Day 2

Sunday 1 September 2002

RESYNCHRONISATION THERAPY IN HEART FAILURE: ARE WE DOING ANY GOOD?

77 Sustained clinical efficacy of biventricular pacing in sinus rhythm patients: 2 years follow-up from the MUSTIC study

C. Leclercq[1], C. Linde[2], S. Cazeau[3], L. Kappenberger[4], R. Sutton[5], C. Bailleul[6], C. Daubert[1] on behalf of MUSTIC Study Group. [1]*University Hospital, Cardiology, Rennes, France;* [2]*Karolinska Hospital, Stockholm, Sweden;* [3]*St Cloud, France;* [4]*Lausanne, Switzerland;* [5]*London, United Kingdom;* [6]*Le Plessis Robinson, France*

Background: Previous controlled and randomized studies have shown that biventricular pacing improved short term (3 to 6 months) functional status in patients with advanced heart failure, intraventricular conduction delay and left ventricular systolic dysfunction. However, few data on long term follow-up are available. The aim of the present study was to evaluate the long term clinical benefit of permanent biventricular pacing (follow up = 2 years) in sinus rhythm patients included in the MUSTIC trial.
Method: The MUSTIC trial was a cross-over (2 x 3 months) designed study to assess the effect of biventricular pacing. After the two cross-over phases, the patient were followed every 3 months in the pacing mode selected according to their preference (biventricular or no pacing). 67 patients in sinus rhythm (63 ± 10 years), all in NYHA class III with a mean LV ejection fraction (LVEF) of 23 ± 7% were included in this study. After completion of the cross-over phases, all patients were programmed in biventricular pacing mode. To date, 35 patients completed the 2-years follow-up
Results:

	Baseline	1 year	2 years
Heart rate (bpm)	75±12	70±10*	70±13*
NYHA class	2.8±0.4	2.1±0.5*	2.1±0.6*
6 min walk (m)	340±97	418±112*	386±150*
Peak VO2 (ml/min/kg)	14±4.5	16.6±3.6*	NA
QOL questionnaire	45±23	30±22*	29±22*
LVEF radionuclides (%)	24±7.7	30±12*	NA

* $p<0.01$ vs baseline, NA = not available

Conclusion: These data show that the short-term functional benefit observed with biventricular pacing in advanced heart failure patients remains stable over 2 years. This therapy seems useful to improve quality of life and exercise tolerance in such patients.

78 Cardiac resynchronization therapy reduces the risk of hospitalization for heart failure and length of stay: results from the MIRACLE trial

W. Abraham[1], D. Hayes[2], J. Sackner-Bernstein[3], A. Curtis[4]. [1]*University of Kentucky, Lexington, United States of America;* [2]*Mayo Medical Center, Rochester, United States of America;* [3]*St. Luke's - Roosevelt Hospital Center, New York, United States of America;* [4]*University of Florida-Shands, Gainesville, United States of America*

Cardiac resynchronization therapy (CRT) is safe and well tolerated, improves symptoms, NYHA class, quality of life and functional capacity in patients (pts) with HF and ventricular dysynchrony. We examined the effect cardiac resynchronization on the risk of hospitalizations for heart failure and related length of hospital stays. Method. A total of 453 pts were implanted with an InSync cardiac resynchronization system and randomized, 225 pts in the Control group and 228 pts in the CRT group. Pts were required to be on stable medical regimen for at least 1 month prior to enrollment. If on beta-blocker therapy, therapeutic dose maintained was for 3 months prior to enrollment. Initiation or discontinuation of drug therapy during the 6-month control period was discouraged. Results. Results are presented through 6-months follow-up (the double-blind randomization period). There were 34 Control pts with a total of 50 hospitalization days for HF. In the CRT group, there were 18 pts with a total of 25 hospitalization days for HF.

Event	Control (n=225)	CRT (n=228)	p-value
Freedom from use of IV Meds for Worsening HF (95% CI)	83.9% (78.1%, 88.3%)	92.7% (88.4%, 95.5%)	0.004
Freedom from HF Hospitalizations (95% CI)	84.6% (78.9%, 88.8%)	91.5% (86.8%, 94.6%)	0.015
Mean Length of Stay for HF Hospitalizations (days)	7.04 ± 8.41	3.38 ± 3.43	0.024

Conclusion: Pts in the Control group experienced an increase in HF symptoms as evidenced by a greater need for inotropic support and intravenous fluids. This analysis suggests that CRT is associated with a significant reduction in the risk of hospitalization for worsening HF and in the total days hospitalized for HF when compared to the Control group.

79 Cardiac resynchronisation therapy – a cost effective treatment for cardiac failure

L J. Dixon, G. Thompson, M. Harbinson, G. Murtagh, G. Richardson, E.W. Chew. *Regional Cardiology Centre, Belfast City Hospital, Belfast, United Kingdom*

Health care costs for heart failure are substantial.It is the leading medical cause of hospitilisation, accounting for 5% of acute admissions. Heart failure admissions are lengthly,and readmission rates are high, with 20% of patients readmitted within 30 days, and 50% within 3 months. It consumes 2% of the National Health Service budget. Hospital treatment constitutes 65-75% of these costs.Against this background of limited resources, and the need for alternative treatment options, cardiac resynchronisation therapy has emerged.
30-50% of patients with cardiac failure are suitable for resynchronisation therapy. 41 patients have received cardiac resynchronisation therapy in the Belfast City Hospital over a 22 month period, with a mean follow up of 10 months.We recorded the total number of days and the number of heart failure related days spent in hospital, in the 6 months pre and post biventricular pacing, in a group of 22 patients who have reached 6 month follow up period.
Total days in hospital, for all causes, decreased from a total of 511 pre pacing to 111 post($p<0.001$). Admissions for heart failure decreased substantially, from a total of 489 to 19 days($p<0.0003$) in the 6 months following pacing.The mean duration of stay for heart failure before therapy, was 24 days, decreasing to 5.2 days following therapy($p<0.001$). Total number of admissions for heart failure also decreased significantly, from a total of 23 prior to pacing, to 7 following pacing($p<0.002$). Total cost of hospital stay in the 6 month period prior to pacing estimates at £122640. In the 6month period following pacing, this decreased to £26640. Device costs estimate at £66000, thus total costings estimates at £92640.This represents a saving of approximately £30000, a significant cost saving in this group of patients. If the figures are projected onto a larger scale, the savings will be extremely significant.
Conclusions Our initial results are very promising, showing significant reductions in all cause, and heart failure admissions, along with decreased number and duration of admissions. Significant cost savings are also evident. We await the results of larger, longterm follow up trials to fully appreciate the benefits and cost effectiveness of this treatment.

80 Effects of cardiac resynchronization therapy on regional myocardial deformation as measured by echocardiographic strain rate imaging

O.A. Breithardt[1], C. Stellbrink[1], L. Herbots[2], A.M. Sinha[1], K. Markus[1], P. Claus[2], P. Hanrath[1], G.R. Sutherland[2]. [1]*Universitätsklinikum Aachen, Dept. of Cardiology, Aachen, Germany;* [2]*Univ-Hospital Gasthuisberg, Dept. of Cardiology, Leuven, Belgium*

Cardiac resynchronization therapy (CRT) aims to improve hemodynamic function in patients (pts) with heart failure (HF) and left bundle-branch block (LBBB) by early stimulaton of late activated regions. Tissue Doppler imgaging (TDI) has been proposed for quantification of asynchrony and patient selection. However, myocardial velocities (V,cm/s) are dependent on overall heart motion. Strain rate (SR,1/s) and strain (S,%) calculation (based on regional velocity gradients) is able to display true regional deformation properties independent of global heart motion and might thus be superior to V for detection of contractile asynchrony. Negative values for SR and S indicate shortening in the longitudinal direction.
Methods: Colour TDI data (>145 frames/s) were obtained from the apical 4-chamber view in 8 HF-pts with LBBB (mean age 64±7, QRS 179±26ms, EF 22±7%) after implantation of a biventricular CRT pacemaker system. Peak systolic V and S, mean SR during ejection (mSR) and the regional delay between QRS onset and peak V (deltaV-t,ms)and peak S (deltaS-t,ms) were compared in mid septal and lateral wall segments during intrinsic conduction (OFF) and during CRT in the same echo examination. Analysis was performed on custom made software, enabling exact timing of global cardiac events.
Results: (table) Peak V and S were severely reduced in both walls. Septal mSR increased and lateral mSR decreased with CRT. Peak regional S was not significantly affected. The delay between septal and lateral peak S was markedly reduced, while the timing of regional peak V was not altered.

	V-sep (cm/s)	V-lat (cm/s)	mSR-sep (1/s)	mSR-lat (1/s)	S-sep (%)	S-lat (%)	deltaV-t (ms)	delta S-t (ms)
OFF	2.4±0.8	1.8±0.5	-0.14±0.3	-0.76±0.3	-13±7	-12±5	60±38	108±68
CRT	2.8±0.4	1.3±0.6¶	-0.5±0.3*	-0.5±0.3*	-9±3	-12±5	62±37	43±34*

*$p<0.05$ vs. OFF, ¶$p<0.05$ versus sep (paired/unpaired t-test)

Conclusions: CRT acutely improved the regional inhomogeniety in mSR and reduced deltaS-t compared to no pacing. We suggest, that these changes in deformation properties reflect the redistribution of regional wall stress and improved contractile synchrony by CRT and may have significant implications for CRT efficacy in this population. In contrast to previous reports, systolic velocities did not display these effects. Strain rate imaging offers new insights in the pathophysiology of LBBB and CRT.

81 Chronic improvement of left ventricular ejection fraction and stroke volume in CHF-patients after CRT by means of 3D-TEE reconstruction

C. Butter[1], E. Wellnhofer[1], M. Seifert[1], M. Schlegl[1], W. Hoersch[2], A. Goehring[2]. [1]*Charite & Deutsches Herzzentrum, Berlin, Germany;* [2]*CRM Guidant, Brussels, Belgium*

Background: 3D-transesophageal echocardiography (3D-TEE) offers the possibility to overcome known limitations of conventional 2D echo like geometric assumptions and asynchronous movement patterns. This study evaluated the effects of chronic cardiac resynchronisation therapy (CRT) with respect to left ventricular volume, stroke volume (SV) and ejection fraction (LVEF) in patients (pts) with severely impaired cardiac function and conduction disorders.
Methods: 20 CHF pts were analyzed with 3D-TEE. Etiology of CHF was either idiopathic or ischemic, LVEF<30%, QRS>120ms and NYHA II-IV. During an invasive test, hemodynamic parameters (aortic pulse pressure, LV +dp/dt) were recorded to detect the optimal pacing site and AV-delay for CRT. Pts were implanted with a LV pacing device (either pacemaker or defibrillator) and a LV lead at the optimal determined pacing site. Prior chronic pacing and at 12 month follow up, the pts underwent 3D-TEE to investigate potential differences in LV volume-derived parameters between intrinsic depolarization (ID) and CRT at the optimal AV-delay.
Results: A significant increase ($p < 0.0001$) between baseline-ID and 12month-CRT at the optimal AV delay was found for SV and LVEF at a nearly constant LV enddiastolic volume (LVEDV). SV increased by 45.3% from 43.7±13.7 ml (ID) to 63.5±19.0 ml (CRT). LVEF improved by 47.6% during CRT from 16.4±5.1% (ID) to 24.2±5.9% (CRT). At baseline and at 12monthFu LVEF and SV were significantly improved by CRT compared to ID ($p < 0.0001$).

n=20	Baseline	12 month Fu	% Change	p-value	Unit
LVEF ID	* 16.4 ± 5.1	19.3 ± 5.1	25.9 ± 45.1	0.05	%
LVEF CRT	21.1±5.5	*24.2±5.9	18.4±28.9	0.02	%
SV ID	**43.7±13.7	51.4±16.6	23.2±37.9	0.04	ml
SV CRT	57.2±15.6	**63.5±19.0	14.0±28.7	0.10	ml
LVEDV ID	278.4±89.1	276.7±106.6	0.8±21.0	0.90	ml
LVEDV CRT	283.4±94.7	277.4±108.0	-0.9±21.0	0.66	ml

*,**p<0.0001 Student-t test, mean±sd

Conclusions: 3-D TEE reconstruction of the left ventricle is a feasible method to detect acute and chronic LV volume differences in heart failure pts with wide QRS duration. We demonstrated that acute and chronic CRT significantly improves LVEF and SV. Chronic CRT leads to nearly 50% increase of LV ejection fraction at a nearly constant LVEDV.

CATHETER ABLATION OF VENTRICULAR TACHYCARDIA

104 Mechanisms of ventricular tachyarrhythmia originating from the aortic sinus of Valsalva

Y.G. Li, C.W. Israel, G. Grönefeld, S.H. Hohnloser. *J. W. Goethe University Hospital, Cardiology, Frankfurt, Germany*

Background: It has recently been demonstrated that the aortic sinus of Valsalva (AS) is one origin for ventricular tachycardia (VT) or extrasystoles (VES). However, the mechanism of this type of tachycardia is still not well defined. The aim of this study was to delineate the different electrophysiological mechanisms of the VT/VES originating from the AS.
Methods and Results: Endocardial mapping was performed in 7 patients (pts; 5 men, mean age: 44 ± 17 years) with symptomatic VT/VES originating from the AS. Adenosine was administered during VT/VES in all pts. Adenosine-sensitive was defined as termination of VT or suppression of VES. Two different reactions to adenosine were found: adenosine-sensitive in 3 pts (group A) and non-adenosine sensitive in 4 pts (group B). In group A, all pts were free of structural heart disease. VT was not inducible by programmed ventricular stimulation in all pts. All successful ablation sites were in the left AS. In group B, there were 2 patients with dilative cardiomyopathy, the other two had no structural heart disease. Five sustained VTs could be induced and terminated by programmed ventricular stimulation. Successful ablation was performed in the noncoronary AS in 3 VTs and in the left AS in 2. Abnormal (diastolic or presystolic) potentials were recorded during sinus rhythm (mean interval from the end of QRS to the potential 121 ± 98 ms) and during VT (mean interval from the potential to QRS 64 ± 45 ms) at effective sites in the AS. Concealed entrainment was demonstrated at all successful ablation sites.
Conclusion: Two different mechanisms may contribute to the development of VT/VES originating from the AS: ATP-trigged activity and reentry. Larger studies are needed to compare the electrophysiological characteristics of both groups.

105 Functional his-Purkinje block: an important mechanism of bundle branch reentrant tachycardia without a prolonged HV interval during sinus rhythm

Y.G. Li[1], G. Grönefeld[1], C.W. Israel[1], F. Bogun[2], S.H. Hohnloser[1]. [1]*J. W. Goethe University Hospital, Cardiology, Frankfurt, Germany;* [2]*University of Michigan Medical Center, Cardiology, Ann Arbor, MI, United States of America*

Background: The electrophysiological mechanism of bundle branch reentrant tachycardia (BBRT) with a normal HV interval during sinus rhythm (SR) is unknown.
Methods and results: From 178 patients with different types of ventricular tachycardia (VT), 13 were found to have BBRT as the underlying electrophysiological mechanism. Of those 13 patients (9 male, 4 female, mean age 64 ± 13 years), 6 were documented to have a HV interval shorter or equal to 55 ms (group A), whereas 7 had a prolonged HV interval (> 55 ms; group B) during SR. The PR interval (169 ± 32 vs 339 ± 138 ms, p=0.01), the AH interval (101 ± 26 vs 225 ± 126 ms, p=0.04) and QRS duration (116 ± 17 vs 167 ± 29 ms, p=0.003) during SR were significantly shorter in group A than in group B. In group A, the HV interval was significantly longer during VT than during SR (73 ± 18 vs 47 ± 7 ms, p=0.007). There were more patients with functional His-Purkinje block (split His potential, jump of HV interval or phase 3 intra-His-Purkinje block) induced by programmed atrial stimulation or burst pacing in group A than group B (6/6 patients vs 0/7 patients, p<0.001). Successful ablation of the right bundle branch was performed in all 13 patients without deteriorating AV block. During an average follow-up of 27 ± 17 months, 2 patients died in each group and VTs (other than BBRT) or ventricular fibrillation were documented by ICD electrogram storages in 4 patients.
Conclusion: A prolonged HV interval during SR is not a prerequisite for BBRT. Functional conduction block within the His-Purkinje system appears to be the electrophysiological substrate for this type of BBRT. Radiofrequency ablation of the right bundle branch is effective in suppressing BBRT. Despite this, however, ICD-implantation may be still necessary.

106 Cooled tip catheter ablation of epicardial outflow tract tachycardia through the aortic sinus of Valsava

K. Kurzidim[1], T. Neumann[2], D. Vukajlovic[2], N. Guettler[2], J. Sperzel[2], H.F. Pitschner[2]. [1]*Kerckhoff-Clinic, Cardiology, Bad Nauheim, Germany;* [2]*Kerckhoff-Clinic, Cardiology, Bad Nauheim, Germany*

Monomorphic repetetive tachycardia originating in the LV-outflow tract (LVOT) usually cannot be ablated by a conventional approach due to their epicardial site. The ECG typically shows inferior axis and left bundle branch block pattern. In contrast to RVOT-tachycardia early R/S transition in V3 and a r-wave in V1 can be observed. We describe catheter ablation of epicardial LVOT-tachycardia through the aortic sinus of valsalva (AoSv).
Methods: In 7 pts with highly symptomatic monomorphic VT (5 males, 1 pt with valvular CMP, 5 pts without heart disease) an epicardial site of the arrhythmic focus could be confirmed by pace mapping and earliest local activation within the AoSv. Angiography of the coronary arteries served to define a spacial safety margin with respect to the ablation catheter. High frequency current was delivered using a closed loop irrigated tip catheter system (Chilli Cool®, Boston Scientific). ECG, Holter, Echo and transesophageal Echo (TEE) were performed the following day and after 3 months.
Results: 2 foci were located in the left, 3 in the right and 2 in the acoronary AoSv. Using a target temperature of 40°C a cumulative energy of 203-14953 J was delivered with 2-14 applications. In 6/7 pts acute success could be achieved. Successfully ablated pts were completely asymptomatic during follow-up, no VT could be documented with Holter-ecg. TEE during follow-up could not reveal any damage to the ascending aorta or the aortic valves. In 1 pt only transient suppression of monomorphic VT was obtained. No procedure related complications could be observed.
Conclusions: Monomorphic VT with epicardial origin in the LVOT can be successfully treated by cooled tip catheter ablation through the AoSv. Cooled tip catheter ablation may be favourable in this setting due to its potential to create deep lesions necessary to reach remote foci. Damage to surface tissue may be reduced by lower temperatures at the catheter/tissue interface. Lower temperatures may also reduce the risk of local clot formation which is crucial to all left sided procedures and especially for catheter ablation in the sinus of valsalva.

107 Prediction of future arrhythmic events in patients with cardiac sarcoidosis: role of clinical variables and programmed ventricular stimulation

A. Aizer, E. Pe, J. Ghosh, J.A. Gomes, D. Mehta. *Mount Sinai Medical Center, Cardiology, New York, United States of America*

Cardiac sarcoidosis is associated with a significant incidence of sudden cardiac death related to ventricular arrhythmias. There is little data on the predictors of sudden death in these patients. The role of clinical parameters and electrophysiology study in predicting future arrhythmic events was determined.
Methods: 25 patients with cardiac sarcoidosis were included in the analysis. Clinical parameters evaluated included age, gender, symptoms (palpitations, presyncope, syncope) presence of non-sustained VT and left ventricular function. All patients underwent programmed ventricular stimulation at 2 ventricular sites with up to triple premature beats. Comparison was performed using the Fisher's exact and Mann Whitney U tests.
Results: Seven patients (28%) were inducible for sustained ventricular arrhythmias. None of the above parameters, including left ventricular ejection fraction, predicted inducibility at electrophysiology study. All inducible patients received implantable defibrillators. Patients were followed for 1 to 128 months (mean 32 months). No patient with an implantable defibrillator died of sudden death during the follow-up. Four of seven patients (57%) with implantable defibrillators received appropriate therapy for ventricular arrhythmias. Mean time from implantation to first event requiring therapy was less than 5 months.
Conclusions: In this patient population with cardiac sarcoidosis, none of the clinical variables studied predict inducibility at electrophysiology study. Patients who are inducible with electrophysiology study are at high risk of potentially fatal ventricular arrhythmias. These arrhythmias can be successfuly treated with implantable cardiac defibrillators, avoiding sudden death.

108 Nonsurgical transthoracic epicardial ablation of incessant ventricular tachycardia: an alternative when other means have failed

J. Brugada, A. Cuesta, L. Mont. *Hospital Clinic, Cardiovascular Institute, Barcelona, Spain*

Background: Management of patients with incessant ventricular tachycardia is often a difficult clinical problem. Drugs and radiofrequency catheter ablation are not always effective. A nonsurgical transthoracic epicardial ablation technique recently described can be an alternative in patients refractory to conventional therapy.
Methods AND RESULTS: Since 1998, 14 patients presented with incessant ventricular tachycardia despite the use of 2 or more intravenous antiarrhythmic drugs. In all except one patient who presented an endocardial ventricular thrombus we tried to perform a radiofrequency catheter ablation procedure using the usual endovascular technique. The procedure was effective in 9 patients (69%) and ineffective in 4. In the 4 ineffective patients and in the 1 with the ventricular thrombus, an epicardial ablation approach was used. They were 4 males, 73±7 years old, 4 with ischemic heart disease and 1 with dilated cardiomyopathy. The left ventricular ejection fraction was 30±19% and 4 out of 5 were in refractory heart failure at the moment of the procedure. Three out of the 5 patients previously received an implantable cardioverter defibrillator (ICD). The epicardial ablation was effective in the 4 patients with ischemic heart disease and ineffective in the one with dilated cardiomyopathy who received a cardiac transplantation. No complications occurred. After a mean follow-up of 20±12 months [3-40], a single episode of ventricular tachycardia different to the initial one and successfully treated by the ICD has been documented in one of the patients. No significant differences were found between those with successful endocardial or epicardial ablation.
Conclusions: In patients with incessant ventricular tachycardia despite the use of drugs or standard endocardial ablation, the epicardial approach was very effective and should be considered as an alternative.

109 Epicardial fat tissue does not modify amplitude and duration of the epicardial electrograms and/or ventricular stimulation threshold

A. Davila[1], R. Dias[2], M. Scanavacca[2], E. Sosa[2]. [1]*Instituto do Coraçao, Unidade Clinica de Arritmia, Sao Paulo, Brazil;* [2]*Heart Institute (InCor), Unidade Clinica de Arritmia, Sao Paulo, Brazil*

One of the possible reasons for epicardial RF catheter ablation of epicardial circuits to fail is the presence of epicardial fat interposed between the tip of the ablation catheter and the epicardial surface of the heart. Awareness of the presence of epicardial fat could help planning a special strategy to deal with this circuits. The aim of this study was to determine possible modifications caused by the presence of fat tissue in epicardial electrograms and ventricular stimulation threshold. Methods: Bipolar epicardial electrograms were recorded with a standard ablation catheter (distal par of electrodes with a 4 mm tip) during open-chest prior to extracorporal circulation in 10 patients (6 women, 52±6 years/LVEF=43±11%) undergoing CABG surgery. The electrograms were recorded from areas with and without fat tissue as the surgeon firmly hold the catheter against the heart. Then, stimulation threshold was obtained for each one of the areas. Signals were recorded with a filter ranging between 80-500 Hz and a gained of 20mm/mV at a paper speed of 100 mm/sec and analyzed off-line. The layer of epicardial fat was defined as thick if > 5 mm based on a subjective evaluation of the surgeon. Results: Electrograms were obtained from 44 areas without epicardial fat and compared to 45 areas with fat randomically distributed among the free-wall of the left ventricle and the right ventricular outflow tract. The presence of fat does not modify the stimulation threshold among areas with and without fat (4.8±1.6 versus 4.6±1.8 mA. In most areas, peak-to-peak amplitude (40±5 mm versus 43±4 mm) and the duration of the epicardial bipolar electrogram (43.6±5 versus 43.5±6 ms) was not modified by the presence of fat. Stimulation threshold was higher only in areas with a very thick layer of epicardial fat (> 5 mm). Conclusion: The presence of a layer of epicardial fat < 5 mm interposed between the tip of the ablating catheter and the epicardial surface of the heart does not modify the amplitude and duration of the bipolar epicardial electrogram and the epicardial ventricular stimulation threshold.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

114 Apoptosis and structural and metabolic dysfunction or injury of cardiomyocytes in arrhythmogenic right ventricular cardiomyopathy

E. Czarnowska, B. Wozniewicz, B. Cukrowska, A. Sowinska. *The Children Memorial Health Institute, Pathology, Warsaw, Poland*

The pathogenesis of progressive myocardial atrophy in arrhythmogenic right ventricular cardiomyopathy (ARVC) is not established. Apoptosis, which could be triggered by myocarditis (MC), has recently been suggested as a possible mechanism involved in myocardial loss however, metabolic changes in the myocardium have not been reported.
The aim of the study was to analyse structural and metabolic features and apoptosis of cardiomyocytes in samples from the right ventricle (RV) obtained from patients with recognised ARVC and ARVC with coexisting MC.
Materials and Methods: Samples of the RV free wall obtained by endomyocardial biopsy from 11 paediatric patients (aged from 6 to 17 years) with ARVC recognised according to criteria of McKenna et al. (1994) in whom MC coexisted in 5 cases and samples from 6 patients (aged from 4 to 17 years) with isolated MC who served as controls were investigated. Histopathological evaluation (hematoxylin-eosin and Azan staining) and TUNEL assay were conducted on paraffin sections, histochemical tests (succinic dehydrogenase, SDH, lactate dehydrogenase, LDH, cytochrome oxidase, COX) on frozen sections, and ultrastructural examinations on glutaraldehyde/osmium fixed sections.
Results: Histological examination revealed infiltration of myocardium with fibro-fatty tissue in ARVC but not in MC cases. In some areas of the myocardium histochemistry demonstrated decreased SDH and COX activity correlated with increased LDH activity in both ARVC and MC cases. TUNEL assay showed apoptotic myocardial cells localized in regions invaded by fibro-fatty tissue and also in regions of compact packed cardiomyocytes in ARVC and MC. Ultrastructural study revealed separation of the fascia adherens junctions within the region of intercalated discs in 6, and thinning of the glycocalyx in 5 cases of ARVC, which were not observed in any case of MC.
Conclusions: The occurrence of cardiomyocytes apoptosis in an area not invaded by adipocytes and fibrosis and presence in such areas cardiomyocytes with histochemical features of low metabolic activity and also with membranes separation in the region of intercalated discs and/or thicker than normal glycocalyx may suggest the significance of these features in the pathogenesis of ARVC. However further investigations correlated with clinical signs are necessary to evaluate the role of these findings in the process of myocardial atrophy and/or as prognostic markers in ARVC.

