the thrombocyte function is diminished under a treatment with some statins.
Citrated blood is drawn from patients after stenting (n=20) without a relevant comedication, from patients with atorvastatin medication (n=20) and from patients treated with other statins (pravastatin, fluvastatin) not metabolized via CYP 3A4 (n=10) just before the clopidogrel medication started, 5h after the loading dose (300mg) was taken and 48h later (75mg/d). Between these groups we also separate long term and short term statin treatment.
In not fixed centrifugated blood we examined the CD62P-(p-selectin)-expression of ADP-stimulated (1, 3, 10, 30, 100uM ADP) thrombocytes with a flow cytometer (Beckman-Coulter Epics).
For this three evaluated groups we found till now (n=15) after 48h clopidogrel treatment for the relative inhibition of the CD62P-expression after ADP-Stimulation (with 10, 30, 100uM) following results: clopidogrel-monotherapy 75.4%/74.9%/74.1%, atorvastatin 66.7%/65.4%/64.1% and statins like pravastatin 74.9%/75.0%/79.6%.
It seems that - at least in a special group of patients - the comedication with some statins (like atorvastatin) reduces the effect of clopidogrel.

P3704 Clot disruption without thrombolytic agent – Combination of low frequency ultrasound and levovist

K. hagisawa[1], T. Nishioka[2], B. Takase[1], T. Matsui[1], A. Kurita[1]. [1]*Japan, Naitonal Deense Medical College, Division of Biomedical Engineering, Tokorozawa, Japan;* [2]*Japan SDF Central Hospital, First department of internal medicine, Tokyo, Japan*

Background: We have reported that ultrasound (USD) thrombolysis is effective enough to recanalize the acute thrombotic occlusion in vivo. However, the combined thrombolytic effect of Levovist and USD has not been compared with that of the tissue plasminogen activator. We investigated the rate of clot weight reduction in vitro to evaluate the enhancing effect of Levovist with high and low frequency USD. Methods: Fresh whole blood clots from normal volunteers were placed in a test tube containing 2ml fresh human plasma and simulated clinical dosage of monteplase or Levovist at 37C. Clots mixed with monteplase were incubated for 30 minutes and clots mixed with Levovist were exposed to 1MHz or 27kHz continuous wave USD for 30 minutes and 5 minutes in a bath filled with degassed water. Results: After 30minutes of 1 MHz USD exposure with Levovist, only 11.3±5.4% of clot weight reduction was observed. However, 5 minutes of 27 kHz USD exposure in combination with Levovist resulted in 28.6±5.2% of clot weight reduction, which was similar to that of 30 minutes incubation with monteplase (31.6±11.8%). Conclusion: Combined treatment with Levovist and low frequency (27 kHz) ultrasound showed similar degree of thrombolysis to tissue-plasminogen activator in a shorter period of time (5 minutes vs. 30 minutes).

P3705 ASS, beta blocker and angiotensin-converting enzyme inhibitors as an initial therapy for acute myocardial infarction: results from the Berlin myocardial infarction registry

S. Hoffmann[1], A. Mohadjer[1], B. Maier[2], M. Röhnisch[3], A. Kuckuck[4]. [1]*Vivantes Klinikum am Urban, Cardiology, Berlin, Germany;* [2]*Inst. of Public Health, TU-Berlin, Berlin, Germany;* [3]*Vivantes Klinikum Hellersdorf, ICU, Berlin, Germany;* [4]*Vivantes Klinikum Wenckebach, Cardiology, Berlin, Germany*

Early reperfusion therapy (RT) improves the prognosis of patients (pts) after acute myocardial infarction (AMI). But how important is the early initial therapy with Aspirin (ASS), Beta Blockers (BB) and ACE inhibitors (ACE)?
Method: Using data from the Berlin Myocardial Infarction Registry (BMIR) on 2945 pts with AMI in 1999/2000, the number and mode of performed reperfusion therapy (RT) and the kind of initial medical therapy with ASS, BB and ACE as well as their combination and their influence on hospital mortality (HM) were examined. Adjustment was made for statistically relevant characteristics like age, gender, congestive heart failure and co-morbidity.
Results: RT was performed in 1741 pts (59%). Unadjusted HM in this group of pts was 8,6% (150). The unadjusted HM was significant higher if RT was not performed (19,3%/232 pts; p<0,05). 2703 pts (91,8%) were treated initially with ASS, 67,5% with BB and 50% with ACE. 37,4% received the combination of all the three agents. Unadjusted HM in this group was 5,9%.
Results of a multivariate regression analysis on influence of initial therapy on HM showed that improved survival of pts receiving RT was associated with the initial therapy of BB (OR=0,27, 95% CI: 0,15-0,5), ACE (OR=0,44, 95% CI: 0,2–0,7) and the combination therapy (OR=0,44, 95% CI:0,23-0,85). Survival of pts without RT was also improved with the therapy with ASS (OR=0,36, 95% CI:0,21-0,6), BB (OR=0,46, 95%CI:0,32-0,68), ACE (OR=0,51, 95% CI:0,35-0,75) and their combination (OR=0,52, 95% CI:0,33-0,82).
Conclusion: The initial therapy with ASS, BB, ACE reduces HM significantly. This reduction is independent of early reperfusions therapy. Combination therapy is used only in one third of pts with AMI. These data underline the important role of the concomitant medication in pts with AMI.

P3706 Reduction of hospital mortality in patients with ST-segment elevation myocardial infarction receiving IIb/IIIa antagonists: results of the ACOS-registry

A K. Gitt[1], R. Schiele[1], H. Wienbergen[1], T. Heer[1], C. Meisenzahl[1], M G. Gottwik[2], K. Bestehorn[3], J. Senges[1] on behalf of the ACOS-Study-Group. [1]*Herzzentrum Ludwigshafen, Cardiology, Ludwigshafen/Rhein, Germany;* [2]*Cardiology, Klinikum Nürnberg Süd, Nürnberg, Germany;* [3]*MSD, Haar, Germany*

Background: The benefitial effect of IIb/IIIa-recpetor antagonists (IIb/IIIa) has been proven in randomised trials on acute coronary syndromes (ACS). Little data exist on the frequency of IIb/IIIa use and its influence on outcome of patients with acute ST-elevation myocardial infarction (STEMI) in clinical practice.
Methods: Since June 2000 consecutive patients (pts) with ACS have been enrolled into the ACOS-Registry (Acute Coronary Syndrome, 154 hospitals) in Germany. We analysed the prospective data of STEMI-pts with and without treatment with IIb/IIIa to identify the impact of this treatment on hospital outcome.
Results: Out of 9065 consecutive pts with ACS, 4205 (46%) presented with STEMI, 1520 of these pts (36%) were treated with IIb/IIIa. Determinants for the use of IIb/IIIa in STEMI were prehospital delay < 4 hours (OR 1.31, 1.07-1.62) and the performance of primary PTCA (OR 5.59, 3.29-6.40). Prior STEMI or concomitant diseases (hypertension, diabetes) did not influence the decision. STEMI pts treated with IIb/IIIa were younger and already had received prior PTCA more often than pts who were not treated with IIb/IIIa.

Outcome dependent on treatment

	STEMI with IIb/IIIa	STEMI without IIb/IIIa
Age (years)	63	66
Prior PTCA	8,2%	5,3%
Hypercholesteremia	48,1%	42,6%
Diabetes	21,8%	26,9%
Thrombolysis	5,0%	29,8%
PTCA	60,0%	22,9%
Stent (relative to PTCA)	81,8%	74,6%
Hospital mortality	6,2%	11,2%

p<0,001 for all parameters

After adjusting for differences in baseline characteristics and acute reperfusion therapy, the use of IIb/IIIa in STEMI pts was associated with a 33% reduction of hospital mortality (OR 0.67, 0.43-0.92). The use of IIb/IIIa decreased the length of hospital stay (OR 0.65; 0.53-0.80)
Conclusion: The use of IIb/IIIa in acute STEMI was associated with an additional 33% reduction of hospital mortality on top of the benefit of acute reperfusion therapy and with a shorter hospital stay.

P3707 Tissue factor transfer to platelets in acute myocardial infarction

D. Bonderman[1], J. Jakowitsch[2], C. Adlbrecht[2], A. Teml[2], W. Mosgoeller[3], G. Maurer[2], Y. Nemerson[4], I.M. Lang[2]. [1]*General Hospital, Cardiology, Vienna, Austria;* [2]*General Hospital, Cardiology, Vienna, Austria;* [3]*Institute for Molecular Oncology, Vienna, Austria;* [4]*Mount Sinai School of Medicine, Thrombosis Research, New York, United States of America*

Background: Current data indicate that acute myocardial infarction (AMI) results from local plaque rupture and subsequent platelet adhesion/aggregation in the course of a systemic inflammatory state. One of the known proteins associated with this condition is tissue factor (TF), a potent initiator of the coagulation cascade. Because in vitro activated platelets have been shown to take up TF from leukocytes, we analyzed the TF content of circulating platelets from patients with AMI.
Methods and Results: Venous blood from 12 AMI patients with <6 hours of chest pain was collected in the catheter laboratory prior to administration of glycoprotein IIb/IIIa antagonists. Blood samples from 6 patients with normal coronary arteries served as controls. TF antigen levels associated with 10e+9 washed and freeze-thawed platelets per ml were significantly higher in AMI patients (22.9±12.6pg/ml) than in controls (3.7±5.9pg/ml, p=0.003). In contrast, TF antigen levels in platelet poor plasma of AMI patients (141.3±139.0pg/ml) were not different from controls (111.1±67.50pg/ml, p=0.488). Immunoelectronmicroscopy utilizing a monoclonal antibody directed against TF allowed the localization of TF to the alpha-granules. No TF mRNA was detectable in platelets, while megakaryocytic cell lines expressed various amounts of TF mRNA.
Conclusion: Our data show that platelets incorporate TF in vivo, thereby potentially quenching TF molecules from the circulation. These findings suggest a novel role for platelets in AMI.

DRUG EFFECTS ON BLOOD COAGULATION AND VESSELS

P3708 Simvastatin inhibits leukocyte-endothelial cell interactions during septicemia by staphylococcus aureus alpha-toxin

D. Pruefer[1], J. Makowski[1], M. Dahm[1], H. Oelert[1], U. Sibelius[2], U. Grandel[2], F. Grimminger[2], M. Buerke[3]. [1]*University Hospital, Cardiothoracic and Vascular Surgery, Mainz;* [2]*Justus von Liebig-University, Dept. of Medicine II, Giessen;* [3]*Dept. of Medicine II - Cardiology, Mainz, Germany*

Simvastatin, a HMG-CoA reductase inhibitor (statins) has been shown to lower serum cholesterol-levels in clinical use. Moreover, statins exert beneficial effects in vascular diseases, where leukocyte rolling, adherence, and subsequent transmigration through the endothelial wall in the microcirculation are key steps in the inflammatory response. The aim of the study was to determine if pretreatment with simvastatin attenuates staphylococcus aureus-alpha toxin induced increase in leukocyte-endothelial interactions during exotoxemia. The effects of simvastatin on leukocyte-endothelial cell interactions were observed by intravital microscopy in the rat mesenteric microcirculation. Simvastatin (50 or 100μg/KG) was administered 18h before study. Acute endothelial dysfunction of the mesenteric microcirculation was induced by bolus administration of 40 μg/kg staphylococcus aureus alpha toxin. Exotoxemia induced by staphylococcus aureus alpha-toxin resulted in a significant and time-dependent increase in leukocyte rolling, leukocyte adherence, transmigration of leukocytes, and P-selectin expression on the vascular endothelium compared to control rats. In contrast, pretreatment with simvastatin significantly inhibited inflammatory-induced leukocyte rolling from 70±12 to 18±5 cells/min ($p<0.01$) and adherence from 14±4 to 4±1.5 cells ($p<0.05$) along the venular endothelium of the rat mesentery. In addition, simvastatin pretreatment significantly inhibited transmigration of leukocytes from 10.5 ± 1.2 to 3.5 ± 0.8 ($p<0.05$) cells through the microvascular endothelial wall. Similarly, P-selectin-neutralizing monoclonal antibody significantly inhibited these inflammatory interactions. Immunohistochemical detection of endothelial cell adhesion molecul P-selectin showed a 50% decrease in endothelial cell surface expression following simvastatin pretreatment and stimulation with staphylococcus aureus alpha-toxin.
These results clearly demonstrate that simvastatin potently ameliorates exotoxin-induced leukocyte-endothelial cell interactions associated with sepsis, or endocarditis in clinically relevant doses. Statin treatment may have a therapeutic role in attenuation of vascular activation and injury under exotoxin challenge.

P3709 Platelet function varies according to body mass index in patients undergoing percutaneous coronary intervention. Should clopidogrel loading-dose be weight adjusted?

D.J. Angiolillo[1], A. Fernandez-Ortiz[2], E. Bernardo[1], C.F. Barrera[1], M.E. Viveros[1], S. Vazquez[1], H. Soto[1], C. Macaya[3]. [1]*Cardiovascular Research Laboratory,* [2]*Coronary Care Unit,* [3]*Invasive Cardiology Unit, Hospital Clinico San Carlos, Madrid, Spain*

A 300 mg loading-dose regimen of clopidogrel at intervention time is widely used as an adjunct antithrombotic therapy to reduce the early risk of acute coronary thrombosis following coronary stent implantation (STI). At difference of other drugs used during STI, such as heparin and GP IIb/IIIa inhibitors, loading-dose of clopidogrel is not weight adjusted and few data are available on which is the most effective loading-dose regimen. Methods: To assess whether platelet response to STI may be influenced by weight, we studied 31 consecutive pts undergoing STI. In all pts we assessed body mass index (BMI) determined as weight/height^2 (kg/m^2). All pts were on treatment with aspirin (100 mg/day) and received a 300 mg loading-dose of clopidogrel at intervention time. During intervention 100IU/kg of heparin was administered. Pts receiving GP IIb/IIIa inhibitors were excluded. Platelet function was evaluated as percentage of platelet aggregation (%PA) upon stimuli with ADP (6μM) and collagen (6μg/mL) at baseline and 24 hrs after intervention using light transmittance aggregometry. According to the %PA upon 6μM ADP stimuli 24 hrs after STI, pts were divided into two groups: G1 (%PA >30%) and G2 (%PA <30%). Cut-off value of 30% was the median value of our study population and it is a widely used cut-off clinical value to assess platelet inhibition. Time point of 24 hrs is crucial for early coronary thrombosis and at this time full effect of loading-dose of clopidogrel should be observed. Results (mean±SD): G1 and G2 were composed of 13 (10 men; age:63±7y) and 18 (17 men; age:62±11y) pts, respectively. %PA upon ADP stimuli 24 hrs after STI was 52,92±16,8% in G1 and 18,67±7,6% in G2 ($p<0.001$). G1 presented a greater platelet aggregation than G2 upon stimuli with collagen 24 hrs after STI (55,05±26,34% vs 35,88±20,91%; p=0.032). No differences in platelet aggregation with ADP (54,76±24% vs 44,91±11,24%; p=0.19) or with collagen (47,10±16,83% vs 42,39±16,32%; p=0.44) were observed at baseline between G1 and G2. G1 pts were characterized by a greater BMI than G2 pts (28,14±2,9 kg/m^2 vs 25,8±3,2 kg/m^2; p=0.048). No difference in platelet count, clinical status, or risk factors between the two groups was observed. Conclusions: A lower platelet inhibition is observed 24 hours following STI in pts with a greater BMI. Such data suggest that pts with a higher BMI may need a greater loading-dose of clopidogrel than that commonly used in clinical practice. Assessment of platelet function in larger patient population using different loading-dose regimens are necessary to confirm this hypothesis.

P3710 Previous duration of out-hospital oral anticoagulation in patients hospitalised for haemorrhagic complications

M.A.T.I.C. Gordana, B. Stefanovic, P. Mitrovic, J. Perunicic, B. Terzic, Z. Vasiljevic. *Clinical Center of Serbia, Institute of Cardiovascular Diseases, Beograd, Yugoslavia*

Studies which followed patients(pts) at oral anticoagulant therapy(OACT) had shown that frequency of hemorrhagic complications(HC) was highest in the first months of out-hospital OACT use.The aim of this study is to analyse previous duration of out-hospital OACT use in pts hospitalised for HC of this therapy. Material and method: We studied 78 pts hospitalised with the HC of OACT, at the Emergency Center in Belgrade, during 9 years(1989-98). The most frequent indications for out-hospital OACT use were mechanical prosthetic valve(in 38.5% pts), previous myocardial infarction(25.6%) and atrial fibrillation(17.9%). All studied pts were hospitalised because of the need for transfusion(Hgb less than 90g/l) and/or because of the value of INR at the onset of HC(mean INR was 10.5±8.7). The most frequent HC were skin and/or sceletal muscle hemathomas, gastrointestinal bleeding and hemathuria. The necessity of hospitalisation determined these HC as major bleeding events. All patients survived.
Results: Before the onset of HC, duration of out-hospital OACT use was from 2 days to 20 years, 2.5 years on average. The table shows frequencies of pts with different durations of out-hospital OACT use at the onset of HC.

	OACTuse timing										
	1st month	2nd month	3rd month	3rd-6th month	6th-12th month	2nd year	3rd year	3rd-5th year	5th-10th year	10th-15th year	15th-20th year
% Pts	23	17	3	8	8	13	8	8	9	1	4

Conclusion: In 78 pts with major HC of OACT, 23% of these HC occurred in the first month and 43% occurred in the first three months of out-hospital OACT use. This gets along with previous conclusions that HC are the most frequent at the begining of OACT use.

P3711 Selective serotonin reuptake inhibitors yield additional antiplatelet benefit in patients with heart failure treated with antecedent aspirin

V.L. Serebruany[1], A.H. Glassman[2], A. Malinin[1], D.C. Sane[3], C.M. O'Connor[4]. [1]*Johns Hopkins University, Sinai Hospital, Baltimore;* [2]*Columbia University, New York;* [3]*Wake Forest University School of Med., Winston-Salem;* [4]*Duke University, Durham, United States of America*

Background: Clinical depression has been identified as an independent risk factor for increased mortality in patients following acute coronary events. Enhanced platelet function has been suggested as the mechanism responsible for this adverse association, and participate in thrombotic events in patients with congestive heart failure (CHF). We sought to determine whether antecedent therapy with selective serotonin reuptake inhibitors (SSRI's) would affect platelet activity in such patients.
Methods: Eighty-eight patients with LVEF<40%, NYHA class II-IV were analyzed. Twenty-three patients (26%) were chronic SSRI users (SSRI+), and sixty-five patients were free from SSRI therapy (SSRI-) and served as internal controls. Demographics were similar between groups, except higher prevalence of diabetes, and incidence of previous myocardial infarction in the SSRI+ patients. SSRI+ group was treated more extensively. Platelet characteristics were assessed by aggregometry (conventional-, and whole blood); shear – induced activation, expression of 10 surface receptors, and formation of platelet-leukocyte conjugates by flow cytometry.
Results: SSRI+ patients exhibited a substantial decrease in platelet activity when compared with the SSRI- group which was significant for ADP- (p=0.001), and collagen-induced (p=0.02) aggregation, and the expression of PECAM-1 (p=0.03), GPIb (p=0.03), GP IIb/IIIa antigen (p=0.02), GP IIb/IIIa activity with PAC-1 (p=0.04), and P-selectin (p=0.02). Formation of platelet-leukocyte microparticles was also significantly reduced (p=0.01) in the SSRI+ group.
Conclusion: Despite chronic aspirin use, therapy with SSRI's yielda extra antiplatelet protection in patients with CHF. The inhibitory effects of SSRI's on platelet function observed in our study may be relevant to the association between treatment of depression and improved outcomes not only in patients with ischemic heart disease, but with CHF as well. Recognizing the universal antiplatelet properties of SSRI's, further clinical trials should elucidate the potential benefits of SSRI's in multiple vascular thrombotic conditions, including growing CHF population.

P3712 Effect of low molecular weight heparins (LMWH) use on inflammatory parameters in subacute phase of acute coronary syndromes

G H. Antonakoudis, H G. Antonakoudis, A P. Potamianou, I A. Goudevenos, G P. Vyssoulis, C G. Zouras, E S. Tsiroglou, C G. Christacos. *Asclepeion Hospital, Cardiac, Athens, Greece*

Introduction: LMWH are widely used in acute coronary syndromes (ACS) treatment. Inflammatory response plays a significant role both in pathogenesis and prognosis of ACS while cytokines represent well accepted inflammatory markers. Aim of this study was to investigate possible beneficial effects of prolonged LMWH use on levels of inflammatory cytokines Interleukin-6 (IL-6), Interleukin-2 (IL-2) and Tumor Necrosis Factor á (TNFá) in subacute face of ACS.
Methods: Levels of IL-6, IL-2 and TNFá were measured in 30 pts with ACS at day of hospital discharge. After that study population was randomized in two groups of 15 pts each. In Group A LMWH home treatment continued for three weeks additionally to standard antiischaemic therapy (nadroparin, enoxaparin and dalteparin were used in lower dose to that usually used in acute face treatment) while in Group B only the standard therapy was given. At the end of the study levels of IL-6, IL-2 and TNFá were measured in all patients. Found values were compared to that at the beginning and comparison among two Groups was also performed. Compliance to LMWH therapy was checked by anti-Xá measurement.
Results: IL-6 was decreased in Group A (12.5 ± 7.0 vs 9.4 ± 4.5 pg/ml, p: NS) while it was increased in group B (10.3 ± 4.3 vs 14.8 ± 11.7, p: NS). It is important that IL-6 was decreased significantly in Group A as compared to Group B (-3.4 ± 7.8 vs 4.5 ± 10.5, p: 0.04). IL-2 was also decreased in Group A (0.268 ± 0.501 vs 0.122 ± 0.222 pg/ml, p: NS) while it was almost unchanged in Group B (0.090 ± 0.086 vs 0.090 ± 0.138, p: NS). No difference was found among two Groups (0.146 ± 0.538 vs 0.0002 ± 0.149, p: NS). TNFá was decreased in Group A (31.6 ± 56.2 vs 20.0 ± 18.3 pg/ml, p:NS) and it was decreased significantly in Group B (17.6 ± 38 vs 14.1 ± 2.9, p:0.005). However there was no difference among two Groups (-11.5 ± 38.3 vs −3.4 ± 4.0, p: NS). Mean anti-Xá activity in Group A at the end of the study was 0.57 ± 0.12 UI/ml (range 0.28-0.88 UI/ml)
Conclusions: Results of this study indicate a possible beneficial effect of prolonged LMWH use in subacute face of ACS on levels of inflammatory cytokines especially on IL-6, which is considered as the most important cytokine involved in ACS pathophysiology. However further investigation is needed to confirm if LMWH really have any anti-inflammatory effect beyond their anticoagulant effect.

P3713 Effects of antihypertensive monotherapy on plasma levels of pituitary adenylate cyclase activating polypeptide-38 in hypertensive subjects

J. Elefsiniotis, C. Tsioufis, E. Economou, M. Toutouza, C. Stefanadis, P. Toutouzas. *Hippokration, University of Athens, Department of Cardiology, Melissia, Greece*

Hypertension is a major risk factor for cerebrovascular disease. Pituitary adenylate cyclase activating polypeptide-38 (PACAP-38) is a neuropeptide that produces dose-related, non-endothelial depended dilation of the cerebral vasculatore and neurotrophic-neuroprotective action in the ischemic neurons. The aim of this study was to evaluate the effect of different types of antihypertensive treatment on plasma levels of PACAP-38 in patients (pts) with mild to moderate essential hypertension.
Methods: Forty-nine pts with mild to moderate essential hypertension(HS), never treated before, with no evidence of any other acute or chronic health problem, were evaluated for plasma levels of PACAP-38 (measured by RIA) before and six months after antihypertensive treatment and compared to the corresponding levels of 10 age-,sex-,height- and weight- matched healthy volunteers [control group(CS)]. HS pts were divided in 4 groups (according to their treatment) matched for blood pressure(BP), left ventricular mass index (LVMI), total peripheral resistancies(TPRs), age, sex, weight and height: group A (14/49) was treated with moxonidine, group B (14/49) with perindoprilat, group C (12/49) with amlodipine and group D (9/49) with diltiazem, as monotherapy.
Results: All BP, LVMI, TPRs were found to be normalized after six months antihypertensive treatment in all groups. Comparing plasma levels of PACAP-38 (pg/ml), before and after therapy we found: group A, 20±7 vs. 51±13(P<0,05), group B, 25±7 vs. 25±10 (P=NS), group C, 25±9 vs. 46±20(P<0,05), group D, 23±8 vs. 37±13 (P<0,05) and CS 64±21 vs. 64±19 (P=NS). Only pts in group A, after therapy, were not found significantly different in PACAP-38 levels, as compared to the CS (P=NS).
Conclusion: Six months antihypertensive monotherapy with the I1-imidazoline agonist moxonidine, the dihydropyridine calcium antagonist amlodipine and the non-dihydropyridine calcium antagonist diltiazem resulted in significant elevation in PACAP-38 plasma levels of HS and in this context may all provide neurotrophic-neuroprotective action.

SOCIAL ASPECTS OF CARDIOVASCULAR DISEASE

P3714 How certain can we be when generalizing from the results of clinical research to routine practice?

J.L. Cox, D.E. Johnstone on behalf of the ICONS Investigators, Halifax, Nova Scotia, Canada. *QEII Health Sciences Centre, Medicine (Cardiology), Halifax, Canada*

Background: Randomized controlled trials have been the cornerstone of much clinical research, yet they have commonly excluded as many as 90% of patients for whom the intervention might be used in routine practice. Consequently, generalizability is often an issue when using clinical trial results to estimate outcome probabilities in usual care. We sought to assess whether similar limitations might pertain to the relatively larger proportion of patients consenting to passive follow-up in observational population-based studies. Methods: We compared the demographic and clinical characteristics of the 3305 patients (41.1%) consenting (C) to long term observational follow-up in the baseline phase of a population-wide cardiovascular disease management study (Improving Cardiovascular Outcomes in Nova Scotia (ICONS) [Oct 15/97-Oct 14/98]) versus the 4737 who were not consenting (NC). Results: In virtually every instance, marked differences were seen in C vs NC. Examples include mean age (63.7 vs 71.0 years, p<0.00001), gender (35.8% vs 47.5% female, p<0.00001), and history of hyperlipidemia (43.9% vs 23.0%, p=0.0047), diabetes (24.7% vs 26.3%,p=0.1185), hypertension (49.8% vs 47.4%,p=0.0411), and smoking (60.7% vs 48.1%,p<0.00001). Other important differences included prior CHF (10.5% vs. 21.5%), prior MI (35.0% vs. 27.9%), previous stroke (5.4% vs. 8.7%), and previous revascularization (24.5% vs. 12.9%), all of which were significant at a p<0.00001 level. Marked differences in outcome, including 12 month mortality (2.8% for C and 16.3% for NC, p<0.00001), were noted as well. Conclusion: Generalizability is a pervasive problem in clinical research, even when consent rates are high. We suspect that even where "representative sampling" is applied, individual willingness to participate can bias findings. Society will need to balance protection of individual rights to privacy against the need to understand the epidemiology of disease and its treatment if assessments of patient management and outcomes are to progress beyond the limited insights that can be provided by administrative data.