115 Prognostic factors for arrhythmic events in autosomal recessive arrhythmogenic right ventricular cardiomyopathy (Naxos disease)

N. Protonotarios[1], A. Tsatsopoulou[1], A. Anastasakis[2], E. Karvouni[2], A. Rigopoulos[2], D. Panagiotakos[2], P. Toutouzas[2]. [1]*Yannis Protonotarios Medical Center, Cardiology, Naxos, Greece;* [2]*University of Athens, Cardiology, Athens, Greece*

Background Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a progressive disease causing life-threatening ventricular arrhythmias. Naxos disease is an autosomal recessive form of ARVC with 100% penetrance. Naxos disease population permits the evaluation of arrhythmic risk during a long term follow-up study.
Methods Twenty-eight consecutive patients (14 men,14 women) with Naxos disease underwent serial cardiac assessment with annual resting 12-lead ECG, 24-h ambulatory ECG and two-dimensional echocardiography in a prospective evaluation of up to 16 years. Historical accurate data were also available from isolated community. Arrhythmic events (syncope and documented episodes of sustained ventricular tachycardia)due to the disease, were studied during a maximum duration of 72 years. T-wave inversion and QRS dispersion (the difference between the widest QRS complex in leads V1, V2 or V3 minus that in V6) were studied on standard 12-lead ECG. Right ventricular dilatation and left ventricular involvement were evaluated from two-dimensional echocardiography. Moreover, ECG and structural progression (progressive alteration in dimensions and/or wall motion abnormalities) were studied. Multivariate analysis was performed using the Cox proportional hazards model. In each patient, gender, age, and ECG/echocardiographic parameters were considered as predictors and the first arrhythmic event was the end point of the study.
Results Arrhythmic events occurred in 17 patients (61%). Median age at first event was 42 years. The results from the survival (event free) analysis are presented in Table 1.

Table 1. Risk factors

Risk factor	Hazard ratio	P-value
QRS dispersion ≥40ms	2,55	0,095
Structural progression	7,38	0,005

Conclusions In autosomal recessive ARVC, the multivariate analysis revealed that QRS dispersion equal or more than 40msec and structural progression were the best predictors for the developement of arrhythmic events.

116 Multielectrode non-contact mapping is an effective tool to define the arrhythmogenic substrate in patients with right ventricular tachycardia

C. Carbucicchio[1], P. Della Bella[1], S. Riva[1], N. Trevisi[1], G. De Martino[2], S. Perlangeli[1], M. Casella[1]. [1]*Centro Cardiologico Monzino, Cardiology, Milano, Italy;* [2]*Gemelli, Electrophysiology, Rome, Italy*

Background: Characterization of the substrate functionally involved in right ventricular tachycardia (VT) is limited by point-by-point conventional contact mapping. For this reason, we evaluated the efficacy of a multielectrode non-contact mapping method, capable of simultaneous endocardial mapping of the entire right ventricle, to identify the critical components of the arrhythmia.
Methods: The electrophysiological (EP) characteristics pointed by the non-contact mapping system "Ensite 3000" (Endocardial Soutions) in 28pts (14M, age 40±15yrs) undergoing radiofrequency catheter ablation (RFCA) for VT are reported. According to guidelines diagnostic criteria, 10pts were classified as having arrhtyhmogenic right ventricular dysplasia (ARVD, Group A), 18pts as idiopathic (Group B). Beside conventional EP study, with respect to right ventricular endocardial activation-mapping, the following parameters were analyzed: in sinus rhythm, -delayed activity on virtual unipolar electrograms; during VT, -evidence of a diastolic pathway (activation of a "channel" of endocardium over the diastolic interval) at virtual unipolar electrograms/isopotential color maps, and, -discrete presystolic activity from exit point with radial spread in the surrounding myocardium, in the same unipolar mode. 42 VTs (21, 2.1±0.9/pt, in Group A; 21, 1.2±0.5, in Group B; cycle 269±77ms) were induced (12VTs non-tolerated, 11 non-sustained).
Results: Delayed sinus rhythm activity was detected in 10/10pts (100%; 45±37ms, Group A), and in 4/18pts (22%; 30±20ms, Group B) ($p<.001$). The diastolic pathway was identified in 16/21VTs (76%) vs. 3/21VTs (14%), in Group A and B respectively ($p<.005$). Presystolic activity with "QS" morphology -preceding QRS onset by 38±14ms-, followed by rapid breakout, was found in 0/21VTs (Group A) and 18/21VTs (86%, Group B) ($p<.001$). Interestingly, all 3pts in Group B with VT marked by diastolic pathway, showed no presystolic "focal" activity, 2/3 had delayed activation in sinus rhythm, and 3/3 had an uncommon presentation for idiopathic VT (2 morphologies, 1 with intermediate/superior axis induced by programmed stimulation). RFCA was acutely successful in 5/10 (50%) and in 19/21 (90%) pts (Group A and B, respectively; $p<.05$). No complication occurred.
Conclusions: Multielectrode non-contact mapping is effective to characterize the arrhythmogenic substrate in pts with VT and may document reentry even in absence of ARVD. This may suggest that non-contact mapping helps identifying early forms of disease and improve RFCA efficacy especially in this group of pts.

117 Radiofrequency catheter ablation of ventricular tachycardia in patients with arrhythmogenic right ventricular cardiomyopathy: long-term outcome

A.E. Borger van der Burg[1], M. Bootsma[2], L. van Erven[2], E.E. van der Wall[2], M.J. Schalij[2]. [1]*Leiden University Medical Center, Cardiology, Leiden, Netherlands;* [2]*Leiden University Medical Center, Cardiology, C5-P, Leiden, Netherlands*

Introduction: Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) is a degenerative disease affecting the right ventricle and less often the left ventricle. Thinning of the RV wall and fatty replacement of myocardial tissue can be detected by MR imaging. Ventricular tachycardia (VT) often occur in pts with ARVC and can be treated with radiofrequency catheter ablation (RFCA). This study evaluates both short- and long-term results of RFCA of VT in ARVC patients. Methods: From 1997 until 2001, 41 consecutive pts (26 male, age 47 ±14 yrs) underwent RFCA of drug refractory VT in ARVC. In all pts the diagnosis of ARVC was established by MR imaging. Results: In total 94 different VT's were induced and targeted for ablation during the procedures (2.3±1.9 morphologies per pt). Procedural success (defined as non-inducibility of VT after the procedure) was achieved in 88% of the pts. The procedure and fluoroscopy times were 176±73 and 34±21 minutes respectively. Serious procedure-related complications were observed in 3 (7%) pts: myocardial perforation during RF application occurred in 3 pts, 2 pts underwent immediate surgery; 1 pt recovered after pericardiocentesis. One pt (after surgery) died <48 hrs after the procedure due to cardiogenic shock. Before discharge, 3 pts (7%) underwent ICD implantation either for hemodynamically non-tolerable VT/VF and/or a non-successful ablation procedure. During follow-up (18.5±19.4 months), a recurrence of VT was observed in 7 pts (18%, 86% new VT morphology). No pt died during follow-up. Conclusion: RFCA of VT in pts with ARVC is a successful and relatively safe procedure. The recurrence rate is still high, which might be explained by the progressive nature of the disease. As none of the patients died suddenly a selective ICD implantation approach in these patients is justified.

118 Catheter ablation in arrhythmogenic right ventricular cardiomyopathy: what to gain and what remains?

T. Wichter, M. Paul, P. Kirchhof, L. Eckardt, G. Breithardt, M. Borggrefe. *University of Münster, Dept. of Cardiology and Angiology, Münster, Germany*

In pts with arrhythmogenic right ventricular cardiomyopathy (ARVC), the role of catheter ablation for treatment of ventricular tachycardia (VT) is still controversial. Therefore, we analyzed the acute success and the long-term results during follow-up of up to 15 years after catheter ablation in 43 pts with ARVC. Indications for catheter ablation were incessant VT or very frequent VT recurrences (mainly associated with frequent shocks from an implanted ICD) in 8 pts (19%), drug-refractory VT in 32 pts (74%), and as primary treatment in 3 pts (7%). 21 pts had extensive forms of ARVC with severe global and/or regional RV dysfunction.
Catheter ablation of the targeted VT was acutely successful in 34 of 43 pts (79%). Incessant or very frequent VT was clinically controlled in all of the 8 pts with either no (n=2) or only sporadic subsequent VT recurrences. During follow-up of up to 15 years (mean: 102±20 months), 2 pts died and 32 pts (74%) experienced recurrent VT or VF. Survival rates free of arrhythmic events were 63%, 42% and 31% after 1, 3, and 5 years, respectively. Pts with localized ARVC showed better long-term results than those with extensive RV dysfunction ($p<0.01$). In pts initially considered effectively treated by catheter ablation, the majority of relapses were due to "new VT" that showed different morphologies when compared to the targeted VT during the ablation sessions. These "new VT" may therefore represent new arrhythmic foci that developed during the progressive long-term course of ARVC.
Conclusions: In pts with ARVC, catheter ablation yields high acute success rates for the effective treatment of the targeted VT. Optimal indications for catheter ablation in ARVC are incessant VT or frequent recurrences of VT (ie, causing frequent ICD shocks). These complex clinical situations can be effectively controlled acute and long-term by catheter ablation as the treatment of choice. However, long-term freedom of VT recurrence after catheter ablation in ARVC is rare due "new" VT morphologies during follow-up, reflecting the progressive nature of ARVC particularly in pts with severe RV dysfunction.

119 Problems associated with and long-term effectiveness of implantible cardiac defibrillator therapy in patients with right ventricular dysplasia

D. Mehta, A. Aizer, J. Ghosh, M. Singson, J. Gomes. *Mount Sinai Medical Center, Cardiology, New York, United States of America*

Right ventricular dysplasia (RVD) leads to a significant incidence of recurrent ventricular tachycardia (VT) and sudden cardiac death. Problems associated with and long-term effectiveness of implantible cardiac defibrillators (ICDs) in RVD patients were evaluated.

Twenty-four patients undergoing ICD implantation were included in this analysis. Group one included 12 patients with RVD and group two included 12 ischemic cardiomyopathy controls. Mean follow up was 4.6 years in patients with RVD and 4.2 years in patients with ischemic cardiomyopathy. Parameters compared included: final R wave sensitivity, impedance, pacing threshold, defibrillation threshold, post-implantation deaths, recurrent ventricular arrhythmias requiring therapy and antiarrhythmic drugs used.

Patients with RVD were younger (mean age 53±17 vs. 66±11, $p<0.03$) and had greater left ventricular ejection fraction (54±10% vs. 25±10%, $p<0.001$). Gender distribution and indication for ICD implantation were similar across the two groups. At implantation, RVD patients had lower final R wave amplitudes (6.9±2.4mV vs. 14.3±6.0mV, $p<0.001$). There was no significant difference in lead impedance, pacing thresholds (0.74±0.29V vs. 0.6±0.17V) or defibrillation thresholds (14.4±5.5J vs. 14.0±2.9J). At follow-up, RVD patients experienced a greater number of ventricular arrhythmias (34±61 episodes vs. 16±30 episodes) and required a greater number of antiarrhythmic medications for VT suppression (2.6 drugs vs. 1.4 drugs per patient, $p<0.05$). There were no documented episodes of inadequate sensing in RVD patients and no patient died of ventricular arrhythmia in either group. One patient with ischemic cardiomyopathy died of congestive heart failure and one patient with RVD died of pulmonary embolism. A second patient with RVD also experienced a nonfatal pulmonary embolism.

Conclusions: Patients with RVD have lower final R wave sensing thresholds. However, the lower R wave sensing leads to no significant adverse outcome. Although ICD therapy is effective in terminating ventricular arrhythmias in patients with RVD, the frequency of recurrent episodes often mandates an increased use of antiarrhythmic medications. In addition, patients with RVD may be at high-risk of pulmonary embolism after lead implantation. Long-term anticoagulation should be considered in patients with large right ventricles.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS IN PRIMARY AND SECONDARY PREVENTION

120 Implications of national guidance on the implantation of implantable cardioverter-defibrillators for arrhythmias

C. J. Plummer, R. J. Irving, J. M. McComb. *Freeman Hospital, Department of Cardiology, Newcastle upon Tyne, United Kingdom*

Background: Based on published trial data, the National Institute for Clinical Excellence (NICE) published guidance on the use of implantable cardioverter defibrillators (ICDs) in the UK in September 2000. This estimated that a total implantation rate of 50 devices/million/year (equivalent to 33 to 39/million/year first implants) would be required to implement its recommendations.

Methods: We have audited all cardiac patient contacts with our ICD implanting centre over a month and subsequently all admissions to the 3 coronary care units serving our district over a second month against the published standards of the NICE guidance.

Results: Full implementation of the guidance would have required significant increases in post-MI screening (a 4% increase in echocardiography, a 59% increase in Holter monitoring and a 376% increase in VT stimulation studies) and resulted in a more than 420% increase in ICD implantation.

The incidence of new ICD indications in our district was 105/million/year. This is approximately 3-times the implant rate for first devices anticipated by NICE and 7-times the current UK implant rate. If the NICE guidance were amended to include MADIT II criteria, this would at least double these figures.

Implications of NICE guidance

	Echo	Holter	EPS	ICD
Performed	737	126	5	5
Additional	30	75	19	21
TOTAL	767	201	24	26

Echo = 2D echocardiography, Holter = 24-hour ambulatory ECG monitoring, EPS = Ventricular tachycardia stimulation electrophysiology study, ICD = implantable cardioverter defibrillator implantation

Conclusion: Full implementation of the conservative guidance issued by NICE would require very significant increases in post-MI screening and result in a dramatic increase in ICD implantation in the UK to approximately the level seen in the USA. The personnel, equipment and financial resources required to achieve this exceed those available in our centre and those anticipated by NICE. As recommended in the guidance, this audit process should be repeated in other centres to facilitate planning of evidence-based ICD therapy in the UK.

121 What reduction in mortality can we expect from the ongoing primary prevention implantable cardioverter-defibrillator trials?

T. Brüggemann, C. Ehlers, D. Andresen. *Vivantes Klinikum Am Urban, Dept. of Cardiology, Berlin, Germany*

Results from MADIT demonstrated that mortality can be significantly reduced in highly selected pts. with remote MI by an ICD. Ongoing and just terminated primary prevention trials use various non-invasive inclusion criteria and enrol pts. early after acute MI prior to hospital discharge. It is however unclear, to what amount total mortality can be reduced by an ICD that prevents solely from sudden cardiac death (SCD).

Purpose: We sought to determine the effect of SCD prevention on total mortality in high risk post MI pts. as defined in the different primary prevention trials.

Method: We stratified a consecutive series of 790 post MI pts. <75 years (males 76%, mean age 59±10 yrs.) from our MI data base according to various non-invasive selection criteria. Clinical data: anterior MI 45%, transmural MI 80%, thrombolytic therapy 59%, PTCA 39%, ACVB 11%. A Kaplan-Meier survival analysis was performed for a median duration of 27 months including careful analysis of the mode of death according to the EMIAT classification. Holter ECG and determination of EF was performed prior to hospital discharge (10±6 days after MI). Risk groups were defined according to the following criteria: Ejection fraction (EF) ≤35% + nonsustained ventricular tachycardia (nsVT) on Holter ECG, EF≤30%, EF≤35% + Holter mean HR ≥80/min, and nsVT≥150/min on Holter.

Results: Two-year total mortality was 43.0% (EF<35+nsVT), 24.0% (EF<30), 24.7% (EF<35+HR>80), and 27.6% (nsVT>150). The corresponding rates of the 2-years SCD rate are 10.2% (EF<35+nsVT), 6.5% (EF<30), 7.6% (EF<35+HR>80), and 12.7% (nsVT>150). Mortality and SCD rate were significantly higher in comparison to all respective control groups ($p<0.0001$). The portion of SCD at total mortality in the high risk groups was 23% (EF<35+nsVT), 27% (EF<30), 31% (EF<35+HR>80), and 46% (nsVT>150).

Conclusion: A significant reduction of total mortality from 23% up to 46% can be expected from prophylactic ICDs according to the inclusion criteria used. This estimated reduction rate is in good agreement with recently reported data.

122 High risk of ventricular arrhythmias in patients with idiopathic dilated cardiomyopathy, reduced ventricular function and non-sustained ventricular tachycardia

J. Kuschyk, S. Spehl, N. Aramin, F. Streitner, C. Echternach, B. Schumacher, M. Borggrefe, C. Wolpert. *University Hospital of Mannheim, 1st Depart. of Medicine, Mannheim, Germany*

The value of prophylactic ICD-therapy for patients with an idiopathic dilated cardiomyopathy without survived sudden cardiac death and without documented sustained VT is yet not clear. Besides, the prognosis of patients with an idiopathic dilated cardiomyopathy, severly depressed left ventricular function and non-sustained VT has not been sufficiently studied. Aim of the present study was to assess the incidence of ventricular tachyarrhythmias in those patients after implantation of an ICD irrespective of inducibility at programmed stimulation.

Patients and methods: A total of 25 patients with an idiopathic dilated cardiomyopathy were followed over a mean follow-up of 22±19 months. The mean ejection fraction was 22±12%. In none of the patients sustained VT or syncope had been documented. All patients had only presented with non-sustained VT during Holter-ECG. In 23 patients programmed ventricular stimulation was performed. In 26% a monomorphic VT was inducible. Ventricular fibrillation was induced in 17% of the patients. All patients received an implantable defibrillator. Results: In 9/ 25 patients (36%) 26 episodes of ventricular tachycardia or ventricular fibrillation occurred duing follow-up with a mean of 2.9 episodes per patient. 30% of the patients who had been inducible in programmed ventricular stimulation had a VT event vs. 46.2% of the patients who were not-inducible. In all patients the ventricular tachyarrhythmia was successfully terminated by the implantable defibrillator terminated.

Conclusion: 1. The incidence of ventricular tachycardia or ventricular fibrillation in patients with dilated cardiomyopathy, severely depressed LV function and documented NSVT is 36%. 2. Inducibility does not predict a worse outcome and non-inducible patients had a higher likelihood of VT/VF. 3. There should be prospective trials in this subgroup of patients, who had no syncope, no documented sustained VT, but NS-VT only, since these patients seem to be at a high risk of sudden death.

123 Elevated heart rate preceding the onset of ventricular tachycardia influences ATP effectiveness in patients with implantable cardioverter-defibrillators

C. Kouakam, B. Lauwerier, D. Klug, M. Jarwé, C. Marquié, D. Lacroix, S. Kacet. *Lille University Hospital, Cardiology Departement, Lille, France*

Background: The incorporation of antitachycardia pacing (ATP) into implantable cardioverter defibrillators (ICD) has provided a better tolerated alternative to shocks. ATP has been shown to be effective in terminating approximately 80-90% of spontaneous ventricular tachycardia (VT) episodes. Although ATP is routinely used, little is known about predictors of ATP failure. We aimed to prospectively follow-up patients with ICDs, and to analyze parameters affecting ATP effectiveness.
Methods and Results: Consecutive 118 patients received ICDs for standard indications. Prior to discharge, empirical, standardized ATP therapy was programmed in all patients within VT zones. A total of 1218 spontaneous tachycardia episodes occurred in 51 patients during a mean follow-up of 24.5 ± 12 months. Among these, 888 monomorphic VT episodes were diagnosed. One hundred and four fast VTs were detected in the VF zone and treated with primary shock delivery. ATP was attempted 881 times in the remaining 784 VT episodes. ATP terminated 640 VTs successfully, ATP failed in 55 VTs finally reverted by shocks, and 89 VTs converted to a slower VT outside the VT zone. Fifty-one of these slower VTs reverted spontaneously, and 38 were redetected and treated. Finally, in primary intention-to-treat, ATP was successful in 691 VTs (subgroup ATP+), and unsuccessful in 93 VTs (subgroup ATP-). There were no influence of VT cycle lengh on ATP success rate. Furthermore, ATP efficacy was similar between patients with left ventricular EF less or equal to 35% or > 35%, as well as between patients with ischemic or nonischemic cardiomyopathy. Heart rate immediately preceding the onset of VT was found being the sole parameter affecting ATP effectiveness. Indeed, heart rate was faster in the subgroup ATP- compared to the subgroup ATP+ (103 ± 19 bpm vs 78 ± 14 bpm, respectively, $p < 0.0001$). Interestingly, ATP therapy was less successful among patients discharged without betablockers compared to betablocker-treated patients (79% vs 95%, respectively, $p < 0.0001$).
Conclusions: The present study demonstrates that elevated heart rate preceding the onset of VT, suggestive of an increased sympathetic tone, is the sole parameter affecting ATP effectiveness in patients with ICD.

124 Prognostic significance of electrical storm in patients with implantable cardioverter-defibrillators

F. Brigadeau, C. Kouakam, D. Klug, C. Marquié, M. Jarwé, D. Lacroix, S. Kacet. *Lille University Hospital, Cardiology Departement, Lille, France*

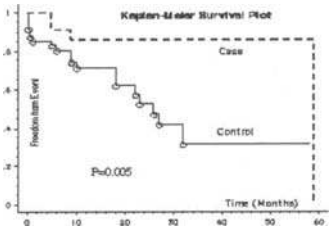
Background: Electrical storm (ES), multiple appropriate therapies (antitachycardia pacing and/or shocks) during a short time period, has been shown to be a frequent problem among recipients of implantable cardioverter defibrillators (ICDs). Some controversy exists today regarding its prognostic significance. This study was undertaken to provide data on incidence and prognostic significance of ES in ICD patients.
Methods and Results: Baseline characteristics of 307 patients with standard indications of ICD were prospectively collected, and chart reviews and episode data retrospectively analyzed. ES was defined as > or equal to 2 ventricular tachyarrhythmias within 24 hours. During a mean follow-up of 39 ± 32 months (median 27, range 7 to 152 months), 123 patients (40%) experienced 294 episodes of ES (2.4 ES/patient). This arrhythmia clustering occurred at an average of 27 ± 25 months after ICD implantation (median 17 months, range 0.07 to 120 months), and most episodes (90%) were due to ventricular tachycardia. Fifty-two patients (42%) suffered one ES episode, and 71 (58%) had > or equal 2 ES episodes. Characteristics and survival of ES patients were compared to those of ES-free patients. Fifty-tree patients died during the follow-up period. The cumulative probability of survival as estimated by the Kaplan-Meier method for the 307 studied patients was 92.3%, 84%, 82.3% at 1, 5 and 10-year follow-up, respectively. The number of all cause and cardiac deaths were 26 and 20, respectively, in the ES group, and 27 and 20, respectively, in the ES-free group. There were no significant difference in actuarial survival at 1, 5 and 10-year follow-up between the two groups. Seventy-nine percent of storm patients were alive at 10-year follow-up compared to 85% of ES-free patients.
Conclusions: ES is a frequent and recurrent trouble in ICD patients, can occur at any time during the follow-up period, and does not seem to be associated with an increased mortality.

125 The comparative efficacy of implantable cardioverter-defibrillator for primary and secondary prevention of sudden cardiac death

F. bokhari[1], D. Newman[2], C. Chow[2], M. Greene[2], J. Edwards[2], P. Dorian[2]. *[1]Toronto, ON, Canada; [2]St. Michael's Hospital, Cardiology, Toronto, ON, Canada*

Primary prevention of sudden cardiac death (SCD) is an accepted indication for ICD implantation.

Objective: The purpose of this case-control analysis is to evaluate the frequency of appropriate use of prophylactic ICD and the appropriateness of current risk stratification schemes. We estimated the frequency of appropriate ICD therapy in primary versus secondary ICD use; 39 patients received an ICD for prophylactic reasons including coronary artery disease with non-sustained VT (23%) or with low heart rate variability (21%) or clinical heart failure and low left ventricular ejection fraction (23%) or unexplained syncope with low left ventricular ejection fraction and dilated cardiomyopathy (33%). Cases were matched to 53 controls, which received an ICD for secondary prevention of episodes of documented sustained tachyarrhythmias, according to age (mean 62±15 vs 62±10 years), left ventricular function (mean 34±14 vs 34±13%), underlying coronary artery disease (72 vs 73%) and beta-blocker use (87 vs 87%) respectively.
Results: Over a mean follow up period of 18 months and 37 months for cases and controls respectively, appropriate therapy (antitachycardia pacing and/or shock) occurred in 13% of cases and 42% of controls(p=0.0029),(Kaplan-Meier curve). The median time to first appropriate therapy was 8 months and 12 months for cases and control respectively(p=0.5). Actuarial one-year mortality was 2.6%(N=1), 7.5% (N=4) for cases and control respectively (p=0.3).



Kaplan-Meier survival plot.

Conclusion: Patients receiving ICD for primary prophylaxis receive appropriate therapy significantly less often than matched patients receiving ICD for secondary prophylaxis.