P3715 Losartan reduces the burden of ESRD: public health implications from the RENAAL study for the European Union

W.C. Gerth[1], T. Hannedouche[2], A. Martinez-Castelao[3], G. Remuzzi[4], G.C. Viberti[5], G. Nocea[6], G.W. Carides[6]. *[1]Merck & Co., Inc., Worldwide Outcomes Research, Whitehouse Station, United States of America; [2]Civil Hospital, Strasbourg, France; [3]Hospital De Bellvitge, Nephrology Department, Barcelona, Spain; [4]Istituto di Ricerche Farmacologiche, Laboratori Negri Bergamo, Bergamo, Italy; [5]KCL Guy's Hospital, Diabetes, Endocrinology & Internal Med, London, United Kingdom; [6]Merck & Co., Inc, Worldwide Outcomes Research, Whitehouse Station, United States of America*

Background: Type 2 diabetes is the leading cause of end-stage renal disease (ESRD) in most industrialized countries in Europe. The RENAAL (Reduction in Endpoints in NIDDM with the AII Antagonist Losartan) Study was a randomized, double-blind, placebo-controlled, multi-national clinical trial of losartan versus placebo on a background of non-ACE/non-AIIA conventional antihypertensive therapy designed to evaluate the renal protective effects of losartan in 1,513 patients with type 2 diabetes and nephropathy. Losartan reduced the incidence of doubling of serum creatinine, ESRD, or death by 16% (p=0.024)and the onset of ESRD defined as the initiation of dialysis or renal transplantation by 28% (p=0.002).
Objective: To extrapolate the potential effect of losartan on the burden associated with ESRD over 3.5 years in the European Union (EU).
Methods: New ESRD cases avoided is calculated by combining type 2 diabetes population estimates for the EU with the percent absolute risk reduction of ESRD (6.1%: 95% CI 1.1 to 10.9; p=0.015) observed in RENAAL over 3.5 years. The number of days each patient experienced ESRD was defined as the length of time from onset of ESRD until the minimum of death or study end. Compared to placebo, losartan reduced the number of days with ESRD by 33.6 (95% CI: 10.9 to 56.3, p=0.004) per patient at risk over 3.5 years. ESRD-free years is calculated by combining the population estimate with the ESRD-free days divided by the number of days in a year (365.25).
Results: EUROSTAT (2000) reports 17.1 million individuals with diabetes in the EU. An estimated 700,000 are diagnosed type 2 diabetics with proteinuria (urine albumin/creatinine >= 300mg/g). Extrapolating the results of RENAAL to these patients we may expect the addition of losartan to the treatment regimen of these patients to lead to a reduction of 42,700 cases of ESRD and 64,400 fewer years with ESRD over 3.5 years.
Conclusion: Treatment with losartan not only reduced the incidence of ESRD, but can also result in a substantial reduction in the burden of ESRD in the European Union.

P3716 Comparison of the Zung self rating depression scale in patients randomised to coronary artery bypass grafting or percutaneous coronary intervention: results from the SoS trial

J. Booth[1], T. Clayton[2], R.H. Stables[3], F. Nugara[4], P. Währborg[5] on behalf of SoS Investigators'. [1]*Royal Brompton & Harefield NHS Trust, London, United Kingdom;* [2]*Hygiene & Tropical Medicine, London School of, London, United Kingdom;* [3]*Cardiothoracic Centre, Liverpool, United Kingdom;* [4]*Royal Brompton & Harefield Hospital, London, United Kingdom;* [5]*Sählgrenska University Hospital, Göteborg, Sweden*

Background: Psychological depression has a high prevalence in patients with coronary artery disease and has been reported as an independent predictor of clinical events. We compared symptoms of depression in patients treated with coronary artery bypass grafting (CABG) or percutaneous coronary intervention with stents (PCI).

Methods: In the SoS Trial 988 patients were randomised to CABG or PCI from 53 centres in Europe and Canada. Patients were considered eligible if they were considered suitable by both the surgeon and the interventionist for coronary revascularisation. Depression was assessed with the Zung Self Rating Questionnaire which has 20 items describing depressive symptoms. The questionnaires were translated into the local language and administered at baseline, 6 and 12 months of follow up. The results are presented as a score between 25 to 100. Patients with scores less than 50 are considered not depressed, between 50 to 60 mildly depressed, over 60 moderately depressed and over 70 severely depressed.

Results: Of the 988 patients randomised into the trial 90.8% completed the Zung at baseline and at least one follow up: CABG 456, PCI 441. The mean score at 6 months was 46.0 in the PCI group versus 44.5 in the CABG group, difference 1.4, 95% CI -0.1 to 2.9, p=0.066. At 12 months the score was 45.3 in the PCI group versus 44.6 in the CABG group, mean difference 0.7, 95% CI -0.9 to 2.2, p=0.41. Both groups showed a small decrease in score at 6 months and 12 months compared to baseline (see table 1). Adjusting for age and beta blockers made no difference to results.

Table 1: Zung mean change from baseline

Mean change (SE)	PCI	CABG	Mean difference (95% CI)	p-value
6 months	-1.5 (0.5)	-4.0 (0.5)	2.0 (0.7 to 3.3)	p=0.004
12 months	-2.2 (0.5)	-4.0 (0.5)	1.3 (-0.0 to 2.6)	p=0.054

Mean change from baseline to 6 and 12 months is shown. Mean difference is estimated for the mean in PCI group minus the mean in the CABG group using analysis of covariance adjusted for baseline values

Conclusion: Mean scores suggest that depression is not a major factor of patients enrolled in the SoS trial. Patients in both group have similar Zung index scores at 6 months and 12 months and show improvement from baseline but the change from baseline is greater in the CABG group.

P3717 Relation between clinical features and psychological factors in women with coronary heart disease

C. Pizzi[1], O. Manfrini[1], M. Metalli[2], T. Aranzulla[1], R. Bugiardini[1]. [1]*University of Bologna, Med. Intern., Cardioangiol., Epatol., Bologna, Italy;* [2]*Imola, Ospedale Nuovo, Bologna, Italy*

Background: Although psychological factors including anxiety, depression, and somatic concerns have been suggested to be a possible cause and/or a trigger of coronary heart disease in women, the evidence supporting this hypothesis is still controversial. The present study was undertaken to assess the relation of psychological status with clinical symptoms in 92 consecutive women presenting with chest pain and inducible ischemia, as shown by exercise stress testing and reversible myocardial perfusion abnormalities.

Methods: All pts underwent quantitative coronary arteriography and 24-hrs ambulatory ECG recording. 22 pts (Gr1) showed normal or almost normal coronary angiograms (maximal stenosis <20%). The other 70 pts (Gr2) were found to have CAD. Psychological profiling was evaluated by the Beck Depression Inventory, Hamilton Anxiety Rating Scale (HAMA), State-Trait Anxiety Inventory (STAI Y-1 and Y-2) and State-Trait Anger Expression Inventory (STAXI).

Results: The scale measuring emotional involvement (STAXI) showed no significant difference between Gr1 and Gr2. Conversely Gr1 scored significantly higher than Gr2 ($p<0.05$ each) on the remaining tests. 12/22 Gr1 and 4/70 Gr2 pts had a score > 28 in HAMA (Gr1A and Gr2A- frank psychiatric abnormalities). The remaining pts were grouped as Gr1B and Gr2B. No significant differences between Gr1 and Gr2 were found in exercise capacity (time to 0.1 mV ST depression: 397 ± 73 vs 419 ± 137 sec.). In contrast, the number of chest pain episodes per week, as assessed in the last month before admission, was greater ($p<0.01$) in Gr1 than Gr2 (1.9 ± 0.3 vs 0.6 ± 0.4). 24 hrs ECG Holter monitoring showed a significantly higher ($p<0.02$) number of ischemic episodes in Gr1 than in Gr2 (1.6 ± 1.7 vs 0.3 ± 0.3). Significance was greater ($p<0.01$) if comparing Gr1A (2.8 ± 1.3) to Gr1B (0.6 ± 0.2), or Gr2A (1.2 ± 0.8) to Gr2B (0.1 ± 0.4).

Conclusions: (1) A history of anxiety disorders is a common finding among women with chest pain symptoms and normal or almost normal angiograms, but may occur also in CAD. (2) Anxiety correlates with increased transient myocardial ischemia and symptoms during daily life. (3) Potential pathways include the effects of the sympathetic nervous system on coronary circulation. (4) The implication is that treatment and rehabilitation of these women should focus on improving their psychological trait.

P3718 Socioeconomic status and psychosocial factors are related to glycated haemoglobin in non-diabetic men and women

A. Steptoe, P.J. Feldman. *University College London, Epidemiology and Public Health, London, United Kingdom*

Background: Glycated haemoglobin (HbA1c) is an indicator of average blood glucose concentration over the previous 2-3 months, and may be a marker of impaired glucose tolerance in non-diabetic populations. Other measures of the impaired glucose tolerance and the metabolic syndrome have previously been associated with low socioeconomic status (SES). This study assessed the relationship between HbA1c and SES, and associations with psychosocial and behavioural factors relevant to cardiovascular disease risk.

Methods: Participants were 234 non-diabetic men and women aged 47-59 who were part of the Whitehall II epidemiological cohort. SES was defined by grade of employment. Psychosocial factors were assessed using standardized questionnaires.

Results: Glycated haemoglobin ranged from 4.43 – 6.49%. There was a significant trend in HbA1c across grades of employment (P =.016), with mean (s.e.m.) levels of 5.30% (.032) in higher status, 5.34% (.034) in intermediate status, and 5.42% (.037) in lower status groups, after adjustment for age and sex. HbA1c concentration was positively associated with waist/hip ratio (P <.004) and negatively related to alcohol consumption (P =.033), but was not associated with body mass index or smoking. People who reported low control at work (P = 0.026), low internal locus of control (P =.003), low use of active coping strategies (P =.011) and low social supports (P <.001) had higher HbA1c levels. After taking age, sex, waist/hip ratio, alcohol and grade of employment into account, an independent association between low social support and elevated HbA1c remained (P <.001).

Conclusions: Glycated hemoglobin is inversely associated with SES in non-diabetic middle-aged men and women. Impaired glucose tolerance is also related to psychosocial factors that have been implicated in cardiovascular disease risk. These findings are consistent with the hypothesis that SES and psychosocial factors increase risk for coronary heart disease partly through disturbances in metabolic function.

P3719 The cost of treating angina pectoris in the United Kingdom

S. Stewart[1], A. McGuire[2], A. Walker[3], J.J.V. McMurray[4]. [1]The Queen Elizabeth Hospital, Cardiology Dept., Adelaide, Australia; [2]City University, Department of Economics, London, United Kingdom; [3]University of Glasgow, The Robertson Centre, Glasgow, United Kingdom; [4]University of Glasgow, CRI in Heart Failure, Glasgow, United Kingdom

Aims: The prevalence and cost of treating angina pectoris (AP) remains high in "developed" countries. This unique study evaluated the contemporary cost of AP to the National Health Service (NHS) in the UK during the calendar year 2000.

Methods: We applied contemporary estimates of AP-related health care activity to the whole UK population, on an age and sex-specific basis, to calculate its cost to the NHS. Direct costs included were hospital admissions associated with a principal diagnosis of AP and unstable AP, coronary artery by-pass [CABG) and percutaneous angioplasty PTCA procedures, associated outpatient (OPD) consultations, General Practitioner (GP) consultations and prescribed drug therapy. A number of sensitivity analyses were performed to account for potential variances in baseline estimates and the likey impact of changes in the pattern of treating AP.

Results: We estimate that 634,000 individuals (1.1% of the UK population) were actively treated for AP within the community during 2000. These individuals required a total of 2.35 million (m) GP consultations, 16 m individual prescriptions and 254,000 OPD consultations at a cost of £51 m, £81 m and £30 m, respectively. We also calculated that there were a total of 149,000 hospitalisations related to AP; that 117,000 coronary angiograms, 21,400 CABG and 17,700 PTCA procedures (70% of which included placement of an intracoronary stent) were performed and that there were 516,000 post-discharge OPD visits. The cost of each of these was estimated at £208 m, £70 m, £106 m and £61 m and £52 m, respectively. The total direct cost of health care for these patients was, therefore, calculated to be £659 m or 1.3% of total NHS expenditure. Hospital bed utilisation and in-hospital procedures accounted for 32% and 35% (combined 67%) of this expenditure. Sensitivity analyses showed that revascularisation procedures exert the greatest potential inflationary pressure on the total cost of AP. For example, the cost of treating AP would increase by about 4% (£25 - 27 m more) if: a) the prevalence of AP were 20% greater or b) there was a 10% increase in hospital activity. However, if revascularisation rates in the UK approached those of mainland Europe, the total cost of treating AP would increase by £107 m (a 16% increase overall).

Conclusions: Angina pectoris is a major and costly health problem in the UK. It consumed over 1% of all NHS expenditure in the year 2000 - the predominant cost components being hospital bed utilisation and revascularisation procedures. This is likely to be a conservative estimate of its true cost.

P3720 Quality of life in unstable angina – Individual and public preferences differ in levels but are similar when measuring changes over time

M. Janzon[1], M. Henriksson[2], L-A. Levin[2], E. Swahn[1] on behalf of The FRISC II Investigators. [1]Dept of Cardiology, Linköping Heart Center, Linköping, Sweden; [2]CMT, Linköping University, Center for Medical Technology Assessm, Linköping, Sweden

Background & Aim: There is a need for easily administered quality of life evaluations in the clinical setting. The quality adjusted life year (QALY), incorporating in a single measure length of life and quality of life, is a widely used outcome measure in health economic evaluations. The valuation of the quality component in QALYs has been debated. The quality adjustment should mirror preferences for health states but there are different approaches to whose preferences should be used. To illuminate this question empirically we compared patients' valuations of health states they were actually experiencing with the valuations of the same health states from the general public.

Material & Methods: In the randomised FRISC II clinical trial, 341 patients with unstable coronary artery disease valued their quality of life at the acute phase of the disease (the patients were admitted to hospital due to an episode of unstable angina or non-ST-elevation myocardial infarction) and at follow-up after 3 months. Patients' preferences were measured by interviews, using the time trade off technique (TTO). The patients also completed the EuroQol questionnaire, where preferences for defined health states from the general public are available, also elicited by the TTO technique (known as the social tariff).

Results: Average TTO value at the acute phase of disease was 0,75 compared to 0,71 using social tariff values. At three months, average TTO value was 0,81 and average social tariff value was 0,78, representing a quality gain of 0,06 and 0,07 respectively. Comparing TTO values to social tariff values for defined health states show small differences for "mild" health states but for "severe" health states TTO values are generally higher than social tariff values.

Conclusions: Quality of life associated with unstable coronary artery disease is valued higher by the patients than by the general public. Results indicate that using the social tariff from the easily administered EuroQol could be a useful proxy for individual preferences when measuring average changes in quality of life over time.

P3721 Deciding on cardiopulmonary resuscitation (CPR) and the European Convention on Human Rights: experience in a Scottish teaching hospital

H. Tunstall-Pedoe, S. Somerville. Ninewells Hospital and Medical School, Cardiovascular Epidemiology Unit, Dundee, United Kingdom

Introduction At its introduction in the 1960s the decision on whether to initiate cardiopulmonary resuscitation (CPR) on hospital patients was seen as a clinical one. Recent European legislation and national policy documents have emphasized the importance of patients' wishes and patients' rights. Shortly before these came into effect we carried out a study of deaths in a Scottish acute teaching hospital, finding what was recorded in the notes, comparing these with the parallel records produced by the hospital resuscitation team. The results are relevant to the practicalities of attempting to conform to human rights legislation. **Methods** Records of hospital deaths occurring during six months of 1999 were requested for all patients of age 15 and over. The record of the fatal admission was studied for what was recorded on decisions, discussions and actions on cardiopulmonary resuscitation. CPR records produced by the on-call team were collected and examined over the same period.

Results The study was difficult and laborious. Access to case records was delayed up to one year. CPR records had to be chased and secured. What was recorded in the notes was often insufficiently precise for our purposes. During the six month period there were 574 deaths. In 72% of these death was anticipated and in 63% a resuscitation policy was recorded. Discussion with relatives was recorded in 39% but their existence or availability was not routinely recorded in the others. A written record of discussion with the patient was found in 3% of records. Attempted resuscitation was recorded in 99 cases (17%), by definition unsuccessful. Over the same period 120 CPR records were obtained with 19 false alarms and an initial success rate of 44%.

Conclusion Monitoring or audit of resuscitation policy as health departments now require proved to be too laborious done in this way to be routine. Most deaths in this acute hospital were expected and in many of these cases anticipatory discussions had been held with relatives and recorded. This was not true of the patients themselves. Only 17% of deaths were the subject of CPR. There is therefore a chasm to be bridged between previous practice and the apparent demands of legislation and human rights activists. Paradoxically, moribund patients are least able to give informed consent to the withholding of CPR, while fit patients, able to discuss the issue, are most unlikely to suffer cardiac arrest or have CPR withheld. Means of bridging the chasm and resolving the paradox will be discussed.

P3722 The appropriateness of prescription of non-invasive diagnostic tests in cardiology

R. Lorenzoni[1], F. Lattanzi[2], E. Orsini[2], A. Genovesi-Ebert[3], D. Pagano[4] on behalf of Tuscany Group of Evaluation of Appropriateness. [1]Lucca, Italy; [2]Pisa, Italy; [3]Livorno, Italy; [4]Birmingham, United Kingdom

To tackle the problem of the waiting lists of non-invasive diagnostic tests in cardiology, we evaluated the appropriateness of prescriptions of echocardiography, exercise test, Holter monitoring and vascular sonography performed during 4 weeks in ambulatory patients in Tuscany, Italy. Methods: before performing the exam, the appropriateness of the prescription (according to Italian guidelines; class I appropriate, class II doubtfully appropriate, class III inappropriate) and the prescribing physician (general practitioner [GP] vs cardiologist) were recorded. After having performed the exam, the diagnosis (normal vs abnormal) and the clinical utility (useful [if the exam influence the clinical decision-making process] vs unuseful) were registered. Results: we evaluated 5614 records (mean age of patients 63 years, range 14-96; 2587 females) of which 2719 were prescriptions of echocardiography, 1158 of exercise testing, 863 of Holter monitoring and 874 of vascular sonography. Prescriptions were of class I in 45.3% of the cases, of class II in 34.8% of the cases and of class III in 19.9% of the cases. The test was abnormal in 43.8% of the cases; in particular, it was abnormal in 58.3% of class I, in 40.4% of class II and in 17% of class III prescriptions ($p<0.05$). The test was useful in 51.2% of the cases; in particular, it was useful in 72.4% of class I, in 43% of class II and in 17.1% of class III prescriptions ($p<0.05$). A decrease in the incidence of abnormal exams was detected moving from class I to class II and to class III exams (OR 0.40, 95% CI 0.37 to 0.44; $p<0.05$). Similarly, a decrease in the incidence of useful exams was detected moving from class I to class II and to class III exams (OR 0.28, 95% CI 0.26 to 0.30; $p<0.05$). Prescriptions were made by cardiologists in 1882 cases (33.5%); their prescriptions were of class I in 57.3% of the cases, of class II in 32.4% of the cases, of class III in 10.3% of the cases vs 39.2%, 36.1% and 24.7% of GPs' prescriptions ($p<0.05$). Cardiologist-prescribed exams were abnormal in 53.4% of the cases vs 39% of GP-prescribed exams (OR 1.76 95% CI 1.58 to 1.97; $p<0.05$). Cardiologist-prescribed exams were useful in 64.7% of the cases vs 44.4% of GP-prescribed exams (OR 2.26, 95% CI 2.02 to 2.53; $p<0.05$). Conclusions: 1) In Tuscany, Italy, more than half of the prescriptions for non-invasive cardiological tests are inappropriate. 2) Appropriately-prescribed exams give a higher rate of abnormal and useful results. 3) Cardiologists-prescribed exams are more often appropriate, abnormal and useful in respect to GP-prescribed exams.

P3723 Psycho-social factors of cardiovascular disease death risk during the period of reforms in Russia

L.M. Khuranova. *Kabardino-Balkarian State University, Medical faculty, Nalchik, Russian Federation*

Since 1992 an evident growth of cardio-vascular disease mortality rate has been registered in the Russian Federation (RF). That period coincided with socio-economic reforms held, which had drastically changed the life of the most of RF population. In Kabardino-Balkarian Republic (KBR), one of the RF Southern Regions, a high mortality rate in the able men represents one of the most pressing problems. The main causes of death are accidents and cardio-vascular diseases (CVD).

The aim of this research is to study the prognostic relationships between the dynamics of a number of economic and socio-psychological parameters, and that one of CVD-caused mortality. Using the Programme methods, recommended by The State Centre for Prophylactic Medicine, quality and mode of life of 1,340 men, aged 35 to 60, have been studied in the Town of Nalchik and rural areas, including their attititude to reforms. In addition, the RF/KBR (State Committee for Statistics) Goskomstat-provided data on the basic socio-economic parameters of the KBR population's life has been analyzed. Multiple regression analysis has been carried out.

Results obtained: Strong correlations between the CVD-caused mortality rate and dynamics of murders (R=0.63), suicides (R=0.71) have been established. Murders and suicides indirectly characterize a condition of aggressivity and despair in the community. In 70% interrogated an attitude to reforms proved to be negative, with incomes of 40%. lower than minimum life standard; 15% rural-areas inhabitants and 20% town-dwellers having no permanent jobs. CVD-caused mortality rate has been actually influenced by nutrition (R=0.47). Within the recent decade, a consumption of meat by the KBR population has been decreased by 28%, vegetables – 18%, fruits – 34%, with the bread consumption increased by 23%. As known, alterations to the structure of nutrition due to the bread consumption growth on the background of lower consumption of expensive foods, indicates to population's life standards degradation.

Conclusions: Results obtained show, that the CVD-caused mortality rate growth in KBR within the recent decade, has been promoted by the increasing stress level, deterioration of living conditions and negative nutrition structure changes, in relation with reforms held.

P3724 Comparative costs of chest pain unit versus coronary care unit management of acute coronary syndromes without ST-segment elevation

A. Conti[1], B. Paladini[2], S. Magazzini[2], S. Toccafondi[2], M. Zanobetti[2], M. Del Panta[2], F. Falcini[2], G. Berni[1]. *[1]Chest Pain Unit, Emergency Department, Florence, Italy; [2]Careggi Hospital, Chest Pain Unit, Florence, Italy*

Background: Acute coronary syndromes without ST elevation (unstable angina, UA; non ST elevation myocardial infarction, NSTEMI) represent a common cause of hospital admission and involve very high costs. Chest pain unit (CPU) management of these patients (pts) may represent a cost-effective alternative to coronary care unit (CCU) admission. Patients and Methods. During 2001, 142 consecutive pts (mean age 71 y, range 44-92, male 66%) with UA or NSTEMI were treated with GP IIb/IIIa antagonist in addition to standard pharmacologic treatment. Patients were randomly assigned to CPU-management (angiography depending on: recurrent angina, troponin > 0.10 ng/l, D ST, EF < 40%) or CCU-management (early invasive strategy encouraged). Patients were followed-up for CE in-hospital and at 6 months. Results. The two subsets of CPU-pts (n=73) and CCU-pts (n=69) shared similar baseline features, troponin levels, TIMI risk score, and presence of UA or NSTEMI on admission. PTCA was performed in 33% CPU-pts versus 49% CCU-pts (P<.05); CABG in 5.5% versus 5.8% (P=ns). Patients with TIMI risk score <4 (n=82) were managed by angiography and PTCA within 24 hours in 7% and 32% respectively in CPU versus 37% and 66% in CCU (P<.01). Length of stay was 2.4 days in CPU-pts versus 3.6 days in CCU (P<.01). Direct discharge rates were similar (13.7% from CPU versus 14.5% from CCU (P=ns). For pts transferred to the wards, average in-hospital stay was 6.9 days (CPU) versus 6.2 days (CCU)(P=ns). The crossover rate from CPU to CCU, due to clinical instability, was 11%. Average cost of diagnostic and treatment strategy, total differential costs and total costs were 1829, 4453 and 5.955 Euro in CPU-pts, versus 2441, 5275 and 7160 Euro in CCU-pts (P=ns; P<.05; P<.05, respectively). The management of pts with TIMI risk score <4 (n=82), had lower average costs in CPU-pts -56%,-11%,-26% as compared to CCU-pts (P<.01,P<.05,P<.5, respectively). Of note, the outcome in terms of CE in-hospital and at 6 months was not different in the two groups (P=ns). Conversely, no difference were found in pts with TIMI score =/>4 (n=60) managed by CPU or CCU. Conclusions. Management in CPU of pts with UA and NSTEMI is a cost-effective alternative to CCU management; involves less frequent use of high-cost invasive procedures; does not increase the likelihood of in-hospital and short-term recurrence of ischemic events.

P3725 Study improving compliance in hypertension and diabetes with the use of a new talking pill reminder: the SIC trial

L. Matos[1], A. Jánosi[2], M. Illyés[3], M. Lengyel-Matos[3] on behalf of SIC Investigators. *[1]Szent János Hospital, Cardiac Department, Budapest, Hungary; [2]Szent János Hospital, Cardiac Department, Budapest, Hungary; [3]Budapest, Hungary*

Background: Patient compliance (C) is poor in hypertension and diabetes, non-C causing therapeutic failures frequently in all chronic diseases. Traditional interventions to improve C proved to be quite futile in leading to better therapeutic results.

Methods: Hypertensives and type-2 diabetics were enrolled into the study, treated minimally for one year, taking more than two, different drugs per os, minimally twice daily. Blood pressure (BP)self-measurement was perfomed twice daily in pre-set intervals. To improve C a new, pocket-size, talking pill reminder device was used, reminding the patient by the voice of the personal physician of pill intake and/or other regular daily activities like BP measurement. Receiving these messages are indicated by the patient pushing a button, and if this signal is not given, the message is repeated twice in 30-min intervals. Half of the patients were bringing home the device, programmed for their personal medication schedule and took their pills for a month accordingly, than gave back the device, received verbal and written counseling and continued treatment for another month, the other group started treatment with the traditional compliance-improving aids, then changed for the programmed device for the second month. 40 uncontrolled mild-moderate hypertensives and 20 diabetics were enrolled, 39 out of the 60 were females, age 63±12 years, mean BMI 27.4 (females) and 26.3 (men). Results of the two compliance-improving techniques were compared by paired-observation t-test and nonparametric tests.

Results: There was a trend in decreasing both systolic- and diastolic BP with both compliance-improving techniques, but no significant difference between the two periods. There was, however, significantly lower blood-sugar values ($p<0.05$) during the period when the talking reminder was used. The device was preferred by 92% of patients, and by all physicians as compared to the traditional verbal counseling and written reminder.

Conclusion: Mobile, pocket-size talking pill reminder device might significantly improve patient compliance in subsets of patients with poor adherence to therapy. For more detailed data in this field, more controlled studies are needed.

P3726 Are patients really taking aspirin 6 months after an acute myocardial infarction?

G. Cotter[1], I. Dinur[1], E. Shemesh[2], M. Zehavi[3], E. Kaluski[1], O. Milovanov[1], Z. Vered[1], A. Komberg[3]. *[1]Assaf-Harofeh Medical center, Cardiology, Zerifin, Israel; [2]Mount-Sinai Medical Center, Psychiatry, NY, United States of America; [3]Assaf-Harofeh Medical Center, Hematology, Zerifin, Israel*

Nonadherence to (noncompliance with) medical treatment following an acute myocardial infarction (MI) may increase the risk for recurrent adverse events. Therefore, we investigated adherence to Aspirin treatment in a cohort of outpatients after acute MI.

Patients and Methods: To determine which objective adherence detection method should be used, we first studied platelet-aggregation indices (TxB2 production and platelet aggregation induced by different concentrations of Collagen) in a small group of subjects whose Aspirin intake was known. Based on these values, we have divided aggregation results into three groups: adherent, partially adherent and nonadherent. For the "field" study, 100 consecutive patients were scheduled for a routine clinic visit 6-months after an acute MI. All patients were asked not to take their usual morning medications prior to the visit. Consent was obtained upon arrival to the clinic, Aspirin dose was ascertained by questioning, and patients who said that their prescribed Aspirin dose was 100 mg daily were asked to give a blood sample and answer an adherence self-report questionnaire.