MECHANISMS FOR MODULATION OF VASCULAR FUNCTION IN TYPE II DIABETES

169 Effects of low-dose ramipril on cardiovascular events in type 2 diabetes patients with microalbuminuria/proteinuria: the DIABHYCAR study

P. Gueret[1], M. Marre[2], M. Lievre[3], G. Chatellier[4], P. Passa[5] on behalf of the DIABHYCAR study group. *[1]Henri Mondor University Hospital, Cardiology, Creteil, France; [2]Bichat Hospital, Diabetology, Paris, France; [3]Lyon University Hospital, Pharmacology, Lyon, France; [4]Georges Pompidou Hospital, Biomedical Statistics, Paris, France; [5]St Louis Hospital, Diabetology, Paris, France*

High Urinary Albumin Excretion (UAE; microalbuminuria/proteinuria) predicts cardiovascular and renal events in type 2 diabetes patients. The ACE inhibitor ramipril at low dose reduces high UAE in these patients. To examine whether ramipril 1.25 mg/day may reduce the predicted risk, we conducted the DIABHYCAR (DIABetes, HYpertension, CArdiovascular events and Ramipril) study, a multicenter, multinational, placebo-controlled, parallel trial with ramipril 1.25 mg/d on top of the usual treatment in 4912 normotensive or hypertensive type 2 diabetes patients (men or women, aged > 50 years), selected because of permanent high UAE (> 20 mg/L) and plasma creatinine < 150 μM. The primary endpoint was the composite of cardiovascular death, myocardial infarction, stroke, acute heart failure requiring hospitalization, or end-stage renal failure. The study lasted >3 years (median 4.5 y), and study power to detect a 20% difference between the groups was calculated to be at least 85%. Seven hundred thirty nine primary endpoint events were observed (3.83/100 patients-years). No significant effect of Ramipril 1.25 mg was detected on either the primary endpoints [risk ratio (RR) = 0.97 (95% CI 0.85-1.11], or cardiovascular death [RR 1.07 (95% CI 0.85-1.35)], myocardial infarction [RR 0.89 (95% CI 0.61-1.29)], stroke [RR 1.07 (95% CI 0.80-1.44)], acute heart failure [RR 0.84 (95% CI 0.62-1.14)], or end-stage renal failure [RR 0.40 (95% CI 0.13-1.30)]. At one year, blood pressure had decreased by 2.1/1.0 mmHg in the ramipril compared with placebo ($p < 0.001$/ns). The proportion of patients who had proteinuria (UAE > 200 mg/L) at the end of study was 29.1% in the ramipril vs 32.6% in the placebo group ($p = 0.057$). The DIABHYCAR study complements the MICRO-HOPE results by showing that cardiovascular and renal risks need a full dose of ACE inhibitor to be reduced in type 2 diabetes.

170 PPARγ-ligands inhibit endothelial cell migration mediated by different chemoattractants via inhibition of Akt and eNOS

S. Goetze, P. Stawowy, U. Kintscher, F. Blaschke, C. Spencer-Hänsch, K. Graf, E. Fleck, M. Gräfe. *German Heart Institute, Cardiology Dept., Berlin, Germany*

Peroxisome proliferator-activated receptor gamma (PPARγ) plays an important role in the regulation of glucose metabolism and exerts several vascular effects that may provide a dual benefit of this receptor on metabolic disorders and vascular disease. Activating ligands of PPARg include the antidiabetic thiazolidinediones troglitazone and ciglitazone, which have been shown to inhibit vascular smooth muscle cell migration. Migration of endothelial cells in response to various angiogenic factors plays a critical role in the pathogenesis of late atherosclerotic lesions, since it contributes to neovascularization of the atherosclerotic plaque. It was therefore the aim of this study to investigate the effects of PPARg-ligands on endothelial cell migration induced by different migration factors and to examine the chemotactic signaling pathways involved. Using VEGF (20 ng/ml) or leptin (50 ng/ml) as chemoattractants, we observed a significant increase in directed migration of human umbilical vein endothelial cells (EC) by 4.3-fold, or 2.1-fold, respectively (all $p<0.05$). EC migration in response to both migration factors was dose-dependently inhibited by the PPARγ-ligands troglitazone (TRO, 1-20 μM) and ciglitazone (CIG, 1-20 μM), and almost completely blocked at their highest concentrations (all > 95%, all $p<0.05$). To elucidate which chemotactic signaling pathway was affected by the PPARγ-ligands, we next looked at their effects on signal transduction through the phosphatidyl inositol 3 kinase (PI3K) -> Akt -> endothelial nitric oxide synthase (eNOS) pathway and the p42/44 mitogen activated protein kinase (MAPK) → myosin light chain kinase (MLCK) pathway, both of which being known to be required for endothelial cell migration. Inhibition VEGF- or leptin-directed EC migration by the pharmacological PI3K-inhibitor wortmannin (100 nM) or the p42/44 MAPK inhibitor PD98059(30 μM) was confirmed in migration experiments (all > 90%, all $p < 0.05$).

Both, TRO (20 μM) and CIG (20 μM) significantly inhibited VEGF- and leptin-induced phosphorylation of the protein kinase Akt and its downstream target eNOS, whereas phosphorylation and activation of p42/44 MAPK and MLCK in response to the migration factors was not affected by any of the PPARg-ligands. Our study identifies, that PPARγ-ligands inhibit chemotactic signal transduction in EC by targeting the PI3K →Akt→ eNOS pathway. By inhibiting EC migration PPARγ-ligands may protect the vasculature from pathological alterations associated with metabolic disorders.

171 Growth factor- and cytokine-mediated regulation of PPARγ in human monocytes

U. Kintscher[1], D. Bruemmer[1], S. Goetze[1], P. Stawowy[1], E. Fleck[1], W.A. Hsueh[2], R.E. Law[2]. [1]*Deutsches Herzzentrum Berlin, Cardiology, Berlin, Germany;* [2]*University of California, Los Angeles, Div. of Endocrinology and Hypertension, Los Angeles, United States of America*

The nuclear hormone receptor peroxisome proliferator-activator γ (PPARγ) is expressed as two isoforms (PPARγ 1 and 2), is upregulated in atherosclerotic lesions, and an important regulator of monocyte function. Since little is known about growth factor-mediated regulation of PPARγ in monocytes, we studied the regulation of PPAR γ 1 and 2 by different growth factors and cytokines in human peripheral blood monocytes (HPBM) and human THP-1 monocytes.

Human THP-1 monocytes were treated with Angiotensin II (AngII, 1μmol/L), Transforming growth factor-beta1 (TGF-β1, 5ng/ml)), Tumor necrosis factor alpha (TNFα, 10ng/ml), Monocyte chemoattractant protein 1 (MCP-1, 50ng/ml), and C-reactive Protein (CRP, 200μg/ml)). In western immunoblotting experiments, treatment with AngII, TNFα, MCP-1, and CRP showed no effect on PPARγ 1/2 protein expression. Whereas TGF-β1 induced PPARγ 1/2 protein expression by 3.8±0.2-fold in THP-1 cells and by 2±0.1-fold in HPBM after 24h (both $p<0.05$). RNAse protection assays in THP-1 monocytes demonstrated that TGF-β1 (5ng/ml) predominantly induced PPARγ2 mRNA after 2h stimulation with a maximal induction of 14.8±2-fold after 24h ($p<0.01$), whereas PPARγ1 mRNA was only induced by 2.2±0.2-fold after 24h ($p<0.05$). Transient transfection experiments revealed that TGF-β1 (5ng/ml) activates transcription from a PPARγ2 promoter/ luciferase reporter vector by 3.4±0.1-fold ($p<0.05$). Mutation of two CCAAT/ enhancer binding protein (C/EBP) consensus recognition sites reduced the inductive effects of TGF-β1 by 67.4±6.2% ($p<0.05$). To examine if TGF-β1-upregulated PPARγ is transcriptionally active, we performed transient transfection experiments with a PPAR response element (PPRE) driven acyl-CoA oxidase-Tk-luciferase reporter plasmid. TGF-β1 (5ng/ml) alone stimulated PPRE activity by 2.1±0.1-fold, which was further stimulated by the synthetic PPARγ-ligand Rosiglitazone (10μM) to 4±0.3-fold (both $p<0.05$).

The present study demonstrates that TGF-β1 induces monocytic PPARγ1/2 with a predominant stimulation of PPARγ2, which is mediated through a transcriptional mechanism involving C/EBP. TGF-beta1-mediated induction of PPARγ 1/2 in monocytes may play an important role for PPARγ regulation and function in atherosclerotic lesions.

172 Hyperglycemia-induced oxidative stress and vascular inflammation via protein kinase C activation

F. Cosentino[1], A. Kouroedov[1], M. Eto[1], M. Bachschmid[2], M. Volpe[3], T.F. Lüscher[1]. [1]*Zürich University, Institute of Physiology, Zürich, Switzerland;* [2]*University of Konstanz, Biology, Konstanz, Germany;* [3]*University "La Sapienza", Experimental Medicine and Pathology, Rome, Italy*

The link between diabetes mellitus and premature cardiovascular disease is well established. Loss of the modulatory role of the endothelium may be an initiating factor in the development of diabetic vascular complications. Hyperglycemia, which is recognized as the culprit in the pathogenesis of diabetic vascular disease triggers the endothelial dysfunction. The molecular mechanisms by which high glucose reduces availability of NO, increases reactive oxygen species (ROS) generation and stimulates proinflammatory endothelial changes remain poorly understood. This study was designed to investigate the underlying intracellular signaling pathways. Human aortic endothelial cells were exposed to control (5.5 mM) or high glucose (22.5mM) for 48 hours. Protein kinase C (PKC) assay system was performed in cell homogenates. The intracellular formation of ROS was detected using the fluorescent probe H2-DCFDA. Nuclear factor-kB (NF-kB) activity was assessed by gel shift assay. Expression of P-selectin, ICAM-1, VCAM-1 and monocyte chemoattractant protein-1 was measured by Western blotting. Glucose-induced increase of membrane-bound PKC activity (191% vs control, n=4, $P<0.05$) was associated with subsequent generation of ROS (10436±2101 vs 24893±3996 relative units for control and high glucose respectively, n=6, $P<0.05$). Accordingly, N-acetylcysteine (50 mmol/L) and vitamin C (100 mmol/L) did not affect glucose-induced activation of PKC, whereas inhibition of PKC with calphostin C (3x10-7 mol/L) abolished glucose-induced generation of ROS (9820±1121 relative units, n=6). The glucose-induced and PKC-dependent oxidant generation caused NF-kB activation (297±71% vs control, n=3, $P<0.05$). Indeed, the increase of NF-kB activity was abolished by calphostin C as well as N-acetylcysteine (84±22 and 123±33%, respectively). Furthermore, high glucose significantly increased the level of P-selectin (200±69% vs control,$P<0.05$, n=3), ICAM-1 (156±5% vs control, $P<0.01$, n=3) and VCAM-1 (164±26% vs control, $P<0.05$, n=4). Phorbol 12-myristate 13-acetate (PMA, 10-6 mol/L) induced an increase of adhesion molecule expression similar to that elicited by glucose. The effect of glucose and PMA was totally reversed by co-incubating the cells with calphostin C. Protein level of monocyte chemoattractant protein-1 in cells exposed to high glucose was also increased (149±8% vs control, $P<0.001$, n=4). Our results show that intracellular PKC-signaling pathway is the proximal step for hyperglycemia-induced endothelial redox and inflammatory changes.

173 A novel proinflammatory pathway involving the signal transduction sequence of S100A8/S100A9-RAGE-MAPK-NFkappaB

P. Ehlermann[1], K. Eggers[1], P. Most[1], A. Bierhaus[2], P.P. Nawroth[2], H.A. Katus[1], A. Remppis[1]. [1]*Universitaetsklinikum Luebeck, Medizinische Klinik II, Luebeck, Germany;* [2]*Abteilung Innere Medizin I, Universität Heidelberg, Heidelberg, Germany*

Atherosclerosis is an inflammatory disease in which a perpetuated activation of NFkappaB via the RAGE (receptor for advanced glycation end-products)-MAPK signaling pathway may play a central pathogenetic role. As recently Ca^{2+} binding proteins of the S100 family have been identified as novel ligands of RAGE we sought to determine the effects of the proinflammatory heterodimer of S100A8/S100A9 on the RAGE-NFkappaB mediated activation of proinflammatory molecules. Endothelial cells (HUVEC) were preincubated for 72 h with AGE-albumin or albumin for control, whereas AGE-albumin induction resulted in a dramatic upregulation of RAGE. Following this preactivation, cells were stimulated for 48 h with human recombinant S100A8/S100A9. Control stimulations were performed with S100A8 and S100A9 homodimers respectively as well as with S100A1 and S100B. Culture supernatants were screened for IL-6, ICAM-1, VCAM-1 and MCP1 secretion. Heterodimeric S100A8/S100A9 dose dependently enhanced secretion of IL-6, ICAM-1, VCAM-1 and MCP1 in AGE-albumin pretreated HUVEC. These effects could not be detected after stimulation with the homodimeric proteins S100A8, S100A9, S100A1 and S100B. While secretion of IL-6, ICAM-1, VCAM-1 and MCP1 was significantly reduced by PD98059 (30 μM) or simvastatin (10 μM) indicating both a ras and ERK1/2 associated effect of heterodimeric S100A8/S100A9, no effect was seen with SB203580 (20 μM), an inhibitor of the p38/SAPK-pathway. The stimulation of AGE-albumin pretreated HUVEC with the heterodimeric S100A8/S100A9 thus results in a proinflammatory endothelial response which is apparently conveyed by a ras/ERK1/2 dependent signal transduction pathway. These observations appear to be specific since the application of other members of the highly conserved S100 protein family did not exert a proinflammatory response. The heterodimeric proinflammatory protein S100A8/S100A9 might thus play a hitherto unknown but central role in the propagation of NFkappaB associated proinflammatory events triggering atherosclerosis in diabetes and renal failure which are pathophysiological entities associated with a high AGE burden. Thus blocking the proinflammatory activity of S100A8/S100A9 might represent a novel therapeutic modality in treating atherosclerosis.

174 Increased vascular oxidative stress in patients with type II diabetes mellitus is mediated by protein kinase C

T.J. Guzik[1], J. Sadowski[2], B. Kapelak[2], R. Pillai[1], T. Adamek-Guzik[3], R. Korbut[4], K.M. Channon[1]. [1]University of Oxford, J Radcliffe Hosp, Department of Cardiovascular Medicine, Oxford, United Kingdom; [2]Jagiellonian University, Dept of Cardiovascular Surgery, Cracow, Poland; [3]Jagiellonian University, Deptartment of Medicne, J. Dietl Hosp, Cracow, Poland; [4]Jagiellonian University, Department of Pharmacology, Cracow, Poland

Increased oxidative stress may contribute to vascular pathology in patients with type II diabetes mellitus. We have previously shown that oxidative stress in diabetes is mediated by primarily vascular NADPH oxidase, but the mechanisms leading to an increased NADPH oxidase activity remain unclear. We aimed to study the role of vascular protein kinase C (PKC) in mediating NADPH activity in arteries of patients with diabetes.

Methods: Segments of internal mammary artery (IMA) were obtained from 25 patients with non-insulin dependent diabetes (DM) and 25 non-diabetic patients (nonDM) (matched for other risk factors, cholesterol levels, age, sex, and MI) undergoing bypass graft surgery. Both basal and NADPH-stimulated (100μM) superoxide generation was measured using lucigenin enhanced chemiluminescence (5μM) and by dihydroethidium staining in frozen cryosections. Results: Both basal and NADPH-stimulated superoxide generation were significantly higher in IMA from DM patients. Dihydroethidium staining showed that increased superoxide production in DM vessels was observed predominantly in the endothelium and to the lesser extent in the media. Superoxide production was abolished by preincubation with NADPH oxidase inhibitors DPI (10μM) and apocynin (1mM). Moreover, incubation of vascular segments with chelerythrine (3μM), an inhibitor of PKC, significantly inhibited both basal and NADPH stimulated superoxide generation (table). This inhibition was much more marked in diabetic than in non diabetic vessels (63±6% vs 28±5%; $p<0.01$ for basal). PKC inhibitor abolished the difference in both basal and NADPH stimulated superoxide generation, between DM and non DM vessels.

	nonDM-basal	non DM-NADPH	DM basal	DM - NADPH
native	20.4±2.9	1499±244	29.9±4.5*	2844±718*
+ chelery(3uM)	14.6±2.1	919±365	11.1±1.9	1489±533
p value	0.04	0.02	0.001	0.002

*-$p<0.05$ vs non DM

Conclusions: Our results suggest that protein kinase C signaling plays an important role in mediating increased activity of vascular NAD(P)H oxidase in human diabetic arteries. Protein kinase C inhibitors may have vasculoprotective effects in diabetic patients.

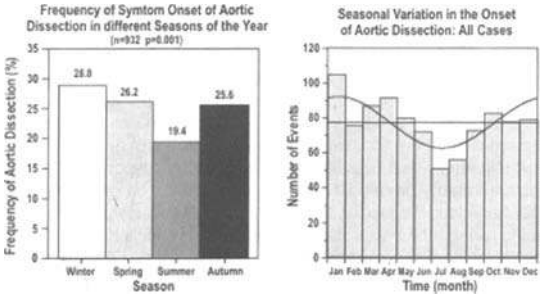
AORTIC DISSECTION

175 Seasonal variation in the risk of acute aortic dissections

R.H. Mehta[1], R. Manfredini[2], F. Hassan[1], E. Bossone[1], J.V. Cooper[1], C. Nienaber[3], E.M. Isselbacher[4], K.A. Eagle[1] on behalf of the International Registry of Acute Aortic Dissection (IRAD). [1]University of Michigan, Cardiology Dept., Ann Arbor, United States of America; [2]University of Ferrara, First Internal Medicine & Hypertension, Ferrara, Italy; [3]University of Rostock, Division of Cardiology, Rostock, Germany; [4]Massachusetts General Hospital, Cardiology, Boston, United States of America

Background: Seasonal variations have been shown to influence the occurrence of a variety of cardiovascular disorders. However, the effects of circannual rhythms on the risk of acute aortic dissection (AAD) have not been studied.

Methods: To evaluate the impact of seasonal changes on the risk of AAD, we studied 957 patients enrolled in the International Registry of Acute Aortic Dissection between 1996 and 2000 (mean age 62+14 years, type A 61%). For the purpose of seasonal analysis patients were grouped according to their symptom onset during the four seasons (winter = December 21st through March 20th, spring = March 21st through June 20th, summer = June 21st through September 20th, and autumn = September 21st through December 20th). Chi-square test for goodness of fit and partial Fourier analysis were employed to evaluate non-uniformity and rhythmicity, respectively, of AAD during various seasonal periods.



Results: A significant seasonal variation occurred in the frequency of AAD with maximum incidence in winter (chi-square=17.5, d.f=3, p=0.001, Figure-left panel). The winter peak was significantly higher compared to the other 3 seasons (chi-square=7.0, d.f=1, p=0.008). Fourier analysis identified a peak incidence of AAD in the month of January (95% confidence limit January-February, p=0.022; Figure-right panel).

Conclusions: Similar to other cardiovascular conditions, AAD exhibits significant seasonal variations with highest incidence in winter. Our findings may have important implications for the prevention of AAD by tailoring treatment strategies to ensure maximal benefits during the vulnerable period.

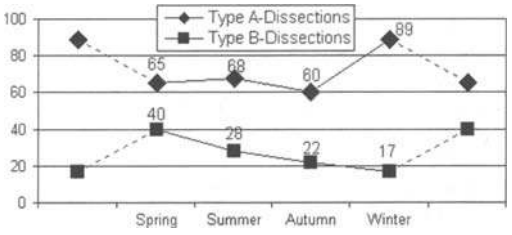
176 Variable seasonal peaks for different types of aortic dissection?

R. Kobza[1], M. Ritter[1], B. Seifert[2], E. Oechslin[1], R. Jenni[1]. [1]University Hospital, Cardiology, Zurich, Switzerland; [2]University of Zurich, Department of Biostatistics, Zurich, Switzerland

Background: Daily clinical practice suggests seasonal variability in the occurrence of aortic dissection.

Methods: We reviewed all records of patients admitted to our hospital for acute dissection from autumn 1990 to summer 2001. The screening and confirmation of the diagnosis of acute aortic dissection was performed exclusively by transesophageal echocardiography.

Results: Within the investigated eleven years' period, acute aortic dissection was diagnosed in 389 patients. In 282 patients acute Stanford type A aortic dissection was found and 107 patients had Stanford type B aortic dissection. Cyclic variation regarding the incidence of the different types of acute aortic dissection throughout the year was analysed by dividing the year into its four seasons of equal length. Each season was compared with the rest of the year using Chi-Square test with Bonferroni-correction (significance for p-values < 0.0125). In type A aortic dissection a significant peak of 89 cases in winter versus 65 in spring, 68 in summer and 60 in autumn was found (p = 0.011, figure). Conversely, in type B aortic dissection, there was a peak incidence in spring with 40 cases versus 28 in summer, 22 in autumn and 17 in winter (p = 0.003, figure).



Number of aortic dissections by season.

Conclusion: The underlying factors for the observed seasonal differences regarding both, type A and type B dissections, are not well understood, but the pattern of type A dissection resembles that of cyclic arterial blood pressure variation, which exhibits a seasonal peak in the coldest season. This is of relevance as hypertension is likely to be one of the most important predisposing factors of aortic dissection. Seasonal changes of blood pressure, however, do not explain the higher rate of type B dissections in spring.

177 Up to 7 years experience with valve sparing aortic root reconstruction (remodelling/reimplantation) for acute type A dissection

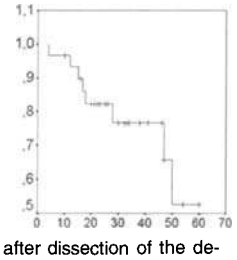
A.W. Erasmi, J.F.M. Bechtel, U. Stierle, H.H. Sievers. *University of Luebeck, Cardiac Surgery, Luebeck, Germany*

Purpose: The operative strategy for treatment of type A dissection remains a major challenge especially if the aortic leaflets are macroscopically intact. Valve preserving techniques are theoretically attractive but require extensive longer-term evaluation for final judgment of these operative techniques. We present our results with two types of valve sparing techniques: the remodeling method according to Yacoub (group 1) in comparison to the reimplantation technique according to David (group 2).
Methods: Between October 1994 and November 2001, 134 patients were operated for acute type A dissection. Among those were n=21 in group 1 (remodeling) and n=15 in group 2 (reimplantation). Age in group 1 was 60±14 and 54±12 years in group 2 (p=0.11). Bypass time was 209 minutes (median) in group 1 versus 212 minutes in group 2 (p=0.62). The number of patients with cardiogenic shock at admission were 6 (26%) and 9 (60%) in groups 1 and 2, respectively (p=0.09). Patients were followed echocardiographically and clinically for up to 55 (median 25) months in group 1 and up to 87 (median 9) months in group 2 (p=0.47).
Results: Hospital mortality was 19% (n=4, group 1) and 20% (n=3, group 2; p=1.0). The only factor significantly associated with hospital mortality was cardiogenic shock on admission (p=0.013). There were 5 (24%, 1 cardiac related) and 1 (8%) late deaths in groups 1 and 2, respectively (p=0.35). Overall survival was 57% at 55 month for group 1 and 73% at 87 month for group 2. In group 1, reoperation due to re-dissection of the aortic root was necessary in 3 patients. In these 3 patients, Glutaraldehyde Resorcin Formalin [GFR] glue was used intraoperatively (p=0.019 as compared with the non-use of GFR glue), and 2 patients had Marfans disease (p<0.001 as compared to patients without Marfans disease). There were no reoperations for re-dissection of the aortic root in group 2 (p=0.28). Echoardiographic results were as follows: aortic regurgitation ≤I° in all patients; the mean pressure gradient across the left ventricular outflow tract was 3.0±1.5 in group 1 and 3.5±1.1 mm Hg in group 2 (p=0.51); the ejection fraction was 56±13 and 68±6% in groups 1 and 2, respectively (p=0.037).
Conclusion: Valve preserving techniques for type A dissection provide encouraging hemodynamic results. The reimplantation technique in this situation seems durable and preferable especially for patients with Marfans disease or when GFR glue is needed. The major risk factor for hospital mortality (cardiogenic shock on admission) requires further attention.

178 Dissection of descending aorta in Marfan syndrome

C. Meuleman[1], C. Muti[2], F. Digne[1], M. DeStJean[3], B. Moura[4], C. Boileau[2], G. Jondeau[1]. *[1]Hôpital A Paré AP-HP, Cardiologie, Boulogne, France; [2]Hôpital Ambroise Paré AP-HP, Marfan out-patient clinic Dept., Boulogne, France; [3]Hopital A Paré, ophtalmologie, Boulogne, France; [4]Hopital A Paré, rhumatologie, Boulogne, France*

Prevalence and natural history of dissection (diss) of the descending aorta (Ao) is not well documented.
1250 patients came to our out-patient clinic dedicated to Marfan syndrome (MFS), mean age 29±15, 215 (51%) females. MFS was diagnosed according to international criteria, with the collaboration of a cardiologist, an ophthalmologist, a pediatrician, a rheumatologist and a genetician. Siblings were invited to come.
Out of 415 MFS patients, diss of the descending Ao occurred in 30 (7,2%); mean age 42±11 yo, 13 (43%) females. Mean follow-up was 3.3±2.5 years after dissection. Diss of the descending Ao was an extension of a diss of the ascending Ao in 27 patients. In only 3 MFS diss was localized only to the descending Ao.
MFS was recognized before diss in 7 patients (23%) who were receiving a beta-blocker (B-). After dissection, 24 patients (80%) received B-; Out of the 6 patients not receiving B-, 2 received calcium antagonist, one ACEI, and 3 no treatment (2 unwilling to take therapy, and one stopped because of side effects).
No diss occurred during pregnancy, but 2 early after delivery (4 days and 8 days). Six patients underwent surgery on the descending Ao: one at the time of diss, and 2.3, 3.4, 4.3, 4.8, 7.1 years after the acute event (mean 4.4 years). 4 patients deceased (1.5, 2.3, 4.2, 9.8 years after dissection; mean 4.5 years). Figure 1 shows the event free survival curve in our patients, for the 60 first months after diss.



Conclusion: dissection of the descending Ao is usually an extension of a dissection of the ascending Ao in MFS. The event-free survival curve after dissection of the descending Ao strongly supports operation before dissection of the ascending Ao occurs.

179 Aortic complication during and after pregnancy in Marfan syndrome

L. Pacini[1], F. Digne[1], J.M. LeParc[2], M. DeStJean[3], C. Muti[4], C. Boileau[4], G. Jondeau[1]. *[1]Hôpital A Paré AP-HP, Cardiologie, Boulogne, France; [2]Hopital A Paré, rhumatologie, Boulogne, France; [3]Hopital A Paré, ophtalmologie, Boulogne, France; [4]Hôpital Ambroise Paré, Marfan out-patient clinic, Boulogne, France*

Pregnancy has been associated with an increased risk of aortic dissection and dilation in women with Marfan syndrome (MFS)
We set up a multidisciplinary out-patient clinic devoted to Marfan syndrome gathering an ophthalmologist, a cardiologist, a pediatrician, a rheumatologist and a genetician.
1450 patients came to this clinic. MFS was diagnosed according to international criteria in 450 MFS including 154 women above 18 y.o.. Eighty six MFS women had 130 children.
MFS was recognised before pregnancy in 11 women who received beta-blocker during pregnancy. No complications occurred.
Aortic surgery was performed in 24 women having children and 13 having no children. However, aortic surgery had to be performed only 4 times during pregnancy for aortic dissection (n=4) and once 4 days after delivery for aortic dilation.
If only women having children younger than 40 are considered (n=45), mean age is 32, i.e. identical to that of women without children. Twelve had been operated on (i.e.27%), compared with 13 of the 68 having no children (i.e. 19%) (p=NS).

Women with and without children

	Women with children	Women without children
Number	86	68
Age	42±12	32±12
Age for pregnancy	25.7	
Aortic dissection	14 (16.3%)	9 (13.2%)
Surgery for aortic dilation	10 (11.6%)	4 (5.9%)
Surgery for aortic diss or dil	24 (28%)	13 (19%)
Mitral surgery	5 (5.8%)	6 (8.8%)

Conclusion: In our group of 86 women with MF syndrome having had pregnancy, 1) underdiagnosis was frequent, 2) few aortic surgery had to be performed during pregnancy, and 3) the rate of aortic complication was not significantly higher in women having children

180 Early and long-term results of total aortic arch grafting in elderly patients

Y. Takahara, K. Mogi, M. Sakurai. *Funabashi Municipal Medical Center, Cardiovascular Surgery, Funabashi, Japan*

Improved techniques of surgical management have progressively reduced the risk of aortic surgery. Moreover, the proportion of aortic aneurysm increases in elderly. As a result, an increasing number of patients over 70 undergo total aortic arch grafting. On the other hand, perioperative cerebral complications cause of poor outcome. This study assesses our experiences with aortic arch grafting using a refined cerebral protection comparatively between elderly and younger patients.
Patient and methods Of 101 consecutive patients underwent aortic arch grafting from June 1994 to January 2002, 37 patients were 70 years or older. Mean age at the time of surgery was 73.4 ± 2.8 years. Aneurysms were atherosclerotic in 25 and aortic dissection in 12. Nine patients were in states of shock preoperatively. The control group consisted of 64 patients under 70 years. There were no significant difference of preoperative conditions between both groups. We conducted total arch grafting using hypothermic antegrade selective cerebral perfusion to every aortic arch branch. Carbon dioxide gas was added to the cerebral perfusion in order to inhibit the increase in the cerebral vascular resistance during hypothermic cerebral perfusion.
Result Hospital mortality was 8.1% in the elder group and 4.7% in the younger group (p=0.49). No operative major cerebral complications were observed, although 4 patients in the younger group experienced temporary neurological symptoms. The rate of postoperative respiratory problems was higher in the elder group (p=0.026). The mean length of postoperative ICU stay was longer in the elder group (p=0.049). The mean length of postoperative hospital stay was not significant different between both group (31.9 days in the elderly and 29.9 days in the younger). The seven year survival was 61.6 ± 10.6% in the elder group and 79.8 ± 5.6% in the younger group (p=0.38). Freedom from aortic events (re-operation, rupture and cholesterol embolism) after 7 years was 88.4 ± 6.4% in the elder group and 70.1 ± 10.5% in the younger group (p=0.66).
Conclusion Early and long-term results of total aortic arch grafting using integrated antegrade cerebral perfusion in patients older than 70 years were satisfactory compared with those of patients under 70 years of age.

LESION SEVERITY: OUR EYES ARE NOT GOOD ENOUGH!

185 Invasive assessment of intermediate coronary stenosis – comparison of intracoronary ultrasound with fractional flow reserve

J. Legutko, D. Dudek, M. Wizimirski, K. Zmudka, J. Dubiel. *Jagiellonian University, Institute of Cardiology, Krakow, Poland*

Background: Intracoronary ultrasound (ICUS) derived minimal lumen cross-sectional area (LAmin, mm^2) <4.0 is used as the cut-off value for revascularization in patient with intermediate coronary lesion (IML). Pressure-derived fractional flow reserve (FFR) <0.75 is strongly related to provokable myocardial ischemia. The aim of the study was to evaluate the usefulness of ICUS assessment of IML in comparison to FFR.
Methods: In 56 pts with stable angina and IML (Diameter stenosis (DS) =40-60% by QCA), without left main stenosis, prior myocardial infarction or left ventricular hypertrophy, FFR was calculated after intracoronary injection of adenosine (40-80 μg for the left coronary artery, 15-30 μg for the right). Than, in all lesions ICUS was performed using automated pull-back (0.5 mm/sec) to calculate LAmin and the lesion length (LL, mm). According to FFR pts were divided into two groups: Group 1: FFR<0.75 (12 pts), Group 2: FFR>0.75 (44 pts). All lesions with FFR>0,75 were not revascularized and followed-up for 12 months to assess the frequency of lesion-related major adverse cardiac events LR-MACE (death, myocardial infarction, target lesion revasularization).
Results: The comparison of QCA, FFR and ICUS parameters between the two groups is shown in table. LAmin>4.0 was obtained in 3 pts (25%) in group 1, and LAmin<0.4 was present in 16 pts (36%) in group 2. There was no LR-MACE during 12 months follow-up among patients with LAmin<4.0 and FFR>0,75.

	Ref.D-QCA	LL-QCA	MLD-QCA	DS-QCA	FFR	LAmin-ICUS	LL-ICUS
Group 1	3.02±0.54	18.3±5.8	1.50±0.17	49.7±7.0	0.67±0.08	3.20±0.45	19.5±7.14
Group 2	3.06±0.38	11.3±3.9	1.48±0.27	51.8±7.8	0.85±0.05	3.74±1.01	11.2±5.13
p=	NS	0.018	NS	NS	0.0027	0.042	0.0017

Conclusions: ICUS assessment of the minimal lumen cross-sectional area has only a limited value in determining the clinical importance of intermediate coronary lesion. Lesion length influence functional severity of intermediate coronary lesion. Even in patients with LAmin<4.0 deferral of intervention based on FFR is safe and associated with good long-term clinical outcome.

186 The angiographical stenotic flow reserve compared to intracoronary haemodynamic parameters for evaluation of coronary lesion severity

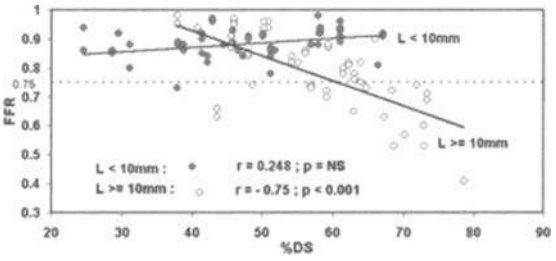
J J. Wiersma[1], S.A.J Chamuleau[1], M. Meuwissen[1], J.H.C. Reiber[2], J.J. Piek[1]. *[1]Amsterdam Medical Center, Department of Cardiology, Amsterdam, Netherlands; [2]Leiden University Medical Center, Department of Radiology, Leiden, Netherlands*

Background: Based on fluid dynamics equations and the geometry of coronary narrowings, quantitative coronary angiography (QCA) provides an estimate of coronary flow reserve (the stenotic flow reserve, SFR).
Objective: A direct comparison between stenotic flow reserve and intracoronary-derived coronary flow reserve parameters (fractional flow reserve (FFR), coronary flow velocity reserve (CFVR) and relative coronary flow velocity reserve (rCFVR)), for functional evaluation of coronary lesion severity as determined by 99mTc MIBI-SPECT as substudy of the ILIAS study (Intermediate Lesions: Intracoronary-flow Assessment vs. 99mTc MIBI-SPECT).
Methods: A total of 201 patients with stable (CCS class 1-3) or unstable (Braunwald class I-II) angina underwent myocardial perfusion scintigraphy in a two day stress-rest protocol to determine reversible perfusion defects.
Quantitative coronary angiography was performed using the CMS-QCA software 3.32 (MEDIS, Leiden, the Netherlands) which includes the analysis of stenotic flow reserve.
FFR, CFVR and rCFVR (defined as the ratio of CFVR of the narrowed vessel and CFVR of the reference coronary artery) were determined with guide wires distal to 163 coronary lesions (mean diameter stenosis of 57%; range 20%-87%), during baseline and maximum hyperemia (induced by 15-20 mcg adenosine ic).
Linear regression was performed to determine the relationship between stenotic flow reserve and FFR, CFVR and rCFVR.
ROC-analysis was performed to determine the best cut off value of stenotic flow reserve and the predictive values of stenotic flow reserve, FFR, CFVR, rCFVR for detection of reversible perfusion defects (by area under curve, AUC).
Results: Linear regression showed moderate relations between stenotic flow reserve and FFR (r=0.64, p<0.0001), CFVR (r=0.51, p<0.0001) and rCFVR (r=0.60, p<0.0001). The area under the curve of stenotic flow reserve was 0.75±0,05 with a best cut-off value of 2.25. The area under the curve of FFR, CFVR and rCFVR was 0,79 ± 0,05, 0,76 ± 0,04, 0,75 ± 0,03 respectively.
Conclusion: Stenotic flow reserve has a moderate agreement with fractional, absolute and relative flow reserve, while the predictive value of stenotic flow reserve for the functional evaluation of coronary lesion severity is similar to the intracoronary derived hemodynamic parameters.

187 The effect of lesion length on the functional significance of coronary lesions

D. Brosh[1], S.T. Higano[2], M.J. Slepian[3], H.I. Miller[4], M.J. Kern[5], D.R. Holmes[2], A. Lerman[2]. *[1]Mayo Clinic - Saint Marys Hospital, Cardiology, Rochester MN, United States of America; [2]Mayo Clinic, Saint Marys Hospital, Cardiology, Rochester, United States of America; [3]Heart Center, Cardiology, Tucson AZ, United States of America; [4]Ichilov Hospital, Cardiology, Tel-Aviv, Israel; [5]Saint Louis University, Cardiology, Saint Louis MO, United States of America*

Background: Fractional flow reserve (FFR) has become the gold standard in physiologic assessment of coronary artery stenosis. This especially holds true for the functional evaluation of angiographically intermediate lesions. An FFR value < 0.75 is considered a reliable physiologic parameter indicating a functionally significant lesion. However, the effect of lesion length (LL) on FFR has not been adequately assessed. The current study was designed to examine the effect of LL on FFR in patients with coronary artery disease.
Methods: We performed FFR measurements by pressure guidewire, in 54 lesions (48 pts.). LL and percent diameter stenosis (%DS) at the lesion site were determined by performing quantitative coronary angiography (QCA) analysis.
Results: Overall, there was a moderate inverse correlation between FFR and %DS (r = -0.55, p < 0.001). Using a receiver operating characteristic (ROC) curve analysis, a LL = 10 mm was identified to be the best cutoff value for predicting a FFR < 0.75 (sensitivity 96%, specificity 63%, positive predictive power 40%, negative predictive power 98%). The correlation between FFR and %DS significantly improved for LL ≥ 10 mm, as compared to LL < 10 mm (r = -0.75, p < 0.001; r = 0.25, p = NS; respectively; Figure). Similar improvement with LL was observed for angiographically intermediate lesions (%DS: 50-70%: r = -0.73, p < 0.001 for LL ≥ 10 mm; r = 0.28, p = NS for LL < 10 mm).



LL effect on lesion functional severity.

Conclusions: This study demonstrates that lesion length differentially effects the correlation between the functional assessment (FFR) and the "anatomical" angiographic assessment (%DS) of coronary lesions and suggests that, lesion length has a significant impact on the physiologic significance of coronary artery lesions.

188 Intracoronary or intravenous adenosine during fractional flow reserve: influence of stenosis severity, collateral steal and branch order

D. Camacho Gaxiola, J. Escaned, J. Garcia, M. Sabaté, F. Alfonso, C. Bañuelos, R. Hernandez-Antolin, C. Macaya. *Hospital Clinico San Carlos, Intervencional cardiology, Madrid, Spain*

Background: Achievement of maximal vasodilatation of coronary microcirculation is a pre-requisite for performance of fractional flow reserve (FFR), a pressure derived index of coronary reserve. Although intravenous (iv) adenosine infusion has been proposed as the method of choice, intracoronary (ic) bolus administration in widely used in clinical practice. Little information is available, however, on the validity of the latter approach, and on adequate ic adenosine dosage.
Methods: Following a prospective study design, in 38 coronary stenosis with intermediate severity (54.2 ± 0.49) FFR was measured during coronary hyperemia induced with adenosine administered intravenously (140μg/kg/min) (FFRiv) and intracoronarily (incremental dosages of 20, 40 and 80μg) (FFRic). The discrepancy between FFRic and FFRiv measurements was estimated as the ratio FFRic/FFRiv. In 19 cases followed by PTCA, collateral flow index (CFI), defined as coronary wedge pressure/aortic pressure, was measured with (CFI-aden) and without concomitant iv adenosine infusion for one minute. Coronary steal was defined as the ratio CFI/CFI-aden. The influence of branch order, stenosis severity, CFI and coronary steal on the discrepancy FFRic/FFRiv was estimated.
Results: There were no adverse events in relationship with adenosine administration. Table I shows FFR data resulting from the different adenosine dosages

	20μg bolus	40μg bolus	80μg bolus	IV 140μg/kg/min
FFR	0.73 ± 0.15	0.72 ± 0.71	0.71 ± 0.20	0.68 ± 0.16
FFR<0.75 (%)	16 (42)	19 (50)	20 (53)	24 (63)
False negatives	8 (21.0%)	5 (13.1%)	4(10.5%)	0 (0%)
FFRic/FFRiv	1.09 ± 1.1	1.07 ± 0.8	1.05± 0.78	—

The discrepancy FFRic/FFRiv was not influenced by branching order (1.73±0.56), CFI (0.15±0.08) and coronary steal (1.23±0.35), but increased with stenosis severity (r=0.66, p=<0.0001), even after adjustment to FFRiv (r=0.68, beta coeff=0.49, p=<0.0001).
Conclusions: 1/ When compared with FFRiv an unacceptable high number of false negative FFRic readings occur even with dosages of 80 μg; 2/ the discrepancy between FFRic and FFRiv was not due to collateral steal; 3/ stenosis severity, on the contrary, increases the discrepancy between FFRic and FFRiv, presumably due to preferential washout of ic adenosine to side branches with less epicardial resistance.

189 Calculation of pressure-derived fractional flow reserve in patients with moderate left main coronary artery stenosis

J. Legutko, D. Dudek, P. Turek, S. Bartus, M. Wizimirski, J. Dubiel. *Jagiellonian University, Institute of Cardiology, Krakow, Poland*

Background: Intracoronary ultrasound (ICUS) is widely used to define clinical significance of borderline left main stenosis (BLM). ICUS-derived: minimal lumen cross-sectional area (LAmin, mm^2) >9.0 and minimal lumen diameter (MLD, mm) >3,0 are proposed as the cut-off values for deferral revascularisation in patients with BLM. Pressure-derived fractional flow reserve (FFR) <0.75 is strongly related to provokable myocardial ischemia. However the application of FFR in patients with BLM was not clearly established. The aim of the study was to evaluate the usefulness of FFR assessment of BLM in comparison to ICUS.
Methods: In 21 pts with isolated BLM, without prior myocardial infarction or left ventricular hypertrophy, FFR was calculated before and after 1, 2 and 3 min of continuous intravenous infusion of adenosine (140 μg/kg/min). Than, in all lesions ICUS was performed using automated pull-back (0.5 mm/sec) to calculate left main LAmin and MLD. According to FFR pts were divided into two groups: Group 1: FFR<0.75 (6 pts), Group 2: FFR>0.75 (15 pts). Results: There was no complications occurring during invasive assessment of BLM. Angiographic percent diameter stenosis (assessed by QCA) was similar in both groups (group 1 vs. group 2: 41±3% vs. 45±6%, p=NS). ICUS-derived LAmin <9.0 and MLD <3,0 was present in all pts in group 1 and only in 2 pts (12%) in group 2. There was a strong positive correlation between FFR and LAmin (r=0,92, p<0,01).
Conclusions: Calculation of pressure-derived fractional flow reserve during intravenous administration of adenosine is safe and useful for the assessment of functional severity of borderline left main stenosis. There is a strong correlation between FFR and ICUS-derived left main minimal lumen cross sectional area.

190 Long-term clinical follow-up after treatment decision concerning an intermediate lesion in patients with multivessel disease

S.A.J. Chamuleau[1], B.L.F. Van Eck-Smit[2], M.G.W. Dijkgraaf[3], A. De Jong[4], J.G.P. Tijssen[4], J.J. Piek[4] on behalf of the ILIAS study investigators. *[1]Academic Medical Center, Cardiology, Amsterdam, Netherlands; [2]Academic Medical Center, Nuclear Medicine Dept., Amsterdam, Netherlands; [3]Academic Medical Center, Clinical Epidemiology & Biostat. Dept, Amsterdam, Netherlands; [4]Academic Medical Center Amsterdam, Cardiology Dept., Amsterdam, Netherlands*

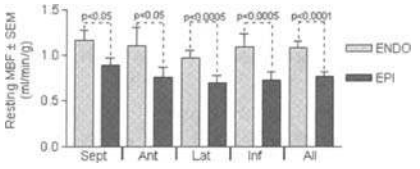
Background: Assessment of functional significance of intermediate coronary narrowings is important for clinical decision making. In the ILIAS multicenter study we investigated the long term prognostic value of intracoronary derived Doppler flow velocity compared to the results of myocardial perfusion scintigraphy (MPS) for patient management of intermediate lesions.
Methods: A total of 191 patients (mean age: 61 years; male: 70%) with stable angina (CCS 2-3) and multivessel disease were included. Patients were referred for angioplasty of a severe lesion in the presence of an intermediate coronary lesion (40-70% diameter stenosis) in another coronary artery. MPS was performed in all patients to determine the presence of reversible perfusion defects in the area of the intermediate lesion. MPS was considered 'positive' when no reversible defect was present in this area. At angiography, in all patients the coronary flow velocity reserve (CFVR) was determined distal to the intermediate lesion. CFVR < 2.0 was considered 'positive'. Next to angioplasty of the severe lesion, angioplasty of the intermediate lesion was only performed if both MPS and CFVR were positive. Long term follow up (>1 year) was performed to document the occurrence of any major cardiac events (PTCA, CABG, myocardial infarction, death). The relative risk was calculated for MPS an for CFVR to predict future events.
Results: The mean percentage diameter stenosis of the intermediate lesion, as measured with quantitative coronary angiography, was 55% (range 35-74%). In 9 (5%) patients, the intermediate lesion was treated with angioplasty based on the results of MPS and CFVR. The mean follow up time was 793 days (range: 360-1525). In total 67 events occurred in 49 patients (3 deaths, 9 myocardial infarctions, 8 CABGs, 47 PTCAs). The mean time to the first event was 273 days (range: 2-1205). The eventrate was 33% (10/30) for patients with a negative, and 35% (57/161) with a positive test result on MPS. On the contrary, the eventrate was 24% (35/145) for patients with CFVR≥2.0, and 70% (32/46) for CFVR<2.0. Thus, the relative risk for was 0.9 (95% CI: 0.5-1.6) for MPS and 2.9 (95% CI: 2.0-4.1) for CFVR. This difference in relative risk was statistically significant (p<0.05).
Conclusion: Selective evaluation of an intermediate lesion using CFVR allows a more adequate risk stratification in patients with multivessel disease than MPS. A CFVR<2.0 was associated a three fold increase of the occurrence of cardiac events during long term follow up (mean of 2 year).

ANY PROGRESS ON CORONARY FLOW AND MYOCARDIAL PERFUSION?

191 Noninvasive measurement of regional subendocardial and subepicardial blood flow in normal humans

M A. Khan[1], P G. Camici[1], R J H. Hall[2], O E. Rimoldi[1]. [1]*Imperial College, MRC Clinical Sciences Centre, London, United Kingdom;* [2]*Imperial College, National Heart & Lung Institute, London, United Kingdom*

Introduction: Ischaemia is more severe in the subendocardial (ENDO) than subepicardial (EPI) layer in animal studies. Technical limitations have prevented the measurement of blood flow (MBF) in these layers in normal humans. We report the first measurements of absolute ENDO and EPI MBF in normal humans using a high sensitivity PET scanner.
Methods: A 3D PET scanner (EXACT3D), using oxygen-15 water, was employed to measure MBF at rest in 11 healthy volunteers (age 49±4) and during dobutamine induced stress in a subset of 7. At analysis the left ventricular wall was divided into equal inner (ENDO) and outer (EPI) halves and MBF measured in septal, anterior, lateral, and inferior regions. The oxygen-15 water kinetic was fitted to a model corrected for spillover from both ventricular cavities, surrounding tissue and for partial volume. MBF is expressed as ml/min/g of perfusable tissue.
Result: Heart rate and blood pressure were 57±10b/min and 116/69mmHg at rest and 105±29b/min and 138/69mmHg during stress respectively (mean maximum dobutamine dose 36±5μg/kg/min). Mean ENDO MBF for the whole heart was 1.1±0.5ml/min/g while EPI was 0.8±0.3ml/min/g ($p<0.0001$), with an ENDO/EPI ratio of 1.5. Resting ENDO MBF was significantly higher than EPI in each of the 4 regions. Stress ENDO and EPI MBF were 2.3±0.7ml/min/g and 2.2±0.7ml/min/g respectively for the whole heart (p=ns) resulting in a ratio of 1.1.



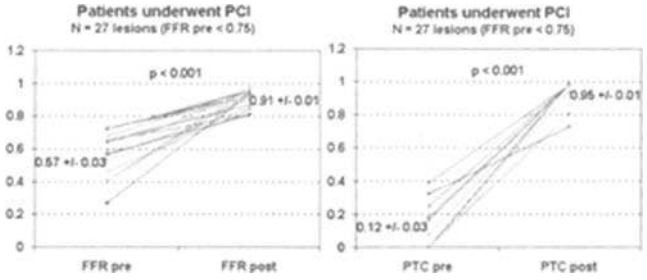
Regional and global ENDO & EPI MBF.

Conclusion: These results show that, as in experimental studies, human resting ENDO MBF is higher than EPI MBF at rest and that there is no regional variation in this relationship. The neural and autoregulatory mechanisms that control this distribution are affected by metabolic vasodilatation and, in normal subjects, transmural MBF distribution becomes uniform during stress.

192 Pulse transmission coefficient – a non-hyperemic index for physiologic assessment of procedural success after percutaneous coronary interventions

D. Brosh[1], S.T. Higano[2], M.J. Slepian[3], H.I. Miller[4], M.J. Kern[5], D.R. Holmes[2], A. Lerman[2]. [1]*Mayo Clinic - Saint Marys Hospital, Cardiology, Rochester MN, United States of America;* [2]*Mayo Clinic, Saint Marys Hospital, Cardiology, Rochester, United States of America;* [3]*Heart Center, Cardiology, Tucson, AZ, United States of America;* [4]*Tel Aviv Medical Center, Cardiology, Tel Aviv, Israel;* [5]*Saint Louis University, Cardiology, Saint Louis MO, United States of America*

Background: Coronary lesions may impair the transmission of pressure waves across a stenosis, potentially acting as a high-frequency filter. The pulse transmission coefficient (PTC) is a novel non-hyperemic parameter that calculates the transmission of high frequency components of the pressure signal through a stenosis. Recently, it has been shown that PTC is highly correlated with fractional flow reserve (FFR) and a cutoff value of PTC <0.6 may predict an FFR <0.75 with high accuracy. Thus, it may apply as a surrogate index for FFR to reflect the physiologic severity of the coronary artery stenosis. This study was designed to study the change in PTC as compared to FFR, following percutaneous coronary intervention (PCI).
Methods: Pressure signals were obtained by pressure guidewire in 27 lesions (27 pts.) pre and post PCI, and were analyzed with a new algorithm (Florence Medical Ltd.) that identifies the high frequency component in the pressure signal. The PTC was calculated as the ratio between distal and proximal high frequency components of the pressure waveform across the lesion. FFR measurements were assessed with intracoronary adenosine.
Results: There was a significant increase in PTC following PCI (0.12 ± 0.03 at baseline to 0.95 ± 0.01 post PCI; p <0.001; Figure). Comparable changes were observed for FFR (0.57 ± 0.03 at baseline to 0.91 ± 0.01 post PCI; p <0.001).
Conclusions: Pulse transmission coefficient is a novel non-hyperemic parameter for physiologic assessment of coronary artery stenoses. Similarly to FFR, pulse transmission coefficient is significantly increased following PCI. Thus, it may serve as an adjunct index for the functional assessment of procedural success following PCI, especially in patients with impaired maximal hyperemia.



The change in PTC vs. FFR following PCI.