Results: Of the 100 patients who were called, 82 came to the clinic.. Eleven reported that they had been prescribed a different dose of Aspirin and six refused to give informed consent. "Full adherence" to Aspirin treatment was determined to be 51% by TXB2 production (the preferred method according to the preliminary analyses). Partial adherence was seen in 21% of the subjects and nonadherence was found in 27%. The results of the adherence questioner where not related to actual adherence.

Conclusions: These results suggest that in "real life" adherence to medical treatment is lower than reported in controlled medication trials that. This may adversely affect patient's outcome and therefore objective adherence monitoring should probably be incorporated into standard practice.

P3727 Afternoon nap significantly affects the circadian periodicity for the time of onset of acute myocardial infarction

D. Tziallas[1], T.M. Kolettis[2], K. Achenbach[1], P. Katsarou[1], C. Douhaniaris[1], G. Patsouras[1], M. Fatourou[1], D. Sideris[2]. [1]UHI, Coronary Care Unit, Ioannina, Greece; [2]University of Ioannina, Cardiology, Ioannina, Greece

Previous studies have indicated that a circadian periodicity exists for the time of onset of acute myocardial infarction (AMI), with a morning peak incidence of events. This circadian variation has been attributed to rises in plasma catecholamines and cortisol and increases in platelet aggregability prior to awakening, and is lost with treatment with beta-blockers or aspirin. However, it is not known whether afternoon nap, common in southern European populations, affects this circadian variation.

Methods: We examined the medical records of all patients admitted with AMI between January and December 2001. The time of onset of chest pain was recorded. Patients accustomed to an afternoon nap (>5 days/week, for >1 hour), (group A), were compared to patients who never rested in the afternoon during the preceding 5 years, (group B). Patients receiving beta-blockers or aspirin were excluded, as were patients who could not be fitted to either group. Circadian periodicity was assessed separately for the two groups, using goodness-of-fit chi-square.

Results: The records of 161 consecutive patients were studied and 95 patients (76 male, mean age 57±13 years) met the inclusion criteria. 56 patients were classified to group A and 39 to group B. Group A displayed a significant (X^2=10.7 $p<0.05$) circadian variability. The incidence of AMI in group A had two peaks, a morning and a marked evening peak. No significant (X2=4.22, $p>0.1$) circadian variability was found in group B.

Circardian periodicity in the two groups

	00 to 06 h	06 to 12 h	12 to 14 h	14 to 20 h	20 to 24 h	total # of pts
nap	9	14	3	24	6	56
no nap	8	10	4	14	3	39

Conclusion: In patients accustomed to afternoon naps, the circadian periodicity for the time of onset of acute myocardial infarction is significantly affected, with most events occurring between 14:00 and 20:00 hours.

P3728 Cognitive function predicts sick leave and early retirement in an unselected population of patients with coronary artery disease

A. Kiessling[1], P. Henriksson[2]. [1]Huddinge University Hospital, Karolinska Institute, Stockholm, Sweden; [2]Karolinska Inst. at Danderyds Hospital, Stockholm, Sweden

Aim: To assess the relation between different principal components of health related quality of life (HRQL) and capacity for work in an unselected population of patients with coronary artery disease (CAD)

Design: Cross sectional study.

Setting: Department of Medicine, Södertälje Hospital, Stockholm County Council, Sweden.

Subjects: 171 consecutive pts <65yrs with CAD.

Methods: Health related quality of life was estimated by the generic single item instrument EuroQol (EQ) and the disease specific Cardiac Health Profile (CHP) questionnaire (16 items). Existence and degree of current angina pectoris were ranked according to the Canadian Cardiovascular Society (CCS; 0-4) classification. Reduced capacity for work was defined as sick leave >50% or early retirement >50% (regardless of reason). Multivariate principal components analysis of the CHP-items identified four independent orthogonal domains representing cognitive, physical/general health, social and emotional function.

Results: Patients with reduced capacity for work had a significantly poorer HRQL as assessed by total CHP score respectively EuroQol as compared to those in full work ($p<0.00008$;ANOVA). However, there was no significant difference in relation to CCS class.

Logistic regression showed that both the principal components general health/physical function (p=0.0033) and cognitive function (p=0.0057) of HRQL predicted reduced capacity for work as manifested by early retirement or sick leave. There was no significant dependence between capacity for work and the principal components representing emotional and social function.

Conclusion: We have shown that perceived cognitive function is an independent predictor of sick leave and early retirement in an unselected population of patients with coronary artery disease.

P3729 Enzymatic infarct size (LDHQ48) as endpoint in randomized trials in non-ST-segment elevation acute coronary syndromes undergoing early coronary angiography

A.W.J. van 't Hof[1], K. Miedema[2], J.H.E. Dambrink[1], J.C.C. van der Horst[1], F. Zijlstra[1], H. Suryapranata[1], M.J. de Boer[1], A.T.M. Gosselink[1]. [1]Cardiology, [2]Clinical Chemistry, Isala Klinieken Zwolle, Zwolle, Netherlands

Background: It is suggested that enzyme rise in patients with acute non-ST elevation acute coronary syndromes (ACS) is due to microembolization of thrombotic material from a ruptured plaque and that immediate coronary intervention of this 'hot' plaque may increase distal embolization. By merely taking the incidence of recurrent myocardial infarction as an end point, one may miss early re-infarctions or infarct-extension in pts whose enzymes have not returned to normal values. The assessment of enzymatic infarct size (LDHQ48) takes total enzyme release over a period of time into account and may better quantify the effect of pharmacological or mechanical intervention. **Patients and Methods:** From April 2000 to Dec 2001, 220 pts with unstable angina, Braunwald class 3, with >1 mm ST depression or a positive trop T (>0.05 ng/ml) were randomised to very early (<12 hrs) angiography (group A) without 2b/3a treatment or to angiography after 24-48 hrs pre-treatment with tirofiban (Group B, 0.4 μg/kg/30 min,/0.1 μg/kg/min 24 hrs). Enzymatic infarct size (LDHQ42) was assessed by the area under the LDH release curve from at least 5 measurements over a period of 48 hrs. All angiography films of patients were analysed by an independent core-lab. **Results:** 75% of patients had elevated trop T on admission or 3 hrs thereafter. Median time to angiography was 6 (grp A) and 51 hours (grp B). During initial hospitalization, revascularization was performed in 75% (PTCA: 61%, CABG:14%, grp A) and 77% (PTCA: 58%, CABG: 19%, grp B) of patients.

	Group A (N=109)	Group B (N=111)	P-value
CPKmb positive	53 (49)	57 (51)	0.69
CPKmb max (SD)	92 (91)	79 (68)	0.43
LDHQ48 (SD)	407 (471)	242 (353)	0.004
negative troponin T(N=50)	278 (499)	191 (260)	0.88
positive troponin T (N=152)	412 (441)	257 (369)	0.004

Conclusion: This study shows that in high risk non ST elevation ACS pts, the use of enzymatic infarct size as an end point is feasible and may overcome the issue of different definitions of myocardial infarction. It may better quantify the effect of mechanical or pharmacological intervention on total enzyme release, compared to a clinical end point alone.

P3730 Composite endpoints in trials after myocardial infarction: lessons from CAPRICORN

I. Ford[1], H.J. Dargie[2], J.L. Lopez-Sendón[3], W.J. Remme[4], N. Sharpe[5], M. Robertson[6], J. Love[6], A. Scherhag[7]. [1]Robertson Centre for Biostatistics, [2]Clin. Res. Initiative in Heart Fail., Univ. of Glasgow, Glasgow, United Kingdom; [3]Hospital Gregorio Maranon, Coronary Care Unit, Madrid, Spain; [4]Sticares, Rhoon, Netherlands; [5]Univ. of Auckland, Dept. of Medicine, Auckland, Australia; [6]Univ. of Glasgow, Glasgow, United Kingdom; [7]F. Hoffmann-La Roche Ltd., PBA, Cardiovascular, Basel, Switzerland

Background: CAPRICORN, a randomised double blind placebo controlled trial in patients with acute myocardial infarction and left ventricular dysfunction, demonstrated a 23% mortality reduction (p=0.031), and significant reductions for major coronary events. Despite significant trends in individual components of CV hospitalisations, the co-primary endpoint of all-cause mortality or CV hospitalisation showed only a positive trend for carvedilol (p= 0.30). The abstract explains this apparently paradoxical result. **Methods:** For four mutually exclusive categories: all death, non-fatal myocardial infarction, heart failure hospitalisation "all other CV" hospitalisations, the numbers of cause specific events and of first events in the composite endpoint, and the numbers of 'hidden' events behind lead non-fatal events were identified. **Results:** The table below gives the cause specific and the lead events in the co-primary endpoint. Many deaths prevented by carvedilol lie behind earlier non-fatal events. Benefits in reducing non-fatal MIs lie behind heart failure or "all other CV" events, and heart failure benefits lie behind "all other CV" events. **Conclusion:** In the "time to first event" analysis of the composite endpoint, the benefits of carvedilol were masked by earlier non-fatal events. Therefore care must be exercised in the adoption of general composite endpoints in trials of myocardial infarction particularly if there is likely to be a high incidence of minor and/or early events which may not be susceptible to reduction by the treatment tested.

Abstract P3730 – Table

Event Category	Placebo (n=984) category specific number	Placebo (n=984) composite first event numbers	Carvedilol (n=975) category specific number	Carvedilol (n=975) composite first event numbers
Death	151	83	116	66
Non Fatal MI	57	45	34	27
Heart Failure	138	101	118	97
All Other CV	194	138	189	150

TRANSCORONARY ABLATION IN HYPERTROPHIC CARDIOMYOPATHY

P3731 Role of transcoronary ablation of septal hypertrophy (TASH) for HCM and mild outflow obstruction even under provocable conditions

F.H. Gietzen, C.H.J. Leuner, L. Obergassel, C. Strunk-Mueller, H. Kuhn.
Staedtische Kliniken Bielefeld, Medizinische Klinik II, Bielefeld, Germany

To evaluate the role of catheter interventional treatment in pts. with HCM and only mild outflow obstruction even under provocable conditions, the symptomatic and haemodynamic benefits of transcoronary ablation of septal hypertrophy (TASH) were compared in 22 pts. with a mild provocable gradient <=50 mmHg (range 10-50 mmHg, 32±15 mmHg, Group I) and in 252 pts. with a marked provocable gradient >50 mmHg (range 55-300 mmHg, 150±45 mmHg, Group II) At baseline Group I pts. had a significantly lower gradient at rest (12±8 v. 56±42 mmHg, p<0.001) and after provocation by a single premature ventricular beat (32±15 mmHg v. 150±45 mmHg, p<0.001). However, both groups did not differ significantly with respect to age (58±16 v. 57±15 y), male sex (41 v. 49%), NYHA-FC (2.8±0.6 v. 2.9±0.6), septal thickness (22±3 v. 22±4 mm), exercise capacity (70±36 v. 75±37 watts), peak oxygen consumption (13.6±5.3 v. 15.1±5.7 ml/kg/min), cardiac index at peak exercise (5.4±2.0 v. 5.7±1.7 l/m^2/min) and pulmonary artery mean pressure at workload (40±12 v. 41±9 mmHg). Seven months after TASH both groups demonstrated a decrease in septal thickness (-35±23 v. -42±19%) and an improvement in NYHA-FC (-1.1±0.6 v. -1.3±0.7), exercise capacity (+24±43 v. +25±37%), peak oxygen consumption (+16±45 v. +13±36%), cardiac index at peak exercise (+24±53 v. +12±36%) and pulmonary artery mean pressure at workload (-13±19 v. -15±19%), that did not differ significantly between pts. with mild and marked outflow obstruction under provocable conditions. However, pts. with only mild outflow obstruction under provocable conditions could be treated by a lower peak CK-activity induced (312±140 v. 515±321 U/L, p< 0.001), a lower amount of ethanol injected (2.0±0.8 v. 2.8±1.8 ml, p< 0.004) and a trend to a lower proportion of re-interventions performed (0 v. 8.7%).

Conclusion: A pronounced symptomatic and haemodynamic improvement after TASH is not restricted to pts. with marked outflow gradients. Similar benefits were found in pts. with no more than mild outflow obstruction even under provocable conditions. Therefore, a marked outflow gradient at rest or after provocation should not be considered a necessary criterion for interventional therapy in pts. with severe symptoms unresponsive to medical treatment.

P3732 Quantification of myocardial injury after percutaneous transluminal septal myocardial ablation in hypertrophic obstructive cardiomyopathy

W.G. van Dockum[1], F.J. ten Cate[2], J.M. ten Berg[3], M.B.M. Hofman[4], A.M. Beek[1], A.C. van Rossum[1]. *[1]VU Medical Center, Cardiology, Amsterdam, Netherlands; [2]Academic Hospital Dijkzigt, Cardiology, Rotterdam, Netherlands; [3]St. Antonius Hospital, Cardiology, Nieuwegein, Netherlands; [4]VU Medical Center, Dept. Clinical Physics and Informatics, Amsterdam, Netherlands*

Background: Percutaneous transluminal septal myocardial ablation (PTSMA) is a nonsurgical therapeutic procedure for reducing left ventricular outflow tract obstruction in symptomatic patients with hypertrophic obstructive cardiomyopathy (HOCM). The aim of this study was to evaluate septal myocardial injury size after PTSMA using delayed contrast-enhanced (DCE) magnetic resonance imaging (MRI).

Methods: 16 patients (mean age 50±16 years, 8 males) underwent MRI before and 4 weeks after PTSMA; volume of ethanol injected during procedure was 1 to 5 mL. Images were acquired on a 1.5 T scanner (Vision/Sonata, Siemens, Erlangen, Germany). Cine gradient-echo MRI was performed for assessment of global left ventricular function at baseline and follow-up. Inversion-recovery turbo-FLASH images (TE 3.4 ms, TR 7.6 ms, TI 250-300 ms) were acquired at follow-up, 20 to 30 minutes after i.v. administration of 0.2 mmol/kg gadolinium-DTPA. Left ventricular function parameters, myocardial mass, and hyperenhanced area's (including central dark zones of hypoenhancement) were quantified using the MASS software package (Leiden University Medical Center, the Netherlands).