193 Coronary stenosis haemodynamics evaluated with a novel dual-sensor wire combining pressure and flow velocity signals

M. Siebes[1], B. Verhoeff[1], J.A.E. Spaan[2], M. Meuwissen[1], B. Atasever[1], M. Voskuil[1], J.J. Piek[1]. [1]*Academic Medical Center, Dept. of Cardiology, Amsterdam, Netherlands;* [2]*Academic Medical Center, Dept. of Medical Physics, Amsterdam, Netherlands*

Background: The lack of high fidelity simultaneous measurements of pressure and velocity distal to a stenosis has hampered the study of stenosis pressure drop-velocity (delP-V) relationships in patients.
Methods: Prototypes of a novel 0.014" dual-sensor guide wire, equipped with both a pressure and velocity sensor, were successfully used in 8 patients with a single stenosis to obtain per beat averages of delP and V from baseline to maximum hyperemia after an i.c. bolus of adenosine. DelP-V relations were constructed before PCI (pre), after balloon dilatation (PTCA) and after placement of a stent and/or upsized stent (UPstent) guided by intravascular ultrasound. Incremental changes in hemodynamics for each PCI step were compared (paired Students t-test) for fractional and coronary flow velocity reserve (FFR and CFVR) and for stenosis resistance index (SRv) calculated as delP/V at maximal hyperemia.
Results: In 4 out of 8 patients, the delP-V relations of the pre-PCI stenosis exhibited flow-limiting behavior (Figure 1) indicative of a compliant stenosis, which was stabilized by PTCA and stent. Dilation and stent placement reduced the lesion induced velocity-dependent delP, with an initial marked reduction in hyperemic delP and subsequent substantial gain in velocity (dotted line in Figure 1). Average percent incremental hemodynamic changes were highest for SRv (56.2% ± 36.7%) compared to CFVR (28.9% ± 29.6%, $p<0.01$) and FFR (14.7% ± 13.8%, $p<0.0001$).

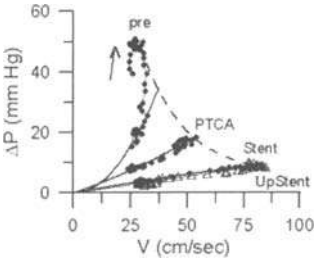


Fig.1: Effect of PCI on delP-V relations.

Conclusion: The hemodynamics of a coronary stenosis before and after each step of PCI is clearly defined by delP-V relations. SRv is a powerful and sensitive descriptor of the functional gain achieved by PCI, since it combines both pressure and velocity, which are affected to variable degrees by PCI.

194 The combination of hypercholesterolemia and hypertension augments alteration in myocardial microvascular architecture

M. Rodriguez-Porcel[1], A. Lerman[2], E.L. Ritman[2], J.D. Krier[3], L.O. Lerman[3]. *[1]Mayo Clinic, Division of Cardiovascular Diseases, Rochester, United States of America; [2]Mayo Clinic, Division of Cardiovascular Diseases, Rochester, MN, United States of America; [3]Mayo Clinic, Division of Hypertension, Rochester, United States of America*

Background: Co-existence of the cardiovascular risk factors hypercholesterolemia (HC) and hypertension (HT) is associated with increased incidence of cardiac events. Both conditions are pro-inflammatory, and impair myocardial microvascular (μV) function. HC also leads to sub-endocardial neovascularization, but it is unknown if HT imposes a synergistic effect. We tested the hypothesis that early concurrent HC+HT increase μV spatial density more than each risk factor alone. Methods. Pigs were euthanized 12 weeks after either a normal (n=6) or HC (n=8) diet, renovascular HT (n=7), or both HC and HT (HC+HT; n=7). Myocardial samples of excised hearts were scanned using micro-computed tomography (micro-CT, 21μm-pixel resolution), and 3-D images reconstructed. Spatial density of small (<200μm) and large (200-500μm) μV was quantified in situ in the sub-epicardium and sub-endocardium. Results. Cholesterol levels were significantly and similarly elevated in HC and HC+HT (416±70 and 372±29 mg/dL, $p<0.001$ vs. normal and HT), while mean arterial pressure was similarly and significantly higher in HT and HC+HT (124±6 and 121±9 mmHg, $p<0.01$ vs. normal and HC). Left ventricular muscle mass (as measured by CT) was similar among all groups. The sub-endocardial spatial density (number/cm^2) of small μV was significantly and similarly increased in HC, HT, and HC+HT compared to normal (table, *$p<0.05$ vs. normal). However, the spatial density of small sub-epicardial μV was increased only in HC+HT. The spatial density of large μV was unchanged in either region.

	Normal	HC	HT	HC+HT
Sub-epicardium	743 ± 91	989 ± 162	909 ± 80	111 ± 76*
Sub-endocardium	736 ± 79	1170 ± 140*	915 ± 76	1116 ± 109*

Conclusions: Organ microvasculature structure can be accurately study with micro-CT. We show, for the first time, that early HC and HT each induce selective neovascularization of small μV in the sub-endocardium, while an interaction between HC and HT extends this to the sub-epicardium as well. Marked transmural alterations in myocardial μV architecture may impair regulation of myocardial perfusion, and may potentially be linked to myocardial ischemia in HC+HT.

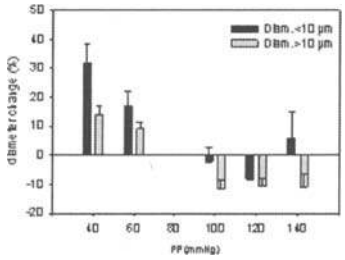
195 Coronary terminal arteriole responses to changes in perfusion pressure: results from a new video microscopy approach to isolated hearts

S. Goebel[1], W.M. Kübler[1], A.R. Pries[1], H. Kuppe[2], H. Habazettl[1]. *[1]Dept. of Physiology, Freie Universität Berlin, Berlin, Germany; [2]Institute for Anesthesiology, Deutsches Herzzentrum Berlin, Berlin, Germany*

Introduction: To date, investigation of coronary arteriole vasomotor activity has been limited to arterioles > 30-40μm due to methodological problems. We now investigated responses of terminal arterioles to changes in perfusion pressure using a new microscopy technique in tetrodotoxin (TTX) arrested isolated hearts.

Methods: Isolated, rat hearts were perfused in a closed loop Langendorff system (filling volume 20 ml), which was placed on a computer-controlled microscope stage. Tilting of the microscope by 90° allowed access to the ventricular surface. A 20x objective was optically coupled to the heart by contact gel and a cover glass. The perfusate was stained with FITC-dextran, microscopic images were generated by a CCD-camera (Kappa CF8/1FMC), recorded on tape, and arteriole diameters were measured offline. After the onset of recirculation and a 30 min stabilization period, TTX (50μM) was added to arrest the heart and maintain oxygen demand at basal levels. Arterioles were identified by flow direction of fluorescent beads (1μm). Vasomotor responses of arterioles (< 25μm) to changes in perfusion pressure (PP: 60,40,100,120,140 mmHg) after baseline recordings at 80 mmHg were studied.

Results: % diameter changes of arterioles <10μm and >10μm from baseline PP are shown in the figure. Smallest arterioles (< 10μm) dilate more prominently at low PP, while larger arterioles show a more pronounced constriction at increased PP.



Conclusion: Consistent with transmural pressure distribution along the arteriolar tree, the pressure range for effective myogenic control is lower in the smallest arterioles than in upstream larger vessels. Thes data also confirm maintained vasomotor reactivity of coronary arterioles TTX arrested isolated hearts.

196 Noninvasive assessment of coronary flow velocity in the everyday echo-laboratory practice. Experience on the first 1000 studies

J. Lowenstein[1], C. Presti[2], C. Tiano[3], C. Quiroz[4]. *[1]Investigaciones Medicas, Cardiodiiagnostico, Buenos Aires, Argentina; [2]Sanatorio Mitre, Estudios Funcionales Cardiovasculares, Buenos Aires, Argentina; [3]Sanatorio Agote, Unit Coronary Care-Echocardiography, Buenos Aires, Argentina; [4]DIM, Echocardiography, Buenos Aires, Argentina*

Coronary flow velocity reserve (CFVR) is a significant parameter to assess the coronary function; the possibility of its determination by a total noninvasive method will make its utilization more accessible and frequent. Objective. to evaluate the feasibility and value of measuring CFVR with transthoracic Doppler echocardiography (TTDE) in the daily practice. Methods. In 1000 consecutive patients (p) (635 male; mean age 64.9 ± 19 years) the diastolic coronary flow velocity was continuously monitored by pulsed- wave Doppler at the distal region of the left anterior descending artery (LAD), at rest and during the hyperemic phase induced by 0.84 mg/kg of Dipyridamole (Dip)for 4 min (803 p), 0.14mg/kg/min of Adenosine (Aden) for 2 min (103 p) or by the infusion up to 40 ug/kg/min of Dobutamine (Dob) (94 p). The test was performed in 323 p with angina, in 124 p with atypical chest pain, in 149 p during the post infarction period, in 32 p with dilated miocardiopathy, in 65 p after CABG, in 76 p following PTCA, in 61 p for preoperative risk evaluation, and in 170 p for others reasons. The CFVR was calculated as the ratio between the maximal and the basal velocity; these data were correlated with the angiograms performed the month after the TTDE in 209 p (Dip 164 p, Aden 28 p, Dob 17 p) Results. A clearly legible Doppler signal was obtained with Dip: 739/803 p, with Aden: 96/103 p and with Dob 66/94 p; the feasibility result was 92 %, 93% and 70% respectively. The results of group A (98 pts with LAD < 70% stenoses) were compared with group B (111 pts with LAD ≥ 70% lessions).

Group	pts (n)	BCFV(cm/seg)	MCFV (cm/seg)	CFVR
A: (LAD < 70%)	98	27.9 ± 8.7* *p = 0.008	65.7 ± 24 #	2.43 ± 0.8 " p < 0.0001 #"
B: (LAD ≥70%)	111	31.2 ± 12*	6.9 ± 19 #	1.5 ± 0.5 "

A CFVR ≥ 2 was registered in 72/98 p with non significant LAD lesions (specificity: 74%) and a CFVR< 2 was determined in 73/83 p with critical LAD stenoses (sensitivity of 88%).Conclusions. CFVR by TTDE has a high feasibility, especially with vasodilator drugs and renders a very useful noninvasive assessment of functionally significant disease in the territory of the LAD.

YOUNG INVESTIGATORS' AWARD SESSION (BASIC SCIENCE)

200 Human endothelial progenitor cells can transdifferentiate into functionally active cardiomyocytes

C. Badorff[1], R. Brandes[2], R. Popp[2], C. Urbich[1], A. Aicher[1], R. Busse[2], A.M. Zeiher[1], S. Dimmeler[1]. [1]*University Hospital, Department of Medicine IV - Cardiology, Frankfurt, Germany;* [2]*University of Frankfurt, Department of Physiology, Frankfurt, Germany*

Background: In addition to promoting angiogenesis, cell therapy may be an approach for cardiac regeneration. Embryonic stem cells can differentiate into cardiomyocytes in vitro and improve heart function in vivo. Recent studies suggest that committed progenitor cells can transdifferentiate into other lineages. However, the transdifferentiation potential of human endothelial progenitor cells (EPCs) is unknown.
Methods and Results: EPCs were obtained from peripheral blood mononuclear cells of healthy adult volunteers by cultivating with endothelial cell medium and growth factors. After 3 days, more than 95% of adherent cells were functionally (dil-ac-LDL-uptake) and phaenotypically (expression of VEGF-R2 and VE-cadherin) EPCs. EPCs were then co-cultivated with neonatal rat cardiomyocytes for 6 days. This lead to significant increases in cell length and size ($p<0.001$) of EPCs to a cardiomyocyte-like morphology. Biochemically, 11,8±2,3% of human EPCs (from n=7 healthy volunteers) expressed alpha-sarcomeric actinin as measured by flow cytometry. Immunocytochemistry showed that human EPC's expressed alpha-sarcomeric actinin, cardiac troponin I (both partly with sarcomeric organisation), ANP and MEF2. Fluo 4-imaging demonstrated calcium transients synchronised with adjacent rat cardiomyocytes in transdifferentiated human EPCs. Importantly, actively contracting human cardiomyocytes were identified. This transdifferentiation of EPCs into cardiomyocytes was not reproduced by conditioned medium, suggesting an important role of cell-to-cell contact. Single cell microinjection of lucifer yellow or labelling of cardiomyocytes with calcein-AM demonstrated gap junctional communication between 51±7% of EPCs (16 hours after labelling, n=4) and rat cardiomyocytes.
Conclusions: Adult human EPCs can transdifferentiate in vitro into functionally active cardiomyocytes when co-cultivated with rat cardiomyocytes. This was demonstrated by morphological, biochemical and functional parameters. The therapeutic use of autologous EPCs may aid cardiomyocyte regeneration in patients with ischaemic heart disease.

201 Beneficial effects of neonatal cardiomyocytes on left ventricular ejection fraction and scar thickness six months after transplantation into infarcted rat hearts

J. Müller-Ehmsen[1], K.L. Peterson[2], L. Kedes[3], P. Whittaker[4], J.S. Dow[4], R.A. Kloner[4]. [1]*University of Cologne, Dept. of Internal Medicine III, Cologne/Köln, Germany;* [2]*University of California, Division of Cardiology, San Diego, United States of America;* [3]*University of Southern California, Institute for Genetic Medicine, Los Angeles, United States of America;* [4]*Good Samaritan Hospital, Heart Institute, Los Angeles, United States of America*

Cardiac cell transplantation is a novel strategy to replace lost myocardium after myocardial infarction and improve cardiac function. However, the longer term effects of such treatment on myocardial dysfunction are not well known. Therefore, we tested the impact of neonatal cardiomyocytes on overall and regional cardiac contractility, left ventricular (LV) volumes and LV geometry 6 months after transplantation into infarcted hearts.
Isolated cardiomyocytes from male neonatal Fischer 344 rats (1-2 d, 3-5 x 10^6/50 µl) or medium were injected into the infarcts of adult syngeneic female animals 1 week after left coronary artery ligation. LV angiography 6 months after cell transplantation revealed a greater ejection fraction in treated animals than in control (0.36±0.03 vs. 0.25±0.02, both n=9, $p<0.01$). There was a trend for greater stroke volume (97±11 vs 71±9 µl, p=0.09) and smaller endsystolic volume (172±18 vs 215±21 µl, p=0.14), while enddiastolic volume was similar. Analysis of regional wall motion indicated that in cell treated rats 29.5±8.3% of the myocardial infarct zone was dyskinetic vs. 55.1±7.3% in control rats (p=0.035). Average chordal shortening within the myocardial infarct zone was positive in treated rats but negative in controls (p=0.02). LV hemodynamics (n=9 each) showed similar enddiastolic pressure, maximal systolic pressure and maximal rate of rise and fall of ventricular pressure (+dP/dt, -dP/dt). Post mortem analysis of LV geometry (hearts were fixed in distension with 10 mmHg intracavity pressure) revealed similar LV volumes and infarct sizes in the treated group as in control (0.42±0.02 vs. 0.45±0.03 ml and 31.5±1.7 vs. 34.2±2.8%). However, scar thickness was greater in treated animals (909±97 µm vs. 619±41 µm, $p<0.02$).
Previously, it was shown that neonatal cardiomyocytes survive in large number for at least 6 months after transplantation into infarcted hearts. Here, we found that these cells increase scar thickness and improve left ventricular ejection fraction and regional wall motion in vivo. These results support the hypothesis that cardiac cell transplantation provides a longer term benefit on LV function after myocardial infarction. Thus, cell transfer may become a meaningful therapeutic option to treat human heart disease.

202 Development of myocardial hibernation in mice is associated with chemokine induction and macrophage recruitment

O. Dewald, N.G. Frangogiannis, M. Zoerlein, D. Duerr, G. Taffet, L.H. Michael, M.L. Entman. *Baylor College of Medicine, Cardiovascular Sciences, Houston, United States of America*

Brief repetitive ischemic events may have an important role in the pathogenesis of the ventricular dysfunction associated with myocardial hibernation. We have previously demonstrated that a single 15 min. episode of murine myocardial ischemia (I) followed by reperfusion (R) is associated with chemokine induction. We hypothesized that brief repetitive myocardial I/R may induce a persistent inflamatory reaction in the mouse heart, potentially leading to fibrosis and dysfunction in the absence of a completed infarction. C57/BL6 mice underwent daily 15 min. left anterior descending coronary occlusions followed by a reperfusion for intervals ranging from 3 to 28 days. The hearts of I/R and sham operated animals were evaluated with and processed for histology and RNA studies. M-mode echocardiography demonstrated a decreased fractional shortening in the I/R animals (sham 46.3±1.5%, 7 days I/R 35.2±2.5%, 28 days I/R 40.83±0.8%, both $P<0.05$; n=7) and regional dysfunction of the anterior left ventricular wall. Collagen staining using picrosirius red showed significant interstitial fibrosis after 7 days of I/R in the anterior left ventricular wall (sham vs. I/R: 4.6±2.0% vs. 21.5±6.5%, $P<0.05$; n=8), that remained unchanged for longer I/R protocols. Ischemic areas had no evidence of infarction, but demonstrated macrophages and fibroblasts accumulation after 3 to 7 days of I/R. A robust mRNA upregulation of the chemokines RNA MIP-1alpha, MIP-1beta, MIP-2 and MCP-1 was noted, peaking after 7 days of I/R and decreasing after 28 days. Mice undergoing 7 and 28 days of I/R followed by a 30 and a 60 day period of recovery, demonstrated a significant decrease in myocardial fibrosis (30 days 13.5±2.3%, 60 days 8.4±1.6%, $P<0.05$; n=8) and improved ventricular function. Brief repetitive I/R induces a murine ischemic cardiomyopathy with features of hibernation (reversible fibrosis and systolic dysfunction). Early chemokine induction may have a role in mediating the interstitial fibrosis and subsequent left ventricular dysfunction.

203 Atorvastatin decreases fas ligand expression and cytotoxicity in activated human T lymphocytes. Role of Rho proteins

L. Blanco-Colio[1], C. Lorz[1], B. Muñoz-García[1], C. Díaz[2], G. Hernández[2], J. Egido[1]. [1]*Fundación Jiménez Díaz, Vascular Research Lab., Madrid, Spain;* [2]*Pfizer, R&D Department. Medical Division, Madrid, Spain*

Background: HMG-CoA reductase inhibitors reduce cardiovascular mortality, though the mechanisms of action have not been completely elucidated. The presence of T cells and apoptotic cells (macrophages and vascular smooth muscle cells) in atherosclerotic plaques is well established, and it is the reduction of cellular content that is a marker of the plaque's vulnerability. One of the main mechanisms of cell death activation is the Fas-Fas ligand system.
Methods and Results: We have studied whether the HMG-CoA reductase inhibitor atorvastatin can regulate the expression of Fas ligand (FasL) and cytotoxicity in human T cells (Jurkat). Transfection studies and mRNA analysis demonstrated that activation of Jurkat cells with phorbol esters (PMA - 50 ng/mL) and ionomycin (0.5 µg/mL) increased FasL expression. This effect was prevented in a dose-dependent manner in the presence of atorvastatin (0.1-1 µM). Mevalonate (10-100 µM), and geranylgeranylpyrophospahte (1-5 µM), but not farnesylpyrophosphate (1-5 µM), prevented the effect of atorvastatin, indicating that protein geranylation is implicated in FasL expression. The C3-exotoxin (0.01-5 µg/mL), that selectively inactivates Rho proteins activation, also decreases FasL expression on activated T cells in a dose-dependent manner. Overexpression of constitutively active RhoA increased FasL promoter activity in Jurkat cells and dominant-negative RhoA decreased FasL promoter activity in activated cells, indicating that RhoA is implicated in FasL expression. In addition, treatment with atorvastatin decreased cytotoxic activity of activated Jurkat cells on FasL-sensitive cells.
Conclusions: Atorvastatin regulates FasL expression in T cells, probably due to the inhibition of RhoA prenylation. These results provide novel information by which atorvastatin may regulate the cytotoxic activity of T cells and the number of total cells in the atherosclerotic plaque. In conclusion, the effect of atorvastatin on T cell activation suggests a potential immunomodulator effect of this statin.

204 A cardiac nitric oxide synthase 1 regulates contraction and calcium fluxes – a novel mechanism in the autocrine control of cardiac function

E. Ashley, C. Sears, C. Lygate, S. Bryant, H. Wallis, S. Neubauer, B. Casadei.
Univ. of Oxford, Dept. of Cardiovascular Medicine, Oxford, United Kingdom

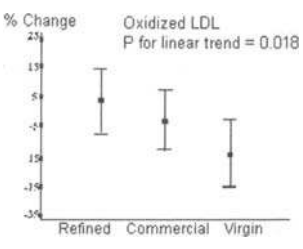
Evidence indicates that endogenous nitric oxide (NO) can modulate myocardial contractility, but the source of NO remains uncertain. We investigated the role of a neuronal type NO synthase (NOS1), recently localised to the cardiac sarcoplasmic reticulum, in the regulation of myocardial contraction.
Left ventricular (LV) contraction was assessed in-vivo using transthoracic echocardiography and invasive haemodynamic monitoring under isoflurane anaesthesia, and in vitro using field stimulation of isolated LV myocytes. Mice with NOS1 gene disruption (NOS1-/-) were compared with their littermate controls (NOS1+/+). In addition, we examined the effects of acute specific inhibition of NOS1 in myocytes with vinyl-L-N5-(1-imino-3-butenyl)-L-ornithine (L-VNIO, 500 μM).
LV dimensions and heart rate were not different in NOS1-/- mice. Specific NOS1 inhibition with L-VNIO or gene disruption of NOS1 enhanced cell shortening of isolated myocytes (% at 6hz NOS1-/- 10.7±0.9 vs NOS1+/+ 7.21±0.8, $p<0.05$). Similarly, LV ejection fraction was 0.54±0.03 in NOS1-/- vs 0.45±0.02 in NOS1+/+ ($p<0.05$). Although the maximum rate of LV relaxation (dP/dTmin) was not different in-vivo or in-vitro, the onset of relaxation was delayed (TR50 in myocytes at 6hz NOS1-/- 26.53±1.44 vs NOS1+/+ 21.27±1.31ms; $p<0.05$).
To investigate the mechanism of increased contraction, we estimated sarcoplasmic reticulum (SR) calcium load by integrating the Na-Ca exchange inward current in response to a ten second application of 10mM caffeine. Acute inhibition or gene disruption of NOS1 was associated with an increase in calcium content of the SR (NOS1-/- 0.78±0.04 vs NOS1+/+ 0.64±0.03pC/pF, $p<0.05$). In addition, we demonstrated that calcium current density was greater in NOS1-/- myocytes and following acute inhibition with L-VNIO (ICa density at 0mV NOS1-/- −11.4±0.5 vs NOS1+/+ -9.1±0.5pA/pF; $p<0.01$). Furthermore, the slow time constant of decay of ICa was increased in NOS1-/- (37.3±21.5) vs NOS1+/+ (26.9±1.6ms) suggesting that increased calcium influx through the sarcolemma may contribute to the greater SR load in NOS1-/- myocytes.
Taken together these findings indicate that NOS1 plays a previously unrecognised role in the autocrine regulation of myocardial function. Since both NOS1 gene transcription and biochemical activity are regulated by calcium, localisation of this enzyme to the SR membrane is consistent with a negative feedback role for NO in myocardial inotropy and intracellular calcium fluxes.

LIPID MODULATING THERAPY: BENEFITS AND DISAVANTAGES

205 Antioxidant effect of olive oil phenolic content in a randomized double-blind controlled clinical trial

J. Marrugat[1], M.I. Covas[1], M. Fitó[1], E. Miró-Casas[1], H. Schroeder[1], M. Farré[1], R. de la Torre[1], C. de la Torre Boronat[2]. *[1]Inst. Municipal Investigació Mèdica, Unitat Lipids & Epidemiol. Cardiovasc., Barcelona; [2]Univ. de Barcelona, Bromatologia i Nutrició, Fac. Farmacia, Barcelona, Spain*

Background: The Mediterranean diet, in which olive oil is the main source of fat, has been shown to reduce the number of recurrences in patients with myocardial infarction. The aim of this study was to determine the effects of olive oil phenolic content on lipid peroxidation.
Methods: A placebo-controlled, double blind, cross-over, randomized, clinical supplementation trial using three olive oils with different phenolic compounds concentration (none, low and high), at moderate raw daily doses (25 ml/day), was conducted in 30 healthy non-smoking male volunteers. Olive oils were sequentially administered over three periods of 3 weeks preceded by two-week washout periods in which refined olive oil was used. Oxidized LDL, LDL resistance to oxidation (lag-time after Cu-oxidation) and antibodies against oxidized LDL (OLAB) were measured.
Results: A decrease in plasma oxidized LDL levels (linear trend, P= 0.018), and an increase in the LDL resistance to oxidation (linear trend, P=0.015) and a non-statistically significant decrease in OLAB were observed associated to the phenolic content of the olive oil administered (see figure). Urine tyrosol levels, as a marker of patient compliance, increased with the phenolic content of the olive oil consumed (linear trend, P= 0.020).



Conclusions: LDL is protected from oxidation by the phenolic content of olive oil, regardless of its MUFA and other antioxidant content. Our results show that regular consumption of a real-life daily dose of olive oil with high phenolic content is more effective protecting LDL from oxidation than that of olive oil with low or no phenolic content.