Results: Left ventricular mass values before and after PTSMA were 233.5 ± 68.1 g vs. 220.2 ± 67.6 g (p<0.001), respectively. Septal myocardial mass pre- and post PTSMA was 80.4 ± 26.8 g vs. 72.1 ± 24.0 (p<0.001), resp. In all patients the injured myocardium was well visualized. The hyperenhanced septal myocardial mass ranged from 3.1 to 33.5 g [mean: 14.6 ± 9.2 g], involving 6.8% ± 4.4 of the post-ablational total LV mass and 21.0% ± 14.0 of the septal myocardial mass. Myocardial injury size was not correlated with the volume of ethanol administered.

Conclusions: The extent of myocardial injury after PTSMA can be determined using DCE-MRI and was not correlated with the volume of ethanol administered. The method may serve as control and feedback for the interventional procedure.

P3733 Left ventricular remodelling following the induced septal infarction in obstructive hypertrophic cardiomyopathy

L. Chojnowska[1], W. Ruzyllo[2], B. Kusmierczyk-Droszcz[3], M. Demkow[2], A. Witkowski[2], L. Malecka[2], C. Kepka[2]. *[1]Institute of Cardiology, Dept. of General Cardiolgy, Warsaw, Poland; [2]Institute of Cardiology, Dept. of General Cardiology, Warsaw, Poland; [3]Institute of Cardiology, Warsaw, Poland*

Non-surgical myocardial reduction (NSMR) is a novel method of non-pharmacological therapy for obstructive hypertrophic cardiomyopathy (HOCM). NSMR results in reduction of the left ventricular outflow tract (LVOT) gradient with symptomatic improvement in patients (pts) with HOCM. However, long-term consequences of induced septal infarction (SI) has not been thoroughly studied.

Methods: In 45 consecutive pts (25 M), followed mean 39.5±4.9 months after NSMR, 2-D and Doppler echo were done at baseline (B), at discharge, and at 3,6,12,24,36 month (mo) follow-up (FU). Echocardiographic measurements (EM) of left ventricle (LV) assessed in this study included: LV end-diastolic dimension (LVDD), LV end-systolic dimension (LVSD), septal thickness (IVS), LV posterior wall thickness (PW), LV ejection fraction (LVEF), LVOT gradient (LVOTG) and mitral regurgitation (MR). We compared results of EM at 36 mo FU to B, and to short-term results (3 mo FU) and to results at 24 mo FU.

Results: 1. The comparison of the EM values at 36 mo FU to B showed following changes: both LVDD and LVSD (43.6±18.4 vs 48.1±5.4mm, p=.0001, and 23.6±4.3 vs 31.6±7.9mm, p=.0001 respectively) increased; IVS (20.8±4.8 vs 16.3±3.6 mm, p=.0001) decreased and PW showed trend to decrease (13.1±3.3 vs 12.4±2.2 mm, NS); LVEF (75.4±9.1 vs 64.5±11.2%, p=.0003) decreased; LVOT gradient was reduced (81.8±26.1 vs 25.4±22.7 mmHg, p=.0001), MR also decreased (2.6±0.5 vs 1.4±0.7,p=.0001). 2. The comparison of the results at 36 mo FU to those at 3 mo FU showed further reduction of LVOT gradient (35.9±28.1 vs 25.4±22.7mmHg, p=.01) and further increase of LVDD and LVSD (45.0±5.5 vs 48.1±5.4 mm, p=.01 and 25.5±5.2 vs 31.6±7.9 mm, p=.01, respectively) but, LVEF did not differ as compared to short-term FU; IVS decreased (17.8±5.9 vs 16.3±3.6mm, p=.001); MR did not change. 3. The comparison the EM results at 36 mo FU to those at 24 mo FU showed ongoing increase of LVDD (46.6±5.8 vs 48.1±5.4mm, p=.02), but its value was still normal; further decrease of IVS (17.8±5.9 vs 16.3±3.6 mm, p=.05) was also observed. The other EM values did not change.

Conclusion: 1. NSMR results in the LV remodelling which causes some positive results as a substantial decrease of both IVS thickness and LVOT gradient. 2. To assess the risk of LV dilatation further careful evaluations of EM are needed, because of ongoing increase of LVDD and slightly decreased LVEF observed at 3 year FU.

P3734 Long-term outcome after percutaneous septal ablation for hypertrophic obstructive cardiomyopathy

D. Welge[1], L. Faber[1], L. Krater[1], H. Seggewiss[2], U. Gleichmann[1], D. Horstkotte[1]. *[1]Heart Center North Rhine-Westphalia, Cardiology Dept., Bad Oeynhausen, Germany; [2]Leopoldina Hospital, Department of Internal Medicine, Schweinfurt, Germany*

Introduction: Septal ablation (PTSMA) improves outflow gradients (LVOTG) and symptoms during mid-term follow-up in symptomatic patients (pts.) with hypertrophic obstructive cardiomyopathy (HOCM). We analyzed the long-term outcome (41±11 [24-67] months) of 178 consecutive pts. treated between 1/1996 and 12/1998.

Results: 3 pts. died during in-hospital stay (VF, pulmonary embolism, and pericardial tamponade in 1 pt. each). Mean CK rise was 599±300 U/l. A DDD-pacemaker (DDD-PM) had to be implanted in 13 pts. (7%), 11 pts. (6%) underwent re-PTSMA and 3 pts (2%) myectomy. 4 pts. were lost to follow-up. There were 2 further DDD-PM implantations and 2 ICD implantations (after out-of-hospital CPR for unknown reasons in a 23 year-old woman, and after sustained VT in a 74 year-old man with coexistent coronary artery disease). 7 pts. died during follow-up: due to stroke (88 and 86 years), coexistent obstructive pulmonary disease (76 years), colon cancer (79 years), after unsuccessful out-of-hospital CPR (25 years), and due to unknown causes (76 and 54 years, resp.). Further clinical and echocardiographic data are shown in the table.

	baseline	last follow-up	p-value
NYHA class	2.8±0.6	1.6±0.7	<0.0001
LA diameter (mm)	48±8	45±8	<0.01
LVOTG at rest (mmHg)	60±35	7±14	<0.0001
LVOTG at Valsalva (mmHg)	127±50	20±28	<0.0001
Maximum workload (Watts)	87±53	121±42	<0.0001

Conclusions: PTSMA results in a persistent LVOTG reduction and exercise improvement during long-term follow up. Degeneration of the AV conduction system together with the PTSMA-induced damage may requiere a DDD-PM implantation in individual patients. A total mortality rate of 10/178 (6%) including all procedure-related deaths compares favourably with the reported natural course of this pt. group with severe HOCM.

P3735 Prediction of the risk of pacemaker dependency after septal ablation for hypertrophic obstructive cardiomyopathy

L. Faber[1], H. Seggewiss[2], D. Welge[1], D. Fassbender[1], H.K. Schmidt[1], D. Horstkotte[1]. [1]*Heart Center North Rhine-Westphalia, Cardiology Dept., Bad Oeynhausen, Germany;* [2]*Leopoldina Hospital, Department of Internal Medicine, Schweinfurt, Germany*

Background and introduction: Damage of the AV conduction system is a major complication of percutaneous septal ablation (PTSMA) that needs early and reliable identification of patients (pts.) at risk for complete heart block (CHB).
Methods and results: In the first 33 pts. who had PTSMA, 7 required a DDD pacemaker (PM) implantation (PM-rate: 21%). AV conduction recovery needed 11 days in one pt.; another pt. suffered from unexpected CHB 9 days after PTSMA. The 7 PM-pts. of this series were compared to those without conduction disturbances. A score was calculated to identify all PM-pts. retrospectively with >12 points. In the following 265 consecutive pts., this score was applied prospectively. 13 of 14 pts. (93%) who needed a PM (PM-rate: 5%) were correctly identified by the scoring system, while 1 pt. with a score of 13 had conduction recovery after short-term steroid therapy. All pts. with <8 points (n=230; 79%) remained free from conduction disturbance and were discharged from monitoring after 3±2 days (vs. 7±4 days in the pts. with >8 points; p<0.01)

	cutoff value	score points
Baseline PQ interval (ms)	> 160	+ 2
Baseline minimal HR (Holter, bpm)	< 50	+ 2
Baseline gradient (Echo, mmHg)	> 70	+ 2
CHB during PTSMA at any time	yes	+ 2
CHB on arrival at coronary care unit	yes	+ 2
AV conduction recovery after 12 hs	yes	- 2
No AV conduction after 12/24/48 hs	yes	+1 / +2 / +3
QRS duration after 48 hs (ms)	> 155	+ 3
Timing of the GOT peak (hs)	> 16	+ 1
	> 20	+ 3

Conclusions: Based on careful monitoring for the first 48 hours after PTSMA, pts. at risk for CHB can be correctly identified. Pts. with a score <8 are at low, those with >12 points at high risk. In the remaining cases watchful waiting may allow AV conduction to recover, thus reducing the number of PM implantations after PTSMA to a rate of 5%.

P3736 Prognosis of patients with hypertrophic obstructive cardiomyopathy after transcoronary ablation of septal hypertrophy (TASH)

T. Lawrenz, F. Gietzen, F. Lieder, L. Obergassel, H. Kuhn. *Bielefeld Hospital, Department of Internal Medicine II, Bielefeld, Germany*

Background and Methods: TASH constitutes a new catheter based therapeutic option for symptomatic patients with hypertrophic obstructive cardiomyopathy (HOCM). Regarding the prognosis after TASH only few data are available in the literature. Based on a validated quality of life questionnaire (QoL) and serial control examinations we analysed the clinical course of all patients treated in our institution up to December 2001.
Results: Between October 1995 and December 2001, 329 pts were treated by TASH (pressure/angiography guided technique, age 60.0 ± 13.1 years, male/female (155/174 pts), 98.8% follow up (325/329 pts), mean follow up time 2.1 ± 1.6 years, maximum 6.2 years). The TASH related total in hospital mortality amounts to 1.8% (6/329pts) and to 0.3% (1/329) excluding 5 pts with severe comorbidity. Sudden out of hospital death occurred in 4 pts and not sudden, not TASH related death in 19 pts (e.g. carcinoma, pneumonia, purulent peritonitis and suicide). Using Kaplan-Mayer life table calculations the corresponding total annual mortality amounted to 4.3% per year. The total cardiac mortality was 1.5% per year including pts with sudden death and 0.6% per year after hospital discharge. The annual cardiac mortality was significant smaller and the QoL-benefit rate of improved pts even somewhat higher (77.3% vs 71.4%, n.s.) in pts treated with small amounts of ethanol (<=2.0 ml vs >2.0 ml ethanol, p=0.031). This amount was an independent prognostic predictor (p=0.047, Cox regression analysis). Advanced age (>61 years) was otherwise a significant predictor of increased prognostic risk in this pt cohort (p=0.002). Regarding the learning curve no significant difference of prognosis was found in two large series of pts (subset pt No 1-165 and 166-329).
Conclusion: There is a low hospital mortality risk of TASH. Prognosis appears to be good. It compares favourable with the prognosis after surgery for HOCM and seems to be significantly better in pts treated with small amounts of ethanol. Apparently there is no difference regarding the clinical benefit from TASH in subsets treated with small or high amounts.

P3737 Role of transcoronary ablation of septal hypertrophy for HOCM, NYHA-FC II and severe symptoms like fatigue, chest pain, palpitations or syncope

F.H. Gietzen, C.H.J. Leuner, L. Obergassel, C. Strunk-Mueller, H. Kuhn. *Staedtische Kliniken Bielefeld, Medizinische Klinik II, Bielefeld, Germany*

To evaluate the role of catheter interventional treatment in pts. with HOCM and severe symptoms like fatigue, chest pain, palpitations or syncope, we compared the results of transcoronary ablation of septal hypertrophy (TASH) in 51 pts. (Group I) complaining on substantial limitations during daily activity despite dyspnoea did not exceed NYHA-FC II and in 202 pts. (Group II) with NYHA-FC III (174 pts.) or IV (28 pts.).
At baseline Group I pts. were characterized by younger age (48±14 v. 59±15 y.*), a male preponderance (82 v. 40%*), a lower proportion of severe SAM (51 v. 71%*), a lower resting gradient (38±32 v. 57±44 mmHg*), a lower pulmonary artery mean pressure at workload (37±9 v. 42±9 mmHg*) and a higher exercise capacity (116±27 v. 65±31 watts*), max. oxygen consumption (20.3±4.8 v. 13.6±4.8 ml/kg/min*) and cardiac index at peak exercise (7.1±1.1 v. 5.5±1.7 l/m^2/min*). However, postextrasystolic gradient (130±47 v. 144±55 mmHg), LVEDP (19±6 v. 20±6 mmHg), septal thickness (22±3 v. 22±3 mm) and the proportion of familiar HOCM (25 v. 21%) and prior syncope (25 v. 29%) did not differ significantly between groups.
At 7 months after TASH the improvement in outflow gradient (-48±31 v. -56±68% at rest*, -49±40 v. -63±33% after provocation*), septal thickness (-32±20 v. -44±18%*), NYHA-FC (-0.7±0.4 v. -1.4±0.6*) exercise capacity (+7±20 v. +30±38%*) and pulmonary artery mean pressure at workload (-5±18 v. -18±18%*) was significantly more pronounced in Group II. However, both groups were not significantly different with respect to a reduction in severe SAM (-86±36 v. -92±27%) and the reported overall subjective improvement (93 v. 94% of pts.). Furthermore, both groups demonstrated a similar and significant reduction in syncope (-80 v. -90% of pts.). Group I pts. could be treated with fewer complications (2 v. 6%) and permanent total AV-Block (0 v. 13%*), since treatment efficacy was achieved by a significantly lower amount of ethanol injected (2.3±1.0 v. 2.9±1.9 ml*). *p<0.05
Conclusion: The clinical improvement observed, justifies a catheter interventional treatment also in pts. with substantial limitations during daily activity despite their dyspnoea at exertion did not exceed NYHA-FC II.