206 The effect of growth hormone replacement therapy on lipid profile, blood pressure and body composition in patients with hypopituitarism

N.K. Eryol[1], F. Tanrýverdi[2], R. Topsakal[1], A. Abacý[1], F. Bayram[2], E. Basar[1], A. Ergin[1], F. Kelestimur[2]. *[1]Erciyes University, medicine faculty, Cardiology, Kayseri, Turkey; [2]Erciyes University, Endocrinology, Kayseri, Turkey*

Growth hormone deficiency can increase cardiovascular mortality and morbidity, negatively affecting some risk factors, like lipid profile as known to predispose to coronary artery disease. The aim of this study was to investigate the effects of growth hormone replacement therapy (GHRT) on impaired lipid profile, blood pressure and body composition.
Method: Twenty patients (13 females, mean age: 51±6 years; 7 males, mean age: 46±13 years) who were followed-up at the Endocrinology Clinic due to hypopituitarism with no cardiac involvement (normal ECG, ECHO, and holter monitoring) were included in the study. The diagnosis was based on the insulin tolerance test. The patients, who were on the replacement therapy also for other pituitary hormone deficiencies, were planned to receive GHRT for 2 years in doses recommended by the Growth Hormone Society Workshop. Data from 20 patients, who received GHRT for 6 months were assessed in this study. At baseline, third and sixth months after GHRT, total cholesterol, triglycerides, HDL- and LDL- cholesterol and fasting blood glucose levels were measured; systolic and diastolic blood pressures, body mass index (BMI), waist-hip-ratio (WHR) were also evaluated.
Results: Before treatment, cardiological findings were normal in all patients. While BMI of the patients did not change during the treatment, WHR decreased significantly (1.008±0.1, 0.954±0.1, 0.943±0.1, p=0.0002). Blood pressures at baseline, were normal and remained so after the treatment. Total (291.6±19.8, 243.8±13.6, 238.3±18.8, p=0.009) and LDL-cholesterol levels (210.5±15.8, 151.4±9.8, 147.7±13.1, p=0.0001) dropped significantly. There was a significant increase in HDL levels (41.3±3.4, 53.5±3.2, 56.2±4.3, p=0.0008). Although triglycerides and fasting glucose levels showed an increasing tendency, the difference from baseline did not reach to a significant level ($p>0.05$).
Conclusion: With a 6-month of GHRT, an improvement in cardiovascular risk factors has been observed –an improvement in lipid profile and a decrease in abdominal obesity. However, it is questionable whether these favorable effects will continue in the long-term. Therefore, it is obvious that there is a need for long-term prospective studies with GHRT

207 Better influence of statin than of fibrate on novel risk factors in combined hyperlipidemia

M. Sebestjen[1], I. Keber[1], B. Zegura[2], S. Simsic[3], M. Fressart[4], M. Stegnar[1]. *[1]University Medical Centre, Department of Angiology, Ljubljana, Slovenia; [2]Department of Gynecology and Obstetric, Maribor Teaching Hospital, Maribor, Slovenia; [3]Microbiology and Immunology, Medical Faculty, Ljubljana, Slovenia; [4]Diagnostica Stago, Asniers, France*

Besides dyslipidemia, hypertension, smoking, obesity, other so-called novel risk factors for coronary artery disease are playing increasingly important role as markers for the development and progression of atherosclerosis. Among them are C-reactive protein (CRP), homocysteine, and proteins involved in haemostasis and synthesized by endothelial cells (tissue factor pathway inhibitor (TFPI), plasminogen activator inhibitor (PAI-1) and tissue plasminogen activator (t-PA)). The effect of cerivastatin and fenofibrate on these parameters was investigated in otherwise healthy middle-aged males with combined hyperlipidemia.
Thirty-eight males, aged 49±5 years were randomised to 12 weeks treatment either with cerivastatin with a daily dose of 0.2 mg to 0.4 mg to achieve an LDL cholesterol goal of <3.0 mmol/l or with fenofibrate 250 mg daily. Fasting serum lipids, CRP, homocysteine, total and free TFPI, PAI-1 and t-PA antigen and activity were measured before and after treatment. The drugs exerted different influences on serum lipids. The decrease of total and LDL cholesterol was significantly greater after cerivastatin (p=0.03, p=0.0008, respectively), while the decrease of triglycerides and the increase of HDL cholesterol were significantly greater in patients receiving fenofibrate (p=0.05 for both). No change in homocysteine level was observed in the cerivastatin group, while in the fenofibrate group it increased significantly from 11.5±4.0 to 16.6±3.2 μmol/l ($p<0.0001$). The CRP level decreased significantly after both treatments, after cerivastatin, from 2.20 (0.90-4.70) to 0.80 (0.40-1.50) mg/l (p=0.001), and after fenofibrate, from 1.60 (1.10-3.30) to 1.10 (0.70-2.70) mg/l (p=0.03). The CRP decrease was significantly greater after cerivastatin (-49,5%) than after fenofibrate treatment (-29,8%) (p=0,04). The decrease of total and free TFPI was significant after cerivastatin (from 80.3±11.2 to 69.5±15.6 μg/l, p=0.005, and from 9.4±1.8 to to 8.0±2.1 μg/l, p=0.01, respectively), but not after fenofibrate. Neither drug affected t-PA antigen and activity while fenofibrate increased PAI-1 antigen (p=0.05) and activity (p=0.004).
Taken together, these data provide additional information on the antiatherogenic mechanisms of these hypolipemic drugs. Further prospective studies, with a larger number of patients are needed to answer the question if these differences, beside their effects on lipids, can explain the greater relative risk reduction in secondary prevention studies with statins, than with fibrates.

208 The efficacy of folate supplementation in fibrate-induced hyperhomocysteinemia

O. Mayer[1], L. Holubec[2], R. Pikner[2], H. Rosolova[1], J. Simon[1]. [1]*Charles University, Medical Faculty, 2nd Dept. of Internal Medicine, Pilsen, Czech Republic;* [2]*University Hospital, Laboratory of Immunoanalysis, Pilsen, Czech Republic*

Purpose: Recently published studies reported, that fibrates may induce hyperhomocysteinemia, as a side effect. In our study we aimed to assess whether this effect depends on concentrations of folate and B12 or on renal functions and whether may be prevented by folate supplementation.
Methods: 58 subjects with total cholesterol (TCHOL)>6mmol/l (m34, f24; mean age 54.0yrs), without any pharmacotherapy and/or other manifest disease, were included to an open, prospective, parallel-group study. After 2 month of diet treatment, subjects were randomly divided in to 2 groups- statins: 3 months fluvastatin 40mg, followed by 3months fluvastatin 80mg or fibrates: 3month micronised fenofibrate 200mg, followed by 3months fenofibrate+ folate 10mg.
Results (see table):

Fibrates: (n=26)	baseline	post-diet	fenofibrate	fenofibrate+folate
TCHOL [mmol/l]	6.82±0.12	6.77±0.14	5.94±0.28***	5.43±0.23
triglycerides [mmol/l]	1.99±0.25	2.02±0.22	1.37±0.16***	1.15±0.18
homocysteine [umol/l]	10.9±0.89	10.8±0.77	15.3±1.15****	10.9±0.56++++
folate [ng/ml]	7.20±0.73	7.36±0.58	7.28±0.74	18.1±0.55++++
B12 [pg/ml]	316±25.1	286±18.8	317±25.2	331±52.7
cystathin C [mg/l]	0.83±0.06	0.83±0.04	0.91±0.03	0.94±0.03
Statins: (n=32)	**baseline**	**post-diet**	**fluvastatin 40mg**	**fluvastatin 80mg**
TCHOL	6.99±0.16	7.12±0.17	5.99±0.14****	5.69±0.18
triglycerides	1.80±0.15	1.71±0.14	1.66±0.16	1.76±0.20
homocysteine	9.9±0.54	10.1±0.57	10.7±0.54	10.1±0.67
folate	7.94±1.08	7.17±0.43	7.37±0.42	8.94±0.69
B12	297±28.4	288±15.5	313±18.8**	306±23.4
cystathin C	0.81±0.02	0.82±0.06	0.91±0.03	0.82±0.06

Wilcoxons paired test: ****p<0.0001, ***p<0.001, **p<0.01 visit 2 vs visit 3; ++++p<0.0001 visit 3 vs visit 4

Conclusions: Treatment with fibrates was followed by a significant increase in homocysteine. This side effect seems to be independent from folate or B12 concentrations and also from cystathin C, a marker of renal functions. Concomitant folate supplementation is able to normalize this fibrate-induced hyperhomocysteinemia.
(supported by grant IGA 6817-3,Ministry of Health CR)

209 Beneficial effects of statins on cardiac function in non-ischaemic heart failure

U. Laufs[1], S. Schackmann[1], S. Wassmann[1], C.H. Heeschen[2], M. Böhm[1], G. Nickenig[1]. [1]*Klinik Innere Medizin III, Geb. 40, Homburg, Germany;* [2]*Universität, Molekulare Kardiologie, Frankfurt, Germany*

Retrospective analyses of clinical trials show beneficial effects of statins on heart failure. Animal studies suggest cholesterol-independent improvement of cardiac function and reduction of hypertrophy and fibrosis.
Patients with non-ischemic dilatative cardiomyopathy (n=25) were randomized to cerivastatin 0.4 mg (statin) or placebo in a double-blind, prospective study. Inclusion criteria were stable heart failure NYHA II-IV defined as stable use of diuretics, angiographic exclusion of coronary artery disease, and established therapy with ACE-inhibitors and betablockers. The mean treatment duration was 16.2 weeks in the placebo-, and 15.4 weeks in the statin group. The left ventricular ejection fraction (EF) as quantitated by radionuclidventriculography was 43.8% before and 34.5% after placebo treatment. In the statin group, EF increased from 45.0 to 54.25% (p=0.34, 2-tailed T-test). In the placebo group, cardiac output decreased from 6.3 to 4.6 l/min (p<0.05), but remained unchanged under statin treatment (5.03 vs 4.76 l/min, p=0.8).
The maximal distance in the 6-min walking test increased from 270 m to 317 m under statin treatment (p<0.05), but did not change in the placebo treated patients. Corresponding to the EF, brain natriuretic peptide (BNP) decreased by 25% (p=0.14) and troponin T (TnT) decreased by 57% (p<0.05) in the statin- but not in the placebo group. Serum levels of plaminogen activator inhibitor 1(PAI) decreased in the statin group from 72 U/ml to 61 U/ml (p<0.05) but were unaltered with placebo treatment. Standardized questionaires showed improvement of quality of life (p<0.05), social activities (p=0.78) and daily activities (p<0.05) with statin treatment but not in the placebo group.
Statins improve left ventricular function and consecutively exercise capacity and quality of life in patients with non-ischemic heart failure suggesting a lipid-independent, non-vascular impact of statins on the diseased myocardium.

210 Effects of lipid-lowering by simvastatin on human atherosclerotic lesions: 2-years follow-up by high-resolution MRI

R. Corti[1], Z.A. Fayad[1], V. Fuster[1], S. Worthley[1], G. Helft[1], J. Weinberger[1], M. Mercuri[2], J J. Badimon[1]. [1]*Mount Sinai School of Medicine, Cardiovascular Institute, New York, United States of America;* [2]*Merck & Co. Inc., Rathway, United States of America*

Background: The aim of this study was to investigate the effects of lipid-lowering by simvastatin on human atherosclerotic lesions. After the preliminary report we are now presenting the long-term follow-up results.
Method and patients: Eighteen asymptomatic hypercholesterolemic patients with documented aortic and/or carotid atherosclerotic plaques were selected for the study. A total of 35 aortic and 25 carotid artery plaques were detected. We performed sequential MRI of the aorta and carotid artery at baseline, at 6, 12, 18 and 24-months after lipid-lowering therapy with simvastatin. The effects of the treatment on atherosclerotic lesions were measured as changes in lumen area (LA), vessel wall thickness (VWT) and vessel wall area (VWA), a surrogate of atherosclerotic burden.
Results: Simvastatin induced a significant (P<0.01) reduction in total and LDL-cholesterol (-23%) and LDL-cholesterol (-38%) levels at 6-weeks and was maintained thereafter. At 6-months no changes in LA, VWT or VWA were observed. At 12-months significant (p<0.01) reductions in maximal VWT and VWA without changes in LA were observed: respectively -9% and -8% for aortic and -11% and -15% for carotid plaques. Further decrease in VWT and VWA was seen at 18 and 24-months of treatment (ranging from -15% to -25%). Surprisingly, at 24-months the LA showed a slight but significant increase (ranging 5 to 7%) for both carotid arteries and aortic lesions.
Conclusion: This long-term in vivo human study demonstrates that effective and maintained lipid-lowering therapy by simvastatin is associated with a significant regression of atherosclerotic lesions. Our observation suggests that initially statins induce vascular remodeling manifested by reduced atherosclerotic burden without changes in the lumen size. Long-term (>24 months) treatment of non-stenotic lesions may, however, results in an increase of luminal size.

EFFECTS OF NEW AND ESTABLISHED LIPID-LOWERING DRUGS

211 Effects of fluvastatin after successful percutaneous intervention in patients with CHD: the Lescol Intervention Prevention Study (LIPS)

P.W.J.C. Serruys on behalf of the LIPS Investigators. *Rotterdam, Netherlands*

Background: Based on evidence from large clinical trials, statins are now well-established as the primary and secondary prevention of fatal and non-fatal coronary events. However, no study has prospectively evaluated the long-term effect of statins on clinical outcomes in patients who have undergone their first PCI, a well defined population at an early stage of disease.
Methods: LIPS is a double-blind, randomized trial designed to compare the effect of fluvastatin (40 mg bid) on major adverse cardiac event, ie MACE (cardiac death, non-fatal MI, repeat-CABG-or PCI)-free survival time in 1677 patients (844 fluvastatin; 833 placebo) with CHD and first successful TCT over a 3 year follow-up (median 3.98 y). Inclusion criteria were: ages 18–80 years; first successful TCT within 6 months before randomization; total cholesterol of 135 – 270 mg/dL (3.5 - 7.0 mmol/L) with fasting triglycerides <400 mg/dL (<4.5 mmol/L).
Results: Statistically significant treatment effect (p=0.0127; log-rank test) in first MACE free survival time was demonstrated for fluvastatin over placebo. For the primary endpoint, the incidence was 21.4% in the fluvastatin group vs 26.7% in the placebo group resulting in a 19.9% reduction in MACE events. Cardiac death occurred in 1.5% in the fluvastatin group and in 2.9% in placebo controls (p=0.0632; log-rank test). No significant difference in non-cardiac mortality was seen between groups (2.7% vs. 3.0% in fluvastatin and placebo, respectively).

Baseline characteristics

Mean age (y)	60.5 ± 10	Anginal status	(%)
Male (%)	84.0	Unstable	49.7
Smoking (%)	26.6	Stable	40.5
Body Mass Index (kg/m^2)	26.6 ± 3.3	Silent ischemia	9.8
Blood pressure (mm Hg)	128.0/75.0	Previous MI	44.3
Heart rate (bpm)	66.0 ± 11	Q-wave	26.8
Diabetes mellitus (%)	12.0	Non Q-wave	17.6
Total Number Of Lesions Treated	2222.0		

Summary: LIPS is the first study to investigate the effects of statin therapy on MACE in patients who have undergone successful primary TCT for CHD and has shown a significant benefit of fluvastatin in time to first event in this population. Final detailed results will be presented.

212 Comparing rosuvastatin and atorvastatin across their dose ranges in patients with hypercholesterolemia

R. Knopp[1], C. Ballantyne[2], R. McPherson[3], R. Chitra[4], D. Schneck[4], S. Simonson[4]. [1]*Northwest Lipid Research Clinic, University of Washington, Seattle, United States of America;* [2]*Baylor College of Medicine, Houston, United States of America;* [3]*University of Ottawa Heart Institute, Ottawa, Canada;* [4]*AstraZeneca, Wilmington, United States of America*

This 6-week, randomized, double-blind trial (4522IL/0033) was conducted in hypercholesterolemic patients to compare the lipid-lowering effects of rosuvastatin (RSV, Crestor®) and atorvastatin (ATV, Lipitor®) across studied dose ranges. Patients with LDL-C ≥4.14 but <6.47 mmol/L (≥160 but <250 mg/dL) and fasting triglycerides <4.52 mmol/L (<400 mg/dL) received once-daily RSV 5, 10, 20, 40, or 80 mg (n=209) or ATV 10, 20, 40, or 80 mg (n=165). Mean percentage changes from baseline to wk 6 in lipid measures across the dose range for each drug were assessed by linear-regression analysis using analysis of covariance. The overall % reduction (from baseline) in LDL-C levels across the 10–80 mg dose range for RSV was –46.6% to –61.9% and for ATV was –38.2% to –53.5%, respectively. RSV (5–80 mg) was superior to ATV (10–80mg) at lowering LDL-C across the dose range (mean % change: –8.4%; P<0.001). RSV produced significantly (P<0.001) greater reductions than ATV across the dose range in total cholesterol (–4.9%), non-high-density lipoprotein cholesterol(non-HDL-C; –7.0%), apolipoprotein (apo) B (–6.3%), LDL-C:HDL-C (–9.5%), total cholesterol:HDL-C (–6.9%), non-HDL-C:HDL-C (–8.4%), and apo B:apo A-I (–7.8%). Dose responses for HDL-C, triglycerides, and apo A-I were not log-linear within each treatment or parallel between treatments; therefore, % changes between treatments were compared on a dose-by-dose basis using analysis of variance. Significant treatment differences were noted as follows: RSV 40 and 80 mg over ATV 40 and 80 mg in HDL-C (+12.3% vs +4.1% and +9.6% vs +2.1%; P<0.001 and P<0.01); ATV 80 mg over RSV 80 mg in triglycerides (–34.4% vs –19.7%; P<0.05; [median % change: –39.1% vs –24.7%]); and RSV 80 mg over ATV 80 mg in apo A-I (+9.2% vs +3.1%; P<0.05). Occurrences of treatment-emergent adverse events were similar between RSV and ATV; additionally, no clinically significant increases in hepatic transaminases or creatine kinases were observed with either trial medication. In summary, rosuvastatin was more effective than atorvastatin in reducing LDL-C across equivalent dose ranges; rosuvastatin was also more effective in decreasing total cholesterol, non-HDL-C, and apo B, improving lipoprotein ratios, and increasing HDL-C to a greater extent than atorvastatin. These findings suggest that the efficacy of a given rosuvastatin dose is at least equal to that of atorvastatin at twice the mg-equivalent dose. The enhanced lipid-altering effects of rosuvastatin should facilitate prompt attainment of lipid-treatment goals in clinical practice.

213 Addition of ezetimibe to ongoing statin therapy: incremental reduction in low-density lipoprotein cholesterol is independent of statin type

P. Mata[1], B. Gumbiner[2], T. Musliner[2], K. Quinto[2], M. Cho[2] on behalf of the Ezetimibe Study Group. [1]*Fundacion Jiminez Diaz, Madrid, Spain;* [2]*Merck/ Schering-Plough Pharmaceuticals, North Wales, United States of America*

Background: This randomized, double-blind, placebo-controlled study evaluated the lipid-altering efficacy of adding ezetimibe (EZE) to ongoing statin therapy in patients with hypercholesterolemia, CHD, or multiple risk factors who required further low-density lipoprotein cholesterol (LDL-C) reduction. The aim of the current analysis was to determine whether EZE had consistent effects on plasma lipids for each of the statins used in this study.
Methods: Patients (n=769) receiving a stable dose of statins for >6 weeks were randomized to placebo (PBO) or EZE 10 mg/d plus their open-label statin regimen for 8 weeks. The primary efficacy variable was % change from baseline to endpoint in LDL-C. Secondary variables included high-density lipoprotein cholesterol (HDL-C) and triglycerides (TG).
Results: Addition of EZE to ongoing simvastatin (Simva), atorvastatin (Atorva), and "Other" statin therapy (lovastatin, pravastatin, fluvastatin, and cerivastatin) resulted in incremental reductions of LDL-C compared with therapy with the corresponding statin alone, as shown in the table below. Significant decreases in TG induced by EZE were also observed within each statin category. The effect of EZE treatment on lipid profiles was consistent across the 3 statin groups (ie, there was no significant treatment-by-statin interaction).

Mean % change (SEM)

Treatment	LDL-C	HDL-C	TG*
Simva+PBO (n=117)	-3.1 (1.3)	2.0 (0.9)	-3.3 (2.5)
Simva+EZE (n=123)	-26.8 (1.3)**	1.3 (0.9)	-13.8 (2.5)**
Atorva+PBO (n=162)	-4.0 (1.1)	0.7 (0.8)	-4.3 (2.5)
Atorva+EZE (n=146)	-25.0 (1.2)**	2.5 (0.8)	-16.2 (2.2)**
Other+PBO (n=111)	-3.8 (1.4)	0.3 (1.0)	-0.2 (3.1)
Other+EZE (n=110)	-23.5 (1.4)**	4.4 (1.0)	-12.1 (2.5)**
Pooled Statin+PBO (n=388)	-3.7 (0.7)	1.0 (0.5)	-2.9 (1.5)
Pooled Statin+EZE (n=375)	-25.1 (0.7)***	2.7 (0.5)**	-14.0 (1.4)**

*Median % changes from baseline; **p<0.05 vs Statin+PBO; ***p<0.001 vs Statin+PBO.

Conclusion: Addition of EZE to ongoing statin therapy led to significant improvements in LDL-C and TG independent of the statin to which EZE was added.

214 Consistency of LDL-C lowering effect across subgroups of ezetimibe co-administered with statins

L. Lipka, L. Melani, A. LeBeaut, S. Sun, R. Suresh, E. Veltri on behalf of the Ezetimibe Study Group. *Schering-Plough Research Institute, Kenilworth, USA*

Background: Four phase III, multicenter, randomized, double-blind, placebo-controlled studies examined the efficacy and safety of ezetimibe (EZE) administered with atorvastatin (ATOR; 10, 20, 40, 80 mg), lovastatin (LOV; 10, 20, 40 mg), pravastatin (PRAV; 10, 20, 40 mg), or simvastatin (SIM; 10, 20, 40, 80 mg) in patients with primary hypercholesterolemia.
Methods: After dietary stabilization (NCEP Step I or stricter diet), 2-12 wk washout period and 4-wk, single-blind, PBO lead-in period, patients with baseline LDL-C ≥145 mg/dl, ≤250 mg/dl and TG ≤350 mg/dl were randomized to 1 of the following administered daily for 12 weeks: EZE 10 mg; statin 10, 20, 40, or 80 mg; EZE 10 mg + statin 10, 20, 40, or 80 mg; or PBO. Primary efficacy endpoint was % reduction from baseline at endpoint in direct LDL-C for pooled EZE + statin vs statin alone. Secondary efficacy endpoints included % change from baseline at endpoint for HDL-C and TG.
Results: Mean % changes (SEM) from baseline to endpoint in LDL-C for the pooled statin and EZE+statin groups for the subgroups age, gender, diabetes mellitus (DM), and CHD are depicted (see table). EZE + statin provided enhanced reductions in LDL-C vs statin alone across the subgroups examined. A greater increase in HDL-C and greater reductions in TC and TG were also observed with co-administration of EZE+statin compared to statin alone.

Characteristic	N	Statin	N	EZE+Statin	(EZE+Statin)-(Statin) (95%CI)
Age <65 y	669	-31.7 (0.7)	650	-44.5 (0.7)	-12.8 (-14.7, -11.0)
Age ≥65 y	258	-34.6 (1.0)	264	-50.1 (0.9)	-15.5 (-18.0, -12.9)
Male	388	-31.3 (0.8)	395	-44.8 (0.8)	-13.5 (-15.8, -11.2)
Female	539	-33.4 (0.7)	519	-47.1 (0.7)	-13.8 (-15.8, -11.7)
DM Yes	51	-33.3 (2.0)	49	-46.6 (2.4)	-13.2 (-19.4, -7.1)
DM No	876	-32.5 (0.6)	865	-46.1 (0.6)	-13.6 (-15.2, -12.1)
CHD Yes	75	-29.5 (2.0)	75	-47.8 (1.8)	-18.3 (-23.6, -13.0)
CHD No/Unknown	852	-32.8 (0.6)	839	-46.0 (0.6)	-13.2 (-14.8, -11.6)

Conclusions: When co-administered with ATOR, SIM, PRAV, or LOV, EZE provided effects on the lipid profile that were significantly better than statin alone and were generally consistent across the subgroups examined.

215 PPAR gamma agonist L-805645 induces regression of atherosclerotic lesions, decreases inflammation, and increases smooth-muscle cells

R. Corti[1], J.I. Osende[1], S.D. Wright[2], J T. Fallon[1], H. Jneid[1], E. Dickstein[1], V. Fuster[1], J. J. Badimon[1]. [1]*Mount Sinai School of Medicine, Cardiovascular Institute, New York;* [2]*Merck & Co. Inc., Rathway, United States of America*

Introduction: Peroxisomal Proliferator-Activated Receptors gamma (PPAR-gamma) are nuclear receptors that modulate several genes that play a central role in lipid metabolism. They are present in macrophages and have been postulated to affect plaque stabilization. Our objective was to investigate the effects of a PPAR-gamma agonist (L-805645) alone or in combination with simvastatin. Effects of plaque size and composition were assessed by serial MRI and by immunohistochemistry.
Method: Experimental atherosclerotic (AT) lesions were induced by balloon denudation and atherogenic diet in rabbits. Following the 9-month induction period, AT lesions were assessed by MRI and the animals matched according to lesion severity and distributed among the following study groups: AT-control (n=5) sacrificed and processed for histopathology. The remaining animals were maintained on atherogenic diet plus the corresponding treatments for additional 6-months: AT-progression (n=5) placebo; simvastatin-group (n=5; 10mg/kg/d); PPAR-gamma agonist (n=6; 10mg/kg/d) and combination simvastatin + PPAR-gamma agonist (n=7). The effect of the treatments was assessed by MRI and histopathology. Vessel wall area (VWA), a surrogate for atherosclerotic burden, was normalized to the baseline (pre-treatment) value allowing each animal to serve as its own control.
Results: All the groups showed similar VWA (8.45±0.65 mm^2) at randomization. AT-progression group showed a significant increased (15%; p<0.01) in VWA while all the treatment-groups showed a significant reduction of the established lesions (-11.7%, -4.5% and -21.8% for simvastatin, PPAR-gamma and the combination respectively; p<0.01). All the treatments reduced the macrophages and increase the smooth muscle cells content of the lesions. In addition, they reduced MMP activity when compared to AT-control animals.
Conclusion: PPAR-gamma agonist (L-805645) reduces the size of established AT lesions. In addition, its effect seems to be additive when combined with simvastatin offering a novel and more effective therapeutic approach in atherosclerosis.

216 The reality of statin use in primary care!

D.J. wright, A. Grayson, M. Jackson, C. Dainty. *Cardiothoracic center, Cardiology, Liverpool, United Kingdom*

Management of hyperlipidaemia in patients with ischaemic heart disease is sub-optimal despite the proven benefit of statin therapy. Significant improvement in management has been shown in the EUROASPIRE II study. It is unclear however, whether such changes have also occurred in primary care.
4761 patients were screened from three general practices within the United Kingdom to provide a cohort of 300 patients. 249 (83%) had their cholesterol concentration measured and 141 (47%) were on statin therapy. 129 (43% of total) achieved a target cholesterol of <5 mmol,l of which 85 (64%) were taking statin therapy. Of the remaining 120 patients whose cholesterol exceeded 5 mmol/l, 56 (47%) were taking statin therapy. Thus 60% (85/141)(95% CI 51.2 to 67.4) of those on statin therapy achieved adequate control compared to 40% (44/108)(95% CI 30.9 to 49.8) without statin p<0.008. Those patients with CHD diagnosed on objective evidence were more likely to receive statin therapy than those diagnosed on clinical grounds (55.5% (95% CI 47.5 to 63.2) versus 36.9% (95% CI 29.0 to 45.6); p=0.001. Median doses with 25th and 75th centiles of simvastatin, pravastatin, atorvastatin and cerivastatin were 20mg (10 to 20mg), 20mg (10 to 40mg), 20mg (10 to 40mg), and 150mg (100 to 200mg) respectively.
There is a higher prevalence of cholesterol measurement and statin prescription than in previous series. However, many patients are still not receiving appropriate secondary prevention with statin therapy and many of those that are still fail to achieve target levels. The average doses of statins vary and are lower than the evidence based doses used in large-scale studies, which may help explain the degree of failed treatment.

TISSUE FACTOR: LET'S GO FOR PATHWAYS

217 Inhibition of tissue factor by blockade of NFkB and IKK-2 using gene transfer: NFkB as a therapeutic target for reducing plaque thrombogenicity

C. Monaco, E. Andreakos, S. Kiriakidis, M. Feldmann, E. Paleolog. *Kennedy Institute of Rheumatology, Imperial College, London, United Kingdom*

Background: High content of tissue factor (TF), the main initiator of the coagulation cascade in vivo, has been detected in unstable coronary plaques, mainly in macrophages. The TF gene contains non consensus nuclear factor kappa B (NFkB) binding sites. Our aim was to dissect intracellular signalling pathways involved in regulation of TF in human macrophages and endothelial cells, using a highly efficient adenoviral gene delivery system to investigate the role of NFkB and its upstream activators I kappa B-kinase 2 (IKK-2) and IKK-1.
Methods: Elutriation-enriched monocytes were obtained from single donor plateletpheresis residues, and cultured in the presence of macrophage-colony stimulating factor for differentiation to macrophage-like phenotype. Endothelial cells were isolated from human umbilical cords (HUVEC). Cells were left uninfected or infected with adenoviral vectors encoding I kappa B alpha, an inhibitor of NFkB nuclear translocation, or a dominant negative (DN) form of IKK-2 or IKK-1, or without insert as control. A multiplicity of infection of 100:1, at which the efficiency of infection was>95%, was used. After infection, cells were stimulated with Lipopolysaccharide (LPS) or recombinant human soluble CD40 ligand (CD40L), two major stimuli for TF induction. TF antigen was measured by ELISA on cell lysates, and TF activity by a chromogenic assay on whole cells.
Results: NFkB activation is required for TF induction by LPS and CD40L in HUVEC and macrophages, as TF production by both macrophages and endothelial cells was inhibited by 80%±15 and 76%±19 respectively following IkBa overexpression. Overexpression of IKK-2DN in HUVEC significantly reduced TF induced by LPS and CD40L. However, in macrophages, overexpression of IKK-2DN inhibited CD40L-induced TF production (90%±10; p<0.0001), but could only partially inhibit LPS-induced TF expression (36%±14; p<0.004). Similar levels of inhibition of TF activity were observed. The absence of an inhibitory effect of IKK-2DN was paralleled by a lack of inhibition of NFkB nuclear translocation in macrophages, despite efficient overexpression of the transgene, in contrast to HUVEC. Overexpression of IKK-1DN did not affect TF expression.
Conclusion: Blockade of the NFkB pathway in macrophages and endothelial cells inhibits TF induction, suggesting that inhibition of NFkB could be an effective therapeutic target in reducing plaque thrombogenicity. Moreover, our data show selective usage of IKK-2 in NFkB activation and TF expression in human primary macrophages and endothelial cells.

218 Akt negatively regulates tissue factor expression in human endothelial cells

M. Eto, F. Cosentino, T.F. Luscher. *Cardiology, University Hospital, Zurich, Switzerland*

Activation of the coagulation cascade plays a pivotal role in the pathogenesis of arterial thrombotic disease, in particular acute coronary syndromes. Thrombin induces the conversion of fibrinogen to fibrin, platelet aggregation and tissue factor expression. Thus, thrombin is a key modulator of this positive feedback mechanisms of thrombus formation. However, the signaling pathways responsible for thrombin-induced tissue factor expression in endothelial cells remain unclear. It was the aim of this study to investigate the signaling mechanisms underlying tissue factor induction by thrombin in human aortic endothelial cells (HAECs).
In HAECs, thrombin (4 U/mL) markedly increased tissue factor expression, determined by Western blotting, as well as its cell-surface activity with a maximal induction after 4 to 6 hours of the stimulation. Tissue factor induction by thrombin (6 hours) was concentration-dependent (0.01 to 4 U/mL). Thrombin (4 U/mL) induced the rapid and transient (5 to 10 minutes) increase in Rho A activity, determined by pull-down assay, as well as in p38 MAP kinase and ERK1/2 activities, determined by Western blotting with the phospho-specific antibodies. The Rho-kinase inhibitor, Y-27632 (10 μmol/L) as well as the p38 MAP kinase inhibitor, SB203580 (10 μmol/L) significantly prevented tissue factor induction by thrombin (4 U/mL, 6 hours) ($n = 3$, $P < 0.05$). However, inhibition of MEK/ERK pathway by the MEK1/2 inhibitor, U0126 (10 μmol/L) failed to prevent tissue factor induction by thrombin (4 U/mL, 6 hours). In contrast to Rho A and MAP kinases, thrombin (4 U/mL) induced the rapid and transient (5 to 10 minutes) decrease in Akt phosphorylation and activation level, determined by Western blotting with the phospho-specific antibody. The phosphoinositol 3-kinase inhibitor, wortmannin (100 nmol/L) enhanced thrombin (4 U/mL, 5 minutes)-induced dephosphorylation of Akt. In addition, wortmannin significantly potentiated tissue factor induction by thrombin (4 U/mL, 6 hours) ($n = 3$, $P < 0.05$). Akt dephosphorylation by thrombin (4 U/mL, 5 minutes) was inhibited by Y-27632 but not by SB203580.
In conclusion, Rho-kinase-dependent Akt dephosphorylation and p38 MAP kinase activation are important for thrombin-induced tissue factor expression in human endothelial cells. These findings may provide the molecular insight into the vascular thrombogenicity in acute coronary syndromes.

219 Tissue factor ligand interaction activates stress-activated protein kinase p38 independently of the proteolytic activity of Factor VIIa

B. Weigand[1], R. Michl[1], N. Sabari[1], F.J. Neumann[2], I. Ott[1]. [1]*Deutsches Herzzentrum München, München, Germany;* [2]*Herzzentrum Bad Grozingen, Kardiologie, Bad Grozingen, Germany*

The complex of the transmembrane serine protease receptor Tissue Factor (TF) and its ligand Factor VIIa (FVIIa) modifies intracellular signal transduction pathways. Dependent upon its proteolytic activity FVIIa stimulates protease-activated receptors. In addition, TF ligand interactions induce recruitment of the Actin-binding Protein-280 to the cytoplasmic domain of TF independently of the proteolytic activity of FVIIa and thereby support cell spreading and migration.
Stress-activated kinase-2 p38 enhances intracellular F-actin concentrations by phosphorylation of the F-actin polymerization factor heat shock protein (HSP) 27. Activation of this pathway by oxidants and growth factors results in an increased cell migration
To investigate TF-mediated activation of SAPK-2 p38, smooth muscle cells were incubated with FVIIa and proteolytically inactive FFR-FVIIa. Dose-dependent activation of SAPK-2 p38 kinase activity was found for both ligands to a similar extent. In vitro kinase assays showed an increase in kinase activity by 88±3% after incubation with 500 nM FVIIa and by 75±4% after incubation with 500 nM FFR-FVIIa compared to unstimulated controls. In experiments with the human bladder carcinoma cell line J82, that express high levels of TF, similar results were obtained. The FFR-FVIIa-induced activation of SAPK-2 p38 was specific for TF, because it was abolished by specific inhibitory monoclonal antibodies.
In addition to the interaction of the cytoplasmic domain of TF with the actin-binding protein-280, TF-mediated activation of SAPK-2 p38 may enhance cell motility.

220 Role of risk factors in the modulation of tissue factor activity and blood thrombogenicity

A. Sambola[1], J. Osende[2], J. Hathcock[3], Y. Nemerson[3], V. Fuster[4], J. Crandall[5], J.J. Badimon[4]. [1]Mount Sinai School of Medicine, Cardiovascular Biology Research Lab, New York, United States of America; [2]Mount Sinai School of Medicine, Cardiovascular Biology Research Lab, New York, United States of America; [3]Mount Sinai School of Medicine, Medicine, New York, United States of America; [4]Mount Sinai School of Medicine, Cardiovascular Biology Research Lab, New York, United States of America; [5]Mount Sinai School of Medicine, Endocrinology, New York, United States of America

Background: Several studies suggest a role for circulating tissue factor activity (TF-AcT) in atherothrombotic diseases. We hypothesize the increased BT in T2DM, observed in a previous study was in part mediated by increased circulating TF-AcT. We have extended our study to other certain risk factors such as smoking and hyperlipidemia.

Methods and results: Poorly controlled T2DM patients (n=36), smokers (n=10), untreated hyperlipidemic subjects (n=10) and a group of healthy volunteers (n=15) were studied. T2DM were randomized into a (diet modification plus troglitazone or diet modification plus placebo) for 3 months. Current smokers subjects were advised to smoke two cigarettes. Circulating TF-AcT was determined as FXa generation following the capture of plasma solubilized TF by an immobilized antibody. BT was assessed by Badimon perfusion chamber in T2DM patients. T2DM patients showed significantly higher circulating TF-AcT plasma level, both at baseline and after treatment (370±161 vs 286±163 FXa (pM/min), p=0.0001) than healthy volunteers (195±44, FXa (pM/min), p=0.0001). Patients with improvement in glycemic control showed a significant reduction in circulating TF-AcT (362±135 vs 243±74 FXa (pM/min), p=0.0001) independent of treatment group. However, patients without improvement of glycemic control showed no change in TF-AcT (386.87± 191.04 vs 353.50±221.65, p>0.05). A similar pattern was observed in BT: patients with improvement of glycemic control showed a reduction in thrombus formation (15445±1130 vs 12072±596 $\mu m/mm^2$, p=0.01), while patients without improvement glycemic control achieved no changes in thrombus formation (14236.168± 2310 vs 15362.24±3718.01 $\mu m/mm^2$, p>0.05). The reduction in HbA1c was significantly correlated to the reduction in TF-AcT levels (p=0.014). A positive correlation was also founded between reduction BT and reduction TF-AcT (p=0.007). Smokers increased a 30% TF-Act after two hours to smoke 2 cigarettes (217±72 FXa, pM/min vs 283±106 FXa, pM/min, p=0.003). Hyperlipidemic subjects showed a higher TF-AcT (237±63 FXa, pM/min, p=0.035) than healthy volunteers.

Conclusions: Our observations suggest that the increased incidence of thrombotic complications observed in diabetic, hyperlipidemic and smokers may be related to an increased circulating TF activity. Furthermore, a rationale control of these cardiovascular risk factors could be associated to a reduction of circulating TF-AcT and BT.

221 Tissue factor expression by platelet-monocyte cross talk in stable and unstable angina

C.W.K. Kopp, S. Steiner, D. Seidinger, N. Jordanova, E. Minar, K. Huber. *University of Vienna, General hospital, 2nd Dept. of Medicine, Vienna, Austria*

Background: Tissue factor (TF), the major procoagulant in vivo, is usually absent from blood cells. However, monocyte (Mo) TF-expression and platelet activation are both features of unstable angina and may contribute to this prothrombotic state.

Methods: In 60 coronary artery disease patients with stable (SA, n=44) and unstable angina (UA, n=16) MoTF expression and total (CD42) and activated (CD62P) platelet load was determined by flow cytometry on CD14+ cells. MoTF-dependent procoagulant activity (PCA) was measured by chromogenic assay. Prothrombin fragment F1.2 was determined by ELISA and expression of TF mRNA was confirmed by RT-PCR.

Results: MoTF-antigen level (16.4±3.3 MFI), MoTF-PCA (68.5±38.2 U/10e6 PBMC) and activated platelet load on Mo (CD62P:198±130 MFI) were significantly higher in UA compared with SA (14.1±3.1 MFI, p=0.03; 47.9±18.1U/10e6 PBMC, p=0.04; 126±134 MFI, p=0.03). Both, total (r=0.69, p<0.001) and activated (r=0.47; p=0.002) platelet load positively correlated with MoTF Ag-expression, which further correlated with TF-dependent PCA and F1.2 levels. MoTF mRNA was expressed in 26% of SA and in 37.5% of UA.

Conclusion: We show elevated MoTF-antigen expression paralleled by higher MoTF-dependent PCA in UA compared with SA patients correlating with total and activated Mo-platelet load. This suggests increased platelet-leucocyte cross talk contributing to the procoagulant state in acute coronary syndrome.

222 Tissue factor, tissue factor pathway inhibitor and cytoadhesive molecules in patients with acute coronary syndrome

J. Vojacek[1], M. Maly[1], V. Hrabos[1], M. Mates[1], P. Hajek[1], V. Durdil[1], J. Kvasnicka[2], P. Salaj[3]. [1]University Hospital Motol, Division Cardiology, Prague 5, Czech Republic; [2]1st School of Medicine, Charles Univer, Clinical Hematology, Prague, Czech Republic; [3]Inst Hematology and Blood Transfusion, Prague, Czech Republic

The tissue factor (TF) plays a crucial role in the initiation of blood coagulation after the plaque rupture in patients with acute coronary syndrome (ACS). The aim of the study was to compare the plasma levels of TF, tissue factor pathway inhibitor (TFPI), soluble P-selectin (sP-s), E-selectin (sE-s) and Intercellular Adhesion Molecule – 1 (sICAM-1) in patients with an acute myocardial infarction (AMI) (n=10), unstable angina pectoris (UAP) (n=23), stable coronary artery disease (SAP) (n=17) and normal control subjects (N) (n=10). In addition, plasma levels of TF, TFPI, sP-s, sE-s and sICAM-1 were measured in the blood drawn from coronary sinus (CS) in subgroup of patients with UAP and SAP and difference between concentrations in the CS and systemic blood was calculated. A significant increase in TFPI plasma levels was detected in patients with AMI (373.3±135.1 ng/mL, p<0.01) and UAP (119.6±86.9 ng/mL, p<0.05) in contrast to the patients with SAP (46.3±37.5 ng/mL) and N (45.1±14.3 ng/mL). The plasma levels of TFPI were significantly increased both in the CS and systemic blood in the patients with the UAP. There was only non-significant trend to higher plasma levels of TF in patients with the AMI and UAP as compared to the patients with SAP and N, the values being, respectively, 129.1±30.2 pg/mL, 130.5±57.8 pg/mL, 120.2±45.1 pg/mL and 124.9±31.8 pg/mL. The difference in plasma levels of sICAM-1 between the blood drawn from CS and systemic circulation was significantly correlated to the corresponding differences in plasma levels of sP-s and sE-s.

In conclusion, TFPI levels are increased both in the systemic blood and in the CS in patients with ACS, thus suggesting that not only local, but also systemic activation of coagulation takes place in patients with ACS.

DEGENERATIVE AORTIC STENOSIS, NEW MECHANISMS

223 Matrix metalloproteinase MMP-2 is upregulated and activated in calcific aortic stenosis

J.J. Kaden[1], R. Grobholz[2], D.C. Vocke[1], C.S. Fischer[1], C.F. Vahl[3], K.K. Haase[1], C.E. Dempfle[1], M. Borggrefe[1]. [1]University Hospital of Mannheim, 1st Department of Medicine, Mannheim, Germany; [2]University of Heidelberg, Institute of Pathology, Mannheim, Germany; [3]University of Heidelberg, Department of Cardiac Surgery, Heidelberg, Germany

Background: Fibro-calcification of valve cusps is the main reason for aortic stenosis in the elderly. It is characterized by chronic inflammation and extensive remodeling of the extracellular matrix. The role of matrix metalloproteinase 2 (MMP-2, Gelatinase A), a 72 kDa endopeptidase capable of degrading various components of the extracellular matrix, has not been determined in this disease process.

Methods: Human tricuspid aortic valves with (n=19) and without (n=4) calcific aortic stenosis were obtained at valve replacement or autopsy, respectively. MMP-2 mRNA was determined in tissue homogenate using RT-PCR. Using a monoclonal antibody against MMP-2, immunohistochemistry on cryosections with semiquantitative scoring and Western blotting with densitometric analysis were performed. Gelatinolytic activity of MMP-2 was measured by gelatin zymography and localized by in-situ zymography with or without MMP activation with 1 mmol/L p-aminophenymercuric acetate (APMA).

Results: MMP-2 mRNA expression was detectable in normal and stenotic valves. MMP-2 immunoreactivity was shown in fibroblasts and fibrocytes in all valves. Staining intensity was significantly higher in stenotic valves by semiquantitative scoring (1.3±0.1 vs 0.5±0.0 score units, P<0.001). Western blotting and gelatin zymography demonstrated bands at 72 kDa with higher band intensities in stenotic valves by densitometry. In-situ zymography showed markedly increased gelatinolytic activity in stenotic valves compared to normal valves. On activation with APMA, gelatinolytic activity was significantly increased in normal valves indicating that MMP-2 is present mostly as a latent proenzyme in these valves. In stenotic valves, incubation with APMA did not result in an elevation of MMP-2 activity indicating that MMP-2 is present already in an activated form in these valves.

Conclusion: MMP-2 is constituously present in human aortic valves and upregulated in calcific aortic stenosis. In normal valves, MMP-2 is present mainly as latent proenzyme with low gelatinolytic activity. In stenotic valves, MMP-2 is activated. These results may indicate a pathogenetic role of MMP-2 in the tissue remodeling in calcific aortic stenosis.

224 The role of matrix metalloproteinases in aortic valve diseases

O. Fondard[1], H. Adle[2], J.P. Couetil[3], M. Jarraya[4], J. Gerota[5], B. Iung[6], A. Vahanian[7], M.P. Jacob[8]. *[1]Faculté de médecine Xavier Bichat, INSERM U460, Paris, France; [2]Hôpital Bichat, Service d'anatomopathologie, Paris, France; [3]Hôpital Bichat, Service de chirurgie cardiaque, Paris, France; [4]Hôpital Saint Louis, Banque de tissus humains, Paris, France; [5]Hôpital Saint Louis, Banque de tissus humains, Paris, France; [6]Hôpital Bichat, Service de cardiologie, Paris, France; [7]Hôpital Bichat, Service de cardiologie, Paris, France; [8]Faculté de médecine Xavier Bichat, INSERM U460, Paris, France*

Background: Human cardiac valve diseases are characterised by pathological remodelling of valvular tissue but the cellular and molecular effectors involved in these processes are not well known. Here, we investigate the role of matrix metalloproteinases (MMPs) MMP-3 and MMP-7 in human aortic valve diseases.
Methods: Pathological valves were collected during surgery, and the controls, non-cryopreserved homografts, were obtained from a human tissue bank. Valves were classified according to their pathology and divided into 3 groups: aortic controls (n=10), aortic stenosis (AS) (n=51), aortic regurgitation (AR) (n=24). Valves were studied histologically at the cellular and extracellular matrix levels. The biochemical analyses (casein zymography, reverse zymography and Western blot) were performed on valve extracts and valve conditioned media (valvular tissue incubated in basal culture medium during 24 hours).
Results: Histological study showed fibrotic, inflammatory and calcified lesions in AS, and degenerative lesions characterised by disorganization of collagen bundles and elastic fibers in AR. Zymography of extracts showed that the MMP-3 activity was significantly increased in AS compared to controls ($p<0.001$) and AR ($p<0.05$) (AS: 8960 ± 1140; AR: 5570 ± 1620; controls: 770 ± 436 densitometric units/μg of proteins). It was also increased in AR compared with aortic controls (NS). In extracts, the MMP-7 activity was significantly increased in AS compared with aortic controls ($p<0.05$) (AS: 5710 ± 1200; AR: 2750 ± 1540; controls: 18 ± 18 densitometric units/μg of proteins). MMP-3 and MMP-7 were absent from conditioned media; this was confirmed by Western blot. Thus, MMP-3 and MMP-7 are stored in the extracellular matrix and do not diffuse into the culture medium.
Conclusion: This study demonstrates the involvement of the MMP system in the extracellular matrix remodelling of both dystrophic and degenerative aortic valve diseases. In addition, these results provide clear further proof of the inflammatory state of the pathological valves, especially in AS.

225 Smoking cessation: transdermal nicotine system (TNS) use among medical staff

D. Glavas, Z. Rumboldt. *University Hospital Split, Department of Internal Medicine, Split, Croatia*

Introduction: Majority of doctors and nurses believe that their duty is to help patients to give up smoking. The aim of the study was to assess smoking habit and the efficacy of TNS (which delivered nicotine at 0.7 mg/cm^2/24 h) among medical staff-smokers in Clinical Hospital Split.
Methods: The sample consisted of 311 persons: 207 (66.6%) females, 104 (33.4%) males, 119 (38.3%) doctors, 192 (61.7%) nurses. There were 112 (36%) smokers: 36.7% (76/207) females, 36.5% (38/104) males, 36.9% (44/119) doctors, 36.5% (70/192) nurses.
In a randomised double-blind study during 3 weeks included were 112 smokers subdivided in 2 groups: TNS and placebo. Abstinence was evaluated with questionnaires and measuring CO in expired air.
Results: The abstinence rates after 3-week period were 39.3% in the nicotine group and 19.6% in the placebo group. The difference was significant ($p<0.05$). Five years later in the observed population there were 101 (32.5%) smokers: 37.7% (78/207) females, 17.3% (18/104) males, 20.2% (24/119) doctors, 38% (73/192) nurses. There was no difference between the former TNS and placebo group.
Conclusions: This study has shown that short TNS treatment is effective in smoking cessation. Five years later in the observed population there were less smokers (-3.5%, n.s.), especially among doctors (-16.7%,$p<0.01$) and males (-19.2%,$p<0.01$). Further intervention in this field, like drug application is necessary, particularly among nursing staff.

226 Increased thermal heterogeneity in degenerative aortic valve stenoses: first human application of aortic valve thermography catheter

C. Stefanadis, K. Toutouzas, E. Tsiamis, S. Vaina, I. Kallikazaros, K. Tentolouris, C. Pitsavos, P. Toutouzas. *Hippokration Hospital, Dept of Cardiology, Athens, Greece*

Background: Recent studies suggest that valvular degeneration in aortic valve stenosis (AVS) could be caused by inflammatory processes. Inflammation leads to heat release locally in atherosclerotic plaques. Thus, the present study was designed to investigate whether thermal heterogeneity is present in patients (pts) with and (AVS) by the first human application of an aortic valve thermography catheter.
Methods: The study population consisted of 10 pts with AVS undergoing diagnostic catheterization (mean age: 74.2 ± 8.1 yrs) and 8 pts without AVS (mean age 70.1 ± 9.3 yrs) undergoing diagnostic catheterization for the evaluation of chest pain. In pts with AVS an echocardiography was performed before the catheterization, and mean and maximal pressure gradient was estimated. Temperature measurements were performed by an aortic valve thermography catheter, previously validated. This thermography catheter is 8F in diameter and its proximal part is attached to a connector with a hemostatic valve and to a connector for the thermistor lead-wires. A steering arm passes through the hemostatic valve, and through the lumen of the catheter and is attached to the tip of the catheter. The distal 20 cm of the shaft of the catheter consist of a soft non-thrombotic material and enable this distal part to be curved to 90°. The thermistor lead-wires end to the connector and pass through the lumen of the catheter. The thermistor probe is positioned at the tip of the catheter. Manipulation of the steering arm at the proximal end enables the distal end of the catheter to be altered by remote control so that the thermistor is in contact with the aortic valve or aortic wall. Temperature was measured at different sites of the aortic valve and also on the wall of the ascending aorta. The maximum difference between the temperature of aortic valve and aortic wall was designated as temperature difference (TD).
Results: The procedure of temperature measurement of the aortic valve and the aortic wall in the ascending aorta was successful, without any complications in the whole study group. TD was increased in pts with AVS compared to the subjects without AVS (0.54 ± 0.5 vs 0.05 ± 0.01°C, $p < 0.01$). Moreover, in pts with AVS the mean and maximal pressure gradient was not correlated with TD.
Conclusions: The first human application of an aortic valve thermography catheter was successful and uncomplicated. Thermal heterogeneity is frequently found in human aortic valves in pts with AVS. Further research is warranted in order to evaluate this phenomenon during the progression of aortic valve stenosis.