P3738 Septal ablation for hypertrophic obstructive cardiomyopathy in patients with NYHA Class IV Symptoms

D. Welge, L. Faber, H. Seggewiss, D. Fassbender, H.K. Schmidt, D. Horstkotte. *Heart Center North Rhine-Westphalia, Cardiology Dept., Bad Oeynhausen, Germany*

Background and Introduction: In patients (pts.) with hypertrophic obstructive cardiomyopathy (HOCM) presenting with NYHA class IV symptoms, surgical myectomy has been reported to carry a high perioperative risk. We therefore analyzed our database of 322 consecutive pts. for cases who presented with class IV symptoms at the time of percutaneous septal ablation (PTSMA).
Results: In 16 pts. (5%) PTSMA was performed in a class IV situation. One pt. had previous pacemaker implantation, another one surgical myectomy. Mean age was 71±12 (43-88) years. Medical treatment consisted of Ca^{2+}-antagonists in 12, beta-blockers in 4 pts.. The mean ethanol dose was 3.7±2.2 ml, resulting in a CK peak of 623±360 U/l. During in-hospital stay of 16±5 (8-26) days, one pt. (6%) died, 2 pts. (12%) required DDD pacing, and 3 pts. had successful CPR due to tachy- (n=2) or bradyarrhythmic (n=1) events. During late follow-up, 3 pts. died (88 years: unknown cause after 3 months; 83 years: stroke after 8 months; 79 years: colon cancer after 28 months). From the 12 pts. who had their last follow-up 38±11 (26-65) months post-PTSMA, 3 were in class III, 6 in class II and 3 in class I. Additional results are shown in the table.

Table 1

	baseline	last follow-up	p-value
Left atrial diameter (mm)	52±8	47±5	<0.01
Resting LVOT gradient (mmHg)	94±33	0	<0.001
Provoked gradient (mmHg)	149±58	5±11	<0.001
Maximum workload (Watts)	14±26	66±22	<0.01

Conclusions: In a dedicated clinical setting PTSMA is feasible also in pts. presenting with NYHA class IV symptoms. It results in persistent LVOT gradient reduction and symptomatic improvement during long-term follow up. A total mortality rate of 4/16 (25%) including both procedure-related and non-cardiac deaths in 3 years compares favourably to reported natural history data and to surgical results in these elderly pts. with advanced disease.

P3739 Complete relief of syncope during follow-up in patients with HOCM after successful catheter interventional treatment

F. Lieder, F. Gietzen, C. Strunk-Mueller, L. Obergassel, C. Leuner, H. Kuhn.
The Bielefeld Klinikum, Department of Cardiology, Bielefeld, Germany

Background: Syncope is common in HOCM and is associated with an increased risk of sudden death. Surgical or catheterinterventional relief of outflow tract obstruction (LVOTG) often leads to a reduction of syncopal events, but the precise mechanism contributing to this beneficial outcome remains controversial.
Patients and Methods: Therefore, we investigated hemodynamic response to exercise, tilt test and baroreflex sensitivity in a prospective manner before and 6.4 ±1.3 months after Transcoronary Ablation of Septal Hypertrophy (TASH) in 18 consecutive symptomatic pts. (5 female, 54 ±14y, range 29-73) with unexplained recurrent syncope.
Results: In all patients a significant reduction of LVOTG, decrease of IVS thickness and improvement in NYHA functional class could be reached by TASH. Within the 6 month follow-up no patient had experienced any episodes of syncope or presyncope. During symptom limited upright and supine bicycle exercise no patient had an abnormal blood pressure response (ABR), neither before nor after effective TASH. Early and late heart rate recovery (1.min/15.min.) after exercise cessation was significantly diminished after TASH (deltaHR 1.min./15.min: -19.7 ±9.6%/-36.2 ±7.9% before vs. -13.8 ±6.3%/-30.1 ±8.6% after TASH, p=0.015/0.025). Head-up Tilt Test (TT) before TASH induced reflex hypotension with syncope in 6 patients. Tilting induced, maximal increase in HR (deltaHRmax) was significantly higher in these 6 patients compared with the 12 patients with negative TT (+29.3 ±17.8% vs. +11.4 ±8.5%, p=0.035). After TASH TT was negative in all patients, whereas in the 6 patient with positive TT before TASH deltaHRmax was diminished significantly from +29.3 ±17.8% before to +13.4 ±12.4% after TASH (p=0.025). Baroreflex sensitivity did not change during follow-up after TASH (11.5 ±8.0 before vs. 11.2 ±6.8 ms/mmHg after TASH, n.s).
Conclusions: 1) In HOCM patients with recurrent syncope TASH leads to complete relief of syncope during follow up. 2) These patients show neurally mediated syncope during tilt testing in 33%, which completely disappears after TASH. 3) There is a significant reduction of exaggerated tilting induced heart rate increase after TASH. This reduction may reflect TASH induced improvement of abnormal vasodilator reflex response 4) ABR at exercise is not a common feature in these patients. 5) Furthermore after exercise cessation there is a significantly diminished heart rate fall during recovery period after TASH. It can be interpreted as a TASH induced normalisation of prior inadequate adaptation of systemic vascular resistance.

MITRAL VALVE DISEASE

P3740 Relation between QT characteristics and transthoracic echocardiographic parameters in patients with uncomplicated isolated mitral valve prolapse

M. Yazici[1], R. Akdemir[2], C. Uyan[1], E. Erbýlen[1], S. Albayrak[1]. *[1]Cardiology Department, A.I.B.U. Duzce Medical School, Duzce, Turkey; [2]A.I.B.U., Cardiology, Duzce, Turkey*

Background: Sudden death is the least common but obviously the most severe complication of mitral valv prolapse. Some of these patients have been noted to have QT prolongation.Therefore, arrhythmias are likely usual cause of sudden death in patients with MVP. On the other hand complications are more prevalent in those with thickening and redundacy of mitral leaflet and those without leaflet thickening.
The present study was designed to examine between echocardiographic parameters and QT characteristics in with patients uncomplicated and isolated mitral (IMVP) prolapse. Forty-six nonrhaumatic,isolated mitral anterior leaflet prolapse subjects (14 men and 32 women, mean age 25±7) and 24 healthy control subjects (9 men and 15 women, mean age 26±6) were studied. Individuals with accompanying cardiac or systemic disease, or who were on drug therapy that could potentially affect QT characteristics,were excluded. The QT interval was corrected from beggining of d depolarization of the QRS complex to end of the T vawe. Using Bazzet formula, QT interval was corrected (QTC) for heart rate. QTCd was calculated as the difference between the naximum and minimum QT intervals an any of 12 leads. A two dimensional, M mode and Doppler echocardiographic examination was performed. Left atrial diameter and aort diameter were measured with M-mode echocardiography.
Results: There was significant corelation between the amount of billowing leaflet, leaflet thickness, degree of regurgitation and QTC, QCTd in with IMVP. QTC and QTCd correlated positively with the amount of billowing leaflet (respectively: r: 0.33/p<0.04, r: 0.36, p<0.03). QTC and QTCd corelated positively with the leaflet thickness (respectively:r: 0.38/ p<0.02, r:0.4/ p<0.02). In addition, QTC and QTCd corelated positively with degree of regurgitation (respectively:r:0.35/ p<0.03, r:0.4/ p<0.04). But, no corelation were found between any of echocardiographic parameters (LVDD, LVDS, LVEF, FS, AOD, LAD, EDV, ESV) and QT characteristics. Degree of regurgitation was varied mild to moderate.
Conclusions: As a result of the study,it is concluded that the amount of billowing leaflet, leaflet thickness, degree of regurgitation are important parameters in echocardiographic assesment of isolated anterior prolapse.This relation between echocardiographic findings and QTC, QTCd can help to explain unexpected higher sudden death incidence in isolated and uncomplicated mitral valv prolapse subjects.

P3741 Vena contracta width-as a simple method in assessing mitral valve regurgitation. Comparison with Doppler quantitative techniques

A. Lesniak, M. Olszowska, M. Kostkiewicz, P. Podolec, W. Tracz. *Institute of Cardiology, Department of Cardiovascular Diseases, Kraków, Poland*

The aim of the present study was to compare vena contracta width with quantitative Doppler methods for assessing mitral regurgitation (MR). Material: 62 patients (pts) with MR (49 men and 13 women), aged from 35 to 84, mean 54 ± 8 years, were covered by the study. The etiology of MR was: coronary artery disease (42 pts), infective endocarditis (4 pts), rheumatic disease (5 pts), dilated cardiomiopathy (5 pts), mitral valve prolapse (6 pts). Exclusion criteria: aortic stenosis and/or aortic insufficiency, mitral stenosis, mechanic prostheses and atrial fibrillation. Patients were included if they had 1 to 4+ MR as defined by Doppler color and angiography. Methods: The mitral regurgitant volume (RV) and effective regurgitant orifice estimated by the proximal convergence method (PISA), regurgitant fraction (RF) calculated using Doppler were compared with vena contracta width (VCW) measured by color Doppler. The angiographic severity of MR was classified as 1 to 4 grades according to the Sellers criteria. Linear regression analysis was used to compare continuous variables. Results were considered statistically significant for p value < 0,05.
Results: The measurements of VCW are expressed as mean value ± SD and presented in table. P value applies to overall comparison of the four grades by ANOVA, comparisons between individual grades were all significant.

Mean values of VCW

Angiographic Grades	VCW (cm)
1	0,31 ± 0,07
2	0,41 ± 0,03
3	0,65 ± 0,23
4	0,85 ± 0,15
p value	<0,001

There was a good correlation between VCW and ERO (r=0,76, p<0,001), RV (r=0,78, p<0,001), RF (r=0,80, p<0,001). VCW also correlated well with angiographic grades of MR (r =0,86, p<0,001).
Conclusions: 1. VCW measured by color Doppler correlates closely with severity of MR. 2. VCW is a simple, reproducible quantitative measurement of MR. 3. VCW can be used in routine practice for noninvasive assessment of MR.

P3742 Acute effects of cardiac resynchronization therapy on functional mitral regurgitation in relation to cardiac contractility

O.A. Breithardt[1], E. Schwammenthal[2], A.M. Sinha[1], N. Bidaoui[1], A. Franke[1], C. Stellbrink[1]. [1]*Universitätsklinikum Aachen, Dept. of Cardiology, Aachen, Germany;* [2]*Sheba Medical Center, Heart Institute, Tel Hashomer, Israel*

Background: Functional mitral regurgitation (FMR) in heart failure (HF) results from an inbalance between closing and tethering forces which act on the mitral leaflets. Cardiac resynchronization therapy (CRT) in patients (pts) with intraventricular conduction delay may increase the maximal rate of left ventricular pressure rise (LVdP/dt,mmHg/s), increase the transmitral closing pressure (TMPmax,mmHg) and thereby reduce FMR.
Methods: We tested this hypothesis in 16 pts (mean age 65±7years, QRS>120ms,NYHA III-IV) with at least mild FMR, after implantation of a biventricular (BV) pacemaker system (PM) during no pacing (OFF) and during BV-VDD pacing (mean AV delay 110±19ms). Effective regurgitant orifice area (EROA, mm^2) and regurgitant volume (RV, ml) were measured by the proximal isovelocity surface area Method (PISA). LVdP/dtmax was estimated from CW-Doppler tracings of the FMR jet as the time delay between 1m/s and 3m/s and TMPmax by the maximal velocity of the FMR jet. To quantify temporal changes of TMP, we measured the effective TMP 100ms after onset of FMR (TMP100, mmHg). LV sphericity index (SI) was calculated as the ratio of LV end-diastolic volume and a sphere with a diameter equal to LV end-diastolic long axis.
Results: FMR was acutely reduced with CRT in all pts (table). The relative decrease in EROA (%EROA) correlated linearly to the relative increase in contractility: %EROA=-0.73 x %LVdP/dt-9.9, r=0.81, p<0.01. This was associated with an increase in TMPmax and TMP100. SI at OFF was high with 0.55±0.13 and unaffected by CRT.

	EROA (mm^2)	RV (ml/beat)	TMPmax (mmHg)	TMP100 (mmHg)	LVdP/dtmax (mmHg)
OFF	23±14	32±13	74±26	40±16	554±267
BV-VDD CRT	14±9	21±10	88±27	62±19	740±257
	p<0.001	p<0.001	p<0.001	p<0.001	p<0.001

Conclusions: CRT acutely reduces FMR severity and this effect is quantitatively related to an increase in LVdP/dtmax. The results support the concept that an accelerated rise in TMP, as demonstrated by the increase in TMP100, may oppose the pathologic mitral leaflet tethering forces and facilitate effective mitral valve closure. This acute effect was independent of changes in LV geometry, which may further contribute to FMR reduction in the long-term.

P3743 Mitral repair combined with CABG improves haemodynamics and clinical status in patients with grade 2 ischaemic mitral regurgitation

M. di donato[1], A. Boghdady[2], T. Badia[2], V. Montericcio[2], C. Santambrogio[2], L. Menicanti[2], A. Frigiola[2]. [1]*University of Florence, Critical Care Medicine, Florence, Italy;* [2]*San Donato Hospital, San Donato Milanese, Italy*

Background: The optimal management of moderate ischemic mild mitral regurgitation (IMR) at the time of CABG is controversial and the decision to repair the valve is often a surgeon's choice.
Objectives: To investigate the influence of surgical repair of grade 2 IMR on clinical outcome of 60 pts who underwent CABG during the last 3 years at our Center
Patients: No difference in age, clinical and hemodynamic conditions, type and number of by pass, cardiopulmonary by-pass strategy were observed preoperatively. All had grade 2 MR at echocardiogram; 30/60 pts (66±7 yr) underwent combined mitral repair (group1) and 30 did not (64±10yrs) (group2). The decision to repair the valve was at surgeon's discretion. Pts were prospectively recalled for a clinical and echocardiographic control. (Mean time from surgery 24 months; min 12, max 36).
Results: Late after surgery pts with mitral repair had significantly lower ventricular volumes, higher EF and lower mean pulmonary artery pressure. In group 1 the degree of MR and NYHA class were significantly lower (p<0.05 and p<0.01 respectively); signs of congestive heart failure (lower limb edema, gallop, cardiomegaly, diastolic dysfunction) were significantly reduced (p<0.03).

Haemodynamic and clinical data

		EDV (mL)	EF (%)	SPP	MR Grade	NYHA
Group 1	Pre-op	163±61	44±11	38±14	2.0±0	2.4±1.04
(repair)	Post-op	137±35b	48±8b	34±11a	0.37±0.6b	0.73±0.7b
Group 2	Pre-op	165±49	39±11	40±13	2.0±0	2.3±0.9
(no repair)	Post-op	168±53c	40±14c	41±12c	1.96±0.7c	1.9±1.1ad

EDV: end-diastolic volume; EF: ejection fraction; SPP: systolic pulmonary pressure (mmHg); MR: mitral regurgitation; a=p<0.05, b=p<0.01 vs pre-op. c=p<0.05, d=p<0.01 between groups.

Conclusions: Mitral repair at the time of CABG in grade 2 IMR improves clinical outcome at intermediate follow-up. Pts have a reduction of symptoms and signs of CHF, a reduction of ventricular volumes and of mean pulmonary pressure as well as an improvement in pump function, in respect to pts who did not have surgical repair.

P3744 Mechanism of exercise-induced dynamic mitral regurgitation in patients with ischaemic left ventricular dysfunction

P. Lancellotti, L.A. Pierard. *University Hospital, Cardiology Dept., Liege, Belgium*

To determine the mechanisms of exercise-induced dynamic MR during exercise in patients (pts) with ischemic LV dysfunction, we studied 70 pts with an old infarction and < 50% ejection fraction during semi-supine exercise echocardiography. The infarct location was anterior in 28 pts, inferior in 31 and both anterior and inferior in 11. During test, effective regurgitant orifice (ERO) decreased in 13 pts and increased by < 13 mm^2 in 38 and by > 13 mm^2 in 19. Larger degree of MR at rest was not correlated with larger changes in ERO (r = 0.20). Heart rate, blood pressure and ejection fraction increased similarly in each group. The strongest correlation with ERO changes was observed with the difference in systolic mitral tenting area in all and in inferior infarct pts, whereas coaptation height was the most powerful in anterior infarction pts (r = 0.89, p < 0.0001). In addition, larger changes in mitral systolic area correlated with larger increase in ERO in all infarct categories (r = 0.78, p < 0.0001). For local LV remodeling, posterior displacements of both papillary muscles were associated with larger changes in ERO, whereas lateral displacements showed weaker correlation. Changes in wall motion score index were greater in patients with decreased ERO and inferior location (r = 0.68, p < 0.001). In multivariate analysis, an increase in systolic mitral annular (MA) area independently of the infarct location emerged as an independent predictor of ERO variations. No significant improvement in wall motion score index and an increase in systolic mitral tenting area were also associated with greater changes in ERO in the overall population and in inferior infarct pts. Greater apical mitral leaflet displacement measured as height coaptation distance was selected in anterior infarct pts. We conclude that the degree of dynamic MR are dependent of local LV remodeling (regional wall motion) and mitral valvular deformation (tenting area, systolic MA area) but unrelated to global LV function.

P3745 Does Alfieri's mitral valvuloplasty induce restriction?

C. Sportouch[1], J.M. frapier[2], S. cade[1], P. rouvière[2], T. aymard[2], B. albat[2]. [1]*Arnaud de villeneuve, Cardiologie, montpellier cx5, France;* [2]*chu arnaud de villeneuve, cardiac surgery, montpellier, France*

Objective: Alfieri's valvuloplasty could be a limiting factor for exercise tolerance due to the increasing transmitral gradient during stress-test.
Methods: Between June 2000 and June 2001, 15 patients with an echographic grade 3 to 4 mitral regurgitation were operated on according to Alfieri's technique. The mean age was 64.3 ± 16.2 years. In 9 cases, there was a bileaflet prolapsed degenerative valve, in 5 cases there was a pure or associated ischemic mitral regurgitation, and in 1 case an endocarditis on Barlow disease. The operation consisted on suturing the free margins of the prolapsed segments of the two leaflets in 100% of cases. Associated procedures were Carpentier's ring annuloplasty in 66.6% and CABG in 13% of cases. After a mean of follow-up of 5 months, all patient were seen at the outpatient clinic for a clinical evaluation, an echocardiogram, and a cardiorespiratory exercise testing with maximal oxygen uptake (VO2 max) recording.
Results: There was no early or late death. Improvement of the NYHA class was observed in all patients with a conversion from a mean preoperative value of 2.9 ± 1.2 to a postoperative value of 1.3 ± 0.5 (p= 0.0002). Only 13% of patients have had a residual mitral regurgitation. In all cases there was a lowering of the arterial systolic pulmonary pressure from a mean of 48 ± 18 mmHg preoperatively to 36 ± 11 mmHg postoperatively (p= 0.03) and LVEF remained unchanged from 57± 10 to 62± 14% (p=0.26). The mean transmitral gradient was 4.2 ± 1.2 at rest and increased to 8.2 ± 3.4mmHg during peak exercise(p= 0.005) The mean mitral area was 2.3 ± 0.6cm^2. Among the 12 interpretable cardiorespiratory exercise testing, 7 patients have normal exercise tolerance (86.6% mean VO2 max for a >85% normal value), 4 patients have a cardiogenic limitation (62.5% mean VO2 max), and one young patient have a muscular exercise limitation (68% VO2 max) due to exercise deconditioning.
Conclusion: Alfieri's valvuloplasty is a simple and reliable technique in case of bileaflet prolapsed mitral valve on aged patients. According to these results, even if there appear a restrictive aspect of the repair like demonstrated by the valve area and the transvalvular gradient, his impact on clinical status seems moderate.

P3746 Effect of prosthetic ring annuloplasty on mitral leaflet motion: an echocardiography study

S. Varnous[1], C. Acar[1], P. Leprince[1], N. Bonnet[1], E. Lansac[1], A. Pavie[1], C. Duran[2], I. Gandjbakhch[1]. [1]*Hopital Pitie Salpetriere, Chirurgie Thoracique et Cardiovasculai, Paris, France;* [2]*Missoula, Cardiac Surgery, Montana, United States of America*

Objective: Prosthetic ring annuloplasty for mitral valve repair may indirectly influence leaflet motion. The aim of this study was to assess i)the geometric changes of the left ventricle base following ring insertion and ii) their impact of leaflet mobility.
Methods: Twenty-five patients with mitral valve regurgitation who underwent a valve repair were studied with intraoperative multiplane transesophageal echocardiography (TEE) before and after prosthetic ring annuloplasty. Patients who required a repair involving the anterior leaflet were excluded. Three parameters were measured: the antero posterior mitral valve annulus diameter (MAD), the angle between aortic and mitral annuli planes (AMA), the angle between anterior leaflet and mitral annulus plane (ALA). Acquisition of the 3 parameters was performed at end-systolic and maximal diastolic valve opening; using midoesophageal 3-chambers and longitudinal echocardiographic view. Anterior leaflet excursion throughout the cardiac cycle was calculated according to: ALE = diastolic ALA - systolic ALA.
Results: Mitral valve repair techniques were: posterior leaflet resection with annuloplasty (n=19) or annuloplasty alone: flexible Duran ring (n=6). All patients had a excellent functional result with no (n=18) or mild (n=7) mitral regurgitation. There was no significant difference between systolic and diastolic MAD. The MAD was significantly reduced after repair from 37±5mm to 20±3mm ($p<0.001$). The AMA decreased from 115±10 degrees to 105±9 degree ($p<0.001$). The ALA, in systole, increased from 19±5 degrees to 26±6 degrees ($p=0.001$). The ALA in diastole remained unchanged (midesophageal 3-chambers and longitudinal views). Anterior leaflet excursion decreased from 32±11 degrees to 24±10 at midesophageal 3 chambers view and from 42±13 degrees to 33±11 degrees at longitudinal view after repair($p=0.001$).
Conclusion: Leaflet mobility is slightly reduced following ring annuloplasty. Leaflet restriction occurs simultaneously to geometric changes of the left ventricular base as illustrated by a decrease in mitral annulus diameter and a reduction of the aorto-mitral angle. This probably account for an increased chordal tension resulting in usual findings following annuloplasty such as: "spontaneus" correction of a slight anterior leaflet prolapse, motionless aspect of the posterior leaflet.

P3747 Left atrial function and apoptotic markers in mitral regurgitation: effect of valvular replacement

A. Trikas, K. Tentolouris, V. Katsi, K. Vasiliadou, M. Toutouza, C. Chrisochoou, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, Dept of Cardiology, Athens, Greece*

Purpose: Patients with mitral regurgitation (MR) and heart failure (HF) are characterized by left atrial (LA) function changes and apoptotic process activation. This study was undertaken with the purpose of evaluating the effect of valve replacement on the LA function and apoptotic markers of patiens with MR and HF, and to examine their relationship.
Methods: We studied 35 patients in sinus rhythm (mean age 56.2±4.6 years, range 30 to 69), with MR and HF (12 in NYHA II, 13 in NYHA III, and 10 in NYHA III-IV) and 20 age- and gender-matched normal volunteers (G3). Peripheral blood was sampled before (2±4 days, G1) and 6 months postoperatively (G2) and was evaluated for plasma levels of soluble Fas/APO-1 receptor (sFas, ng/ml), TNF-alpha (pg/ml) and Interleukin-6 (IL-6, pg/ml) measured by ELISA method. LA volumes (cm^3) were measured echocardiographically before (G1) and 6 months postoperatively (G2) at mitral valve opening (maximal, Vmax), at onset of left atrial systole (P wave of the electrocardiogram, Vp) and at mitral valve closure (minimal, Vmin) from the apical (2) and (4) chamber views using the biplane are-length method. LA contractile function was assessed with the LA active emptying fraction (ACTEF) = (Vp-Vmin)/Vp.
Results are shown in the table.

	sFas	TNF-a	IL-6	Vmax	ACTEF
G1	8.6±1.8	7.6±1.6	7,2±1.1	124±20	0.25±0.08
G2	6.4±1.7b	5.3±1.9b	5.4±1.0b	88±16a	0.28±0.07b
G3	2.1±0.4a	4.1±0.8a	3.8±0.9a	46±10a	0.35±0.10a

a:$p<0.001$ vs. G1, b:$p<0.01$ vs.G1

A significant negative relation was noticed between ACTEF and sFas, TNF-a and IL-6 levels ($r=-0.76$, $p<0.001$, $r=-0.80$, $p<0.01$ and $r=-0.76$, $p<0.01$, respectively).
Conclusions: Valvular replacement for mitral regurgitation reduces LA atrial size and improves LA contractile function. The latter is probably due to the postoperative inversion of the apoptotic process.

P3748 The calcified mitral ring: a potential site for a severe type of bacterial endocarditis

J.C. Eicher[1], L. DeNadaï[1], F.X. Soto[2], P. Dobsak[3], H. Portier[4], P. Louis[1], J.E. Wolf[1]. [1]*Hôpital du Bocage, Cardiology, Dijon, France;* [2]*Centre Hospitalier, Cardiology, Auxerre, France;* [3]*St Ann University Hospital, CFDR, Brno, Czech Republic;* [4]*Hôpital du Bocage, Infectious Diseases, Dijon, France*

Bacterial endocarditis usually occurs on valve leaflets previously damaged by other disease processes. Ageing induces degenerative, calcific lesions that become increasing causes of endocarditis, but mitral annular calcification (MAC) is still not considered to date as a predisposing factor.
Methods: We conducted a prospective study among patients referred for suspected infective endocarditis (IE). Fourty consecutive patients with proven infective IE of the native mitral valve were included. All the patients underwent multiplane transesophageal echocardiography (TEE), with special attention paid to the presence of MAC, and to the attachment site of the vegetations. Patients with vegetations on the valve leaflets were compared to those where vegetations were seen attached to the mitral annulus.
Results: Among the 40 patients, 30 were found to have classical mitral leaflet endocarditis (group 1), whereas the other 10 (25%) had vegetations specifically involving the mitral ring (group 2). Thirteen % of group 1 patients had mild MAC, but all group 2 patients had moderate to severe MAC. Group 2 patients were older (71 vs 66, NS), had more frequently hypertension (60% vs 30%, NS), chronic renal failure (20% vs 6.7%, NS), cirrhosis (30% vs 6.7%, $p=0.09$), diabetes mellitus (80% vs 16.7%, $p<0.005$) and cancers (50% vs 13.3%, $p<0.05$) than group 1 patients. Staphylococcus was the causative organism in 70% of group 2 patients, whereas Streptococcus was predominant in group 1. Echocardiographic findings in group 2 patients compared to other patients were significantly different regarding vegetation size (25.6 ± 16.5 vs 11.9 ± 8 mm), and occurrence of (1) calcifications within the vegetation (80% ± 7.5%), (2) mitral ring abscess (60% vs 0), and (3) para-annular perforation of the posterior mitral leaflet (70% vs 0). Finally, clinical outcome in group 2 patients was very pejorative, with clinical features of meningoencephalitis in 60%, stroke in 30%, and an in-hospital mortality rate of 70% compared to 30% in the other group.
Conclusion: bacterial endocarditis involving MAC in an unrecognized type of IE characterized by high prevalence of Staphylococcus, particular echocardiographic appearance of large, calcified vegetations attached to the posterior part of the mitral annulus, high frequency of annular abscesses, and poor outcome due to the occurrence in elderly patients with serious co-existing diseases, including diabetes, chronic renal failure, cirrhosis and cancers.