227 Do really statins reduce the progression of aortic stenosis? A need for a prospective randomized trial

F. Antonini-Canterin, P. Faggiano, D. Pavan, R. Piazza, A. Bolis, A. Ciavattone, A. Ruggiero, G.L. Nicolosi. *Ospedale Civile, Cardiologia, Pordenone, Italy*

Background: It has been recently suggested in a retrospective study of 57 statin-treated patients with mild to moderate aortic stenosis (AS) that statins could slow the progression of AS (Circulation 2001; 104:2205-9).
Methods: From our echocardiographic database (1988-2001) we obtained 95 statin-treated patients with mild to moderate AS (initial peak aortic velocity 2-3.9 m/s) and with at least two examinations >6 months one apart of the other (61 males, 34 females, mean age 67.6 ± 8.6 years, mean follow up 54 ± 36 months; initial aortic valve area 1.28 ± 0.26 cm^2). As control group we randomly selected, from the remaining 759 patients with an initially similar degree of AS and with at least two examinations, 95 sex-age matched patients who did not receive treatment with a statin (61 males, 34 females, mean age 67.5 ± 8.7 years, mean follow up 51 ± 34 months; initial aortic valve area 1.28 ± 0.25 cm^2).
Results: The rate of increase of peak aortic velocity was 0.15 ± 0.26 m/s/year in the statin group and 0.15 ± 0.20 m/s/year in the control group (p=ns). The rate of decrease of aortic valve area was – 0.074 ± 0.095 cm^2/year in the statin group and 0.069 ± 0.074 cm^2/year in the control group (p=ns). The mean value of aortic valve area at the end of the study was 1.01 ± 0.31 cm^2 in the statin group and 1.04 ± 0.30 cm^2 in the controls (p=ns). A pattern of rapid progression of AS (increase of peak aortic velocity > 0.3 m/s/year) was observed in 20/95 (21%) of statin-treated patients and in 15/95 (16%) patients who did not receive statins (p=ns). A major clinical end point (death or aortic valve replacement) was found in 21/95 statin-treated patients (22%) and in 13/95 (14%) not treated patients (p=ns).
Conclusion: Despite the theoretical potential benefits of statins on aortic valve lesion, our study does not confirm the first results about their slowing effect on the progression of AS. A prospective randomized controlled trial is then necessary before to extend the indications of statins to patients with AS.

FACILITATED AND RESCUE PERCUTANEOUS CORONARY INTERVENTION IN ACUTE MYOCARDIAL INFARCTION

255 Effects of facilitated percutaneous coronary intervention on myocardial perfusion and clinical outcome in patients treated with tenecteplase and eptifibatide for acute myocardial infarction

U. Zeymer[1], F. Van de Werf[2], R.P. Giugliano[3], M.T. Roe[4], M.M. Kitt[5], J.T. Strony[6], R.A. Harrington[4], E. Braunwald[3] on behalf of the INTEGRITI Investigators. [1]*Klinikum Kassel, Medizinische Klinik II, Kassel, Germany;* [2]*Ziekenhuis Gasthuisberg, Cardiology Univisitair, Leuven, Belgium;* [3]*Brigham and Women's Hospital, Cardiovascular Division, Boston;* [4]*Duke Clinical Research Institute, Durham;* [5]*Cor Therapeutics, Inc., South San Francisco;* [6]*Schering-Plough Resarch Institute, Kenilworth, United States of America*

Background: Recent data suggest that patients with ST elevation myocardial infarction (AMI) arriving in the cath-lab already with TIMI 3 flow of the infarct-related artery have a higher success rates of PCI and an improved clinical outcome. These findings have renewed the interest in facilitated percutaneous intervention (PCI) following medical reperfusion therapy.
Methods: Patients with AMI < 6 hrs were treated with different combinations of reduced-dose tenecteplase and double-bolus regimens eptifibatide in the INTEGRITI study. After patients underwent protocol-mandated angiography at 60 min, facilitated PCI was performed at the discretion of the investigator. We report the results of 97 patients with PCI at 60-90 min after start of thrombolysis.
Results: TIMI 2 or 3 flow before PCI was observed in 21% and 65% of the patients, respectively. Complete (> 70%) ST resolution was seen in 52% before PCI. The intervention was successful in all patients. A stent was implanted in 84/97 of the patients. After PCI all patients had a patent infarct-related artery with TIMI 2 and 3 flow in 9% and 91% of patients, respectively. This resulted in a rate of 81% complete ST resolution 90 min after PCI. Until day 30 we observed 5 deaths, no reinfarction, 1 re-PCI and 3 CABG. TIMI major bleeding occurred in 4 patients.
Conclusion: Facilitated PCI after combination therapy with eptifibatide and reduced-dose tenecteplase is associated with a high rate of epicardial coronary artery patency and myocardial tissue reperfusion and a low rate of reinfarctions and re-interventions. The impact of this combined medical and interventional approach on clinical outcome in patients with AMI will be evaluated in a phase III study (ADVANCE-MI).

256 Microvascular no-reflow phenomenon and myocardial injury after facilitated angioplasty in patients with acute myocardial infarction

J. Zalewski[1], D. Dudek[2], N. El-Massri[1], W. Zajdel[1], T. Przewlocki[1], W. Piwowarska[1], J. Dubiel[3], K. Zmudka[1]. [1]*St. John Paul Hospital II, Institute of Cardiology, Kraków, Poland;* [2]*Institute of Cardiology, Krakow, Poland;* [3]*Institute of Cardiology, Krakow, Poland*

Drug-facilitation of coronary angioplasty in acute myocardial infarction (AMI) is expected to reduce microvascular no-reflow and thus myocardial injury.
We compared invasively-determined parameters of coronary flow (TIMI scale and corrected TIMI Frame Count, CTFC [frame]) and perfusion (TIMI Myocardial Perfusion Grade, TMPG) with biochemical injury (area under the curve of CK-MB release within the first 24 hours, CK-MB24 [U/l x h]) and echocardiographic LV function (ejection fraction, EF [%] 48 hours after the procedure) in 126 consecutive patients (pts) with AMI (mean age 57.1±10.1 years). All pts (52 pts with anterior, 18 pts with lateral and 56 pts with inferior AMI) received half-dose of actilyse plus abciximab before coronary angiography. PCI was subsequently performed in 111 pts.
TIMI-3 was achieved in 73 [65,8%] before and 104 [93,7%] pts after PCI, TIMI-2 in 17 before and 7 pts after PCI, and TIMI-0/1 in 21 befor and 0 pts after PCI. TMPG-3 was achieved in 63 [56,8%] before and 55 [49,9%] pts after PCI, TMPG-2 in 22 before and 31 pts after PCI and TMPG-0/1 in 26 before and 25 pts after PCI. CTFC was 26,1±15,3 before and 19,2±11,3 after PCI ($p<0.05$). Mean EF in TMPG-3 vs. TMPG<3 pts was 62.8±9.4 vs 56.3±7.4 ($p<0.001$) whereas CK-MB24 was 2316±1205 vs. 2895±1773 ($p=0.015$). Mean EF in TIMI-3 vs. TIMI<3 was 60.9±8.1 vs. 56.9±10.3 ($p=0.03$). The table shows the values of mean EF and CK-MB24 in relation to TIMI before and TMPG after PCI.

EF, CK-MB24 in relation to TIMI and TMPG

	TIMI-3 before PCI	TIMI<3before PCI	TIMI<3before PCI	TIMI<3before PCI
	EF [%]	EF [%]	CK-MB24 [U/l x h]	CK-MB24 [U/l x h]
TMPG-3 after PCI	62.5±7.5 (n=48)	65.1±6.4 (n=7)	2206.4±1010.1	3139.8±1632.4
TMPG<3 after PCI	57.8±8.4 (n=25)	55.6±10.2 (n=31)	2851.4±1650.3	2984.9±1551.3

For abbreviations see text of abstract

Conclusion: Achievement of high TMPG with facilitated PCI in AMI is associated with limited myocardial injury independent of initial TIMI flow.

257 Prehospital thrombolytic/abciximab therapy in comparison to PTCA/stent after combined prehospital thrombolysis in acute myocardial infarction

H. Thiele[1], L. Engelmann[2], K. Elsner[1], K. Rahimi[1], M. Hartmann[3], D. Pfeiffer[4], E. Boudriot[1], G. Schuler[1]. [1]*Heart Center, Internal Medicine/Cardiology,* [2]*Intensive Care Medicine, University of Leipzig, Leipzig, Germany;* [3]*Städt. Klinik St. Georg, Internal Medicine, Leipzig, Germany;* [4]*University of Leipzig, Cardiology, Leipzig, Germany*

Background: Prognosis in acute myocardial infarction (AMI) is mainly determined by early reperfusion and the restoration of a normal blood flow in the infarct related artery. However, reperfusion therapy for AMI with thrombolysis has been shown to achieve a 50% TIMI-3-flow only. Early trials combining thrombolysis and PTCA have failed to show a mortality benefit mainly due to encountered bleeding complications. Since the reduced fibrinolytic therapy in combination with a platelet glycoprotein IIb/IIIa inhibitor (COMBO) has recently shown to reduce the rate of AMI related complications, "facilitated" PTCA with stent implantation needs new evaluation.
Methods: Since 12/2000 110 patients with an AMI were randomized in Leipzig, Germany within 6 hours after symptom onset to either a prehospital COMBO (half dose Reteplase + abciximab) with in-hospital conservative therapy (n=54) and elective cardiac catheterization or a prehospital initiated COMBO therapy with immediate in-hospital "facilitated" PTCA plus stent implantation (n=56).
Results: Three patients (3%) had to be excluded due to ECG-misinterpretation. Mean time from symptom onset to medical aid was 112±80 min in COMBO only in comparison to 105±40 min in the COMBO+stent group (p=n.s.). In the COMBO only group 12 patients (22%) had to undergo rescue-PTCA due to failed thrombolysis. In the COMBO+stent group mean TIMI-3-flow before intervention was 55% and after 94%, respectively. Mean CK expressed as area under the curve was 959±900 in the COMBO only versus 610±490 µmolh/l in the COMBO+stent group (p=0.059). Four patients in the COMBO+stent had a major bleeding and 2 patients in the COMBO only group (p=n.s.). Mortality and target vessel revascularization procedures were similar in both groups.
Conclusion: The prehospital combined thrombolytic therapy with abciximab is feasible and initial results suggest that a "facilitated" PTCA results in smaller myocardial infarctions as measured by CK-release without excess in encountered complications.

258 Abciximab initiated before transportation of patients with myocardial infarction for treatment by primary angioplasty improves clinical outcome

S.M.L.A. Beeres, P.V. Oemrawsingh, D. Atsma, J.W. Jukema, E.E. van der Wall, M.J. Schalij. *Leiden University Medical Center, Dept of Cardiology, Leiden, Netherlands*

Background: Abciximab given before primary angioplasty with stent placement for myocardial infarction (MI) improves clinical outcome. This study was done to compare the outcomes after abciximab initiated before transport for primary percutaneous intervention with abciximab started after arrival in the catheterization laboratory.
Methods: 6 month clinical outcome was evaluated of all patients (pts) with extensive anterior MI, referred for direct angioplasty (n=370), in whom abciximab was initiated either on arrival at our catheterization laboratory (Group A) or at referring hospitals before transport to our tertiary care center (Group B). All pts were treated with an abciximab bolus of 0.25 mg/kg I.V. followed by infusion of 0.125 µg/kg/min I.V. for 12 hrs.
Results: From May 1999 to September 2001, 270 pts (age 61±9 yr; 76% Male) were transported without abciximab prior to transport (group A) and 100 pts (age 61±10 yr; 68% Male) in whom abciximab was started in the referring hospital before ambulance transport. The ambulance transport time in both groups was comparable (45±15 min, range 15-60 min). Established coronary artery disease was more frequent in group B (n=38; 38%) compared to group A (n=70; 26%; p=0.04), but other baseline characteristics were similar. Major vascular complications occurred in 7% (n=19) of the pts in group A vs. 8% (n=8) of the pts in group B (NS). In both groups the rate of revascularization procedures within 6 months were similar (n=38; 14% vs. n=15; 15%, NS). In group A, acute coronary syndromes within the first 6 months were more frequent compared to group B (n=48; 18% vs. n=9; 9%; p=0.04). There was no difference in the mortality rate between the groups (n=24; 9% vs. n=8; 8%; NS). The combined end point of non-fatal cardiac events (acute coronary syndromes + any revascularization) was more frequent in group A (n=96; 36%) in comparison to group B (n=24; 24%; p=0.04). Survival without major adverse cardiac events (non-fatal and fatal cardiac complications) was more likely in group B (75%) than in group A (64%; p=0.04).
Conclusion: Abciximab initiated before transportation for primary angioplasty improves 6 month clinical outcome in pts with acute anterior wall myocardial infarction. Although no mortality difference could be demonstrated in this analysis, it still provides an argument for starting abciximab as early as possible and if applicable before transportation to a tertiary care center for percutaneous intervention in pts with extensive MI.

259 Facilitated PTCA in acute myocardial infarction. A meta-analysis of available studies

G. Casella[1], A. Capecchi[2], F. Ottani[3], P. Sangiorgio[2], P.C. Pavesi[2], D. Bracchetti[2]. [1]*Cardiology Ospedale Maggiore, Bologna, Italy;* [2]*Ospedale Maggiore, Cardiology, Bologna, Italy;* [3]*Ospedale San Bortolo, Cardiology, Vicenza, Italy*

Background: The rapid restoration of normal blood flow in the infarct-related artery is the main objective in the treatment of patients with Acute Myocardial Infarction (MI). This goal is usually accomplished with either fibrinolytics or with primary angioplasty (PTCA). However, both methods have several drawbacks. Recently, the term "facilitated PTCA" has emerged to describe a number of different strategies that aim to use pharmacologic agents (fibrinolytics, GP IIb/IIIa inhibitors) to improve the outcome of early PTCA in acute MI. However, to date there are only small, preliminary studies assessing different combination of pharmacologic strategies that compared facilitated PTCA with standard treatment and results are variable. Thus, the present investigation refines these values by means of a formal meta-analysis.
Methods: Six studies were considered suitable for analysis. Odd Ratios (OR) were calculated for 30-days follow-up. Primary end points were a composite of death and non-fatal MI as well as major bleedings, as considered in every single study. Secondary end points were a composite of death, reinfarction and target vessel revascularisation, according to single study definition, and individual cardiac events as well.
Results: A total of 2332 patients were included. At 30 days, the OR for death and non-fatal MI was 0,70 (95% Confidence Interval [IC], 0,50-0,98, p=0,04) in favor of facilitated PTCA. On the other hand, major bleedings were more frequent in patients treated with facilitated PTCA (OR 1,16, 95% CI, 0,84-1,60, p=NS). According to secondary end points, there was a trend toward less mortality (OR 0,70, 95% CI, 0,45-1,10, p=NS) and less non-fatal MI (OR 0,70, 95% CI, 0,43-1,13, p=NS) in favor of facilitated PTCA. Revascularisations were significantly less frequent (OR 0,50, 95% CI, 0,33 -0,74, P=0,0006) in patients treated with facilitated PTCA compared to standard therapy.
Conclusions: According to 30-days clinical outcomes, the present meta-analysis demonstrates that facilitated PTCA has a superior clinical efficacy compared to standard treatment in acute MI. However, our conclusions suffer strong limitations due to consistent differences in pharmacologic treatments applied and the underpowered sample size of each trial. Therefore, randomized, adequately sized trials, to specifically test the safety and efficacy of facilitated PTCA and the correct target population, should be performed. In fact, the logistical and economical rebounds of a widespread application of facilitated PTCA are enormous.

260 Rescue angioplasty for failed fibrinolysis: can we identify those patients who do not benefit?

A.G.C. Sutton, P.G. Campbell, J.A. Hall, A.A. Harcombe, R.A. Wright, M.A. de Belder. *James Cook University Hospital, Cardiothoracic Division, Middlesbrough, United Kingdom*

Introduction: There is no consensus regarding the management of patients with acute ST segment elevation myocardial infarction who have early evidence of failed fibrinolysis (FF). Clinical studies of rescue angioplasty (RA) to date suggest low mortality with a successful procedure, but high mortality with a failed procedure. Whether this reflects a high-risk group or harm in some patients is unclear.
Methods: Clinical variables from a large cohort of patients undergoing angiography after FF were analysed to determine the characteristics of patients who did not benefit from RA.
Results: 324 patients (219M, 95F, mean age 62.6 yr) underwent emergency coronary angiography for FF. Mean treatment times were: (a) onset of pain to lysis 206 mins; lysis to cath lab 196 mins; onset of pain to cath lab 405 mins. 30-day mortality was 9.9% (n=32). 84 patients had TIMI 3 flow in the infarct-related vessel (IRV). 240 patients had < TIMI 3 flow. RA was attempted in 220 patients with < TIMI 3 flow ("RA cohort") and not in the remaining 20, either because angiography produced TIMI 3 flow (n=6) or the anatomy was unsuitable (n=14). Of the RA cohort, 178 (81%) had a successful RA procedure (no death/emergency CABG/TIMI 3 in IRV) [Group A]. 41 underwent RA but final flow was < TIMI 3 [Group B]. 30-day mortality for A and B was 8.5% (n=15) and 29.3% (n=12). 30-day mortality in the RA cohort was 12.3% (n=27). In the 84 with initial TIMI 3 flow, 30-day mortality was 4.8% (n=4). Group B patients were significantly older than Group A patients (mean 66.1 vs. 61.2, p=0.004), had longer pain - lysis times (mean 251 mins vs 203 mins, p=0.06), were more likely to be diabetic (22% vs. 9%, p=0.028) and were less likely to be current smokers (22% vs. 30%, p=0.048). Lysis - lab times were similar in Group A and Group B (210 and 221 mins). Pain - lab times were longer in Group B (470 vs. 419 mins, p=0.05) reflecting the longer pain - lysis time.
Conclusion: Failure to obtain adequate antegrade flow during attempted rescue angioplasty for failed fibrinolysis is more likely in long pain to lysis times, increasing age, diabetics and non-smokers. Clinical variables may be helpful in selecting patients for a strategy of rescue angioplasty after failed fibrinolysis.

THE SPECTRUM OF INFECTIVE ENDOCARDITIS

274 Short-term prognosis of infective endocarditis in a one-year French prospective cohort

F. Delahaye[1], F. Alla[2], C. Selton-Suty[3], F. Lacassin[4], I. Béguinot[5], V. Le Moing[6], J.L. Mainardi[7], B. Hoen[8] on behalf of AEPEI Study Group. [1]*Hopital Louis Pradel, Lyon, France;* [2]*CHU Nancy, Nancy, France;* [3]*Chu Nancy-Brabois, Cardiology Dept., Nancy, France;* [4]*Nouméa, Nouvelle Calédonie, France;* [5]*CHU, Reims, France;* [6]*CHU, Montpellier, France;* [7]*HEGP, Paris, France;* [8]*Hopital Jean Mermoz, Besançon, France*

Objective: To study the short-term prognosis of infective endocarditis (IE) in a large unselected cohort.
Methods: We collected data on all patients hospitalized for IE during year 1999 in several French regions. For each patient, a case report form was filled in by the clinician (clinical and echocardiographic data) and by the microbiologist (microbiological data). Only definite IE according to the Duke criteria were included (559 cases). Tested variables were: age, gender, comorbidities, cardiac history, at-risk procedures and situations, severity of IE (maximal NYHA class, left ventricular ejection fraction, blood creatinine level > 180 µmol/l, Glasgow score, septic shock), vascular phenomena (embolisms, mycotic aneurysm...), immunologic phenomena (glomerulonephritis, Osler's nodes, rheumatoid factor...), signs of infection (C-reactive protein > 120 mg/l, white blood cells > 10,000...), echocardiography findings (location, abscess, prosthesis dehiscence...), and microorganism.
Results: Mean hospital length of stay was 49.7 ± 43.5 days (range: 1-433). In-hospital lethality rate was 17%. In multivariate analysis, it was significantly influenced by: diabetes mellitus: odds ratio: 7.5 [95% confidence interval: 2.5-22.2]; history of immunodepression: 3.5 [1.6-7.6]; type I septic shock: 4.2 [2.1-8.7]; Glasgow score < 8: 2.4 [1.2-4.7]; history of congestive heart failure: 2.5 [1.3-4.7]; NYHA class III or IV: 2.4 [1.4-4]; C-reactive protein > 120 mg/l: 2.8 [1.6-5.1]; mitral location: 1.8 [1.1-3]; intracranial hemorrhage: 8.8 [2.3-34.5]. During the initial hospital stay, 47% of the patients were operated on. The surgery rate was significantly influenced by: age: (ref: <60 years) 60-70 years: 0.48 [0.29-0.80]; 70-80 years: 0.36 [0.22-0.59]; >80 years: 0.03 [0.01-0.14]; history of dyslipidemia: 2.1 [1.1-3.8]; history of native valve disease: 1.5 [1-2.3]; NYHA class III or IV: 2.9 [1.8-4.5]; aortic location: 3.3 [2.1-5.2]; mitral location: 2.3 [1.5-3.6]; abscess at echocardiography: 2.9 [1.6-5.1]; white blood cells > 10,000: 0.6 [0.4-0.9]; embolism other than cerebral, coronary, lower limbs, pulmonary: 2.0 [1.1-3.5]; intracranial hemorrhage: 0.2 [0-0.8].
Conclusion: Our analysis confirms several variables as factors that influence the lethality rate (e.g., intracranial hemorrhage, heart failure...) or the surgery rate (age, embolisms...). But our multivariate analysis shows interesting findings: when other prognostic variables like comorbidities are taken into account, the outcome of IE may be similar whatever the responsible microorganism.

275 Long-term results of homograft aortic valve replacement for endocarditis

C. Thomsen, H. Naegele, R. Schomburg, W. Rödiger, V. Döring, H. Reichenspurner. *Universitätsklinikum Eppendorf, Herzchirurgie, Hamburg, Germany*

Background: Homografts were considered to be the ideal aortic valve substitute. Especially in active endocarditis their pre-treatment with antibiotic solutions and their ability to mold well into the fragile infected aortic annulus was thought to be of advantage. However there are sparse data on the long-term course of this valve type especially in regard to recurrent endocarditis.
Methods: Between 1990 and 1997, a total of 90 cryopreserved aortic homografts were implanted (mean patient age 44±14 years). N=26 had active infective endocarditis (group 1), out of these n=8 prosthetic valves were affected. N=64 had non-endocarditic valve lesions (group 2). In a prospective study patients were examined clinically and echocardiographically at yearly intervals (mean 5.3±3.6 years). Follow-up was complete in 85 cases (94%).
Results: 30-day mortality was 4% in group 1 and 5% in group 2. There were eight late deaths in group 1 and five in group 2. Eight patients in group 1 underwent reoperation during follow-up: indications were recurrent endocarditis in three patients, aortic insufficiency in two patients, aortic stenosis in two patients and ventricular septal defect in one case. In group 2 sixteen reoperations were caused by aortic insufficiency(n=7), homograft valve endocarditis(n=5), primary malfunction(n=2), homograft stenosis(n=1) and combined lesions(n=1). At five years actuarial freedom from homograft valve endocarditis was 75% in group 1 compared to 94% in group 2 (p<0.05).
Conclusions: Valve replacement in the presence of native and prosthetic endocarditis remains a surgical challenge. The role of homografts was questionable since in our study a high rate of recurrent graft endocarditis and structural valve deterioration led to subsequent reoperations in patients with endocarditis as well as in cases with non-endocarditic valve lesions.

276 Systemic arterial embolism in patients with infective endocarditis. A reappraisal in a cohort over two decades

J. Fabri, V.S. Issa, M. Grinberg, D. Favarato, P.M.A. Pomerantzeff, A.J. Mansur. *University of Sao Paulo Medical School, Heart Institute (InCor), Sao Paulo, Brazil*

Emboli is one of the complications that may occur in patients with infective endocarditis, associated with significant morbidity and mortality. Surgical treatment may be indicated in some patients. There are few recent reports of embolism in large series of patients with infective endocarditis. We evaluated clinical characteristics of systemic arterial embolism in a large cohort of patients over the last two decades.

Methods - we studied systemic arterial embolism in 824 episodes of infective endocarditis, from October 1978 to December 2001. The ages of the patients ranged from 0.1 to 84 (36.6 ± 17.7) years; 533 (65%) occurred in men and 291 (35%)in women. The infecting microorganisms were the streptococci in 329 (40%) episodes, enterococci in 57 (7%), S. aureus in 144 (17%), S. epidermidis in 65 (8%) and others in 132 (16%). In 97 (12%) the infecting microorganism was not identified. Surgical treatment was performed in 311 (38%) patients. Prosthetic valve endocarditis occurred in 279 (34%) episodes. Overall 214 (26%) patients died.

Results - 144 (17%)emboli were observed, 79 (55%)of them to the central nervous system and 65 (45%) to other arteries. Forty-one (28%) complications occurred before hospital admission, 20 (14%) on the day of admission, 31 (22%) before day 7 of hospitalization, 23 (16%) between days 7 and 15, 9 (6%) between days 16 and 21, 8 (6%) between days 22 and 28, 12 (8%) after 28 days. Fifty-five (38%) patients died.

The frequency of emboli was higher in prosthetic valve endocarditis (62/144, 43%) relative to native valve endocarditis (82/144, 57%)(p=0.01), in patients operated upon (62/144, 43%) relative to those submitted to medical treatment (82/144, 57%)(p=0,04), and in patients who died (55/144, 38%)relative to the survivors (89/144, 62%)(p=0.0002), and was not associated with age, sex and distribution of the infecting microorganisms.

In conclusion, the incidence of embolism in this series was 17% and decreases over time; a significant proportion of embolism occurred before hospital admission or on the day of admission. Prosthetic valve endocarditis was associated with a higher rate of embolism; mortality was also higher in patients with embolism.

277 Aorto-cavitary fistulization in complicated endocarditis. Clinical and echocardiographic features and prognostic factors of mortality

I. Anguera[1], J.M. Miró[2], I. Vilacosta[3], C. Sarriá[4], T. Ripoll[5], J.A. San Román[6], M. Anguita[7], A. De Alarcón[8] on behalf of Spanish Endocarditis Aorto-cavitary Fistula Working Group. *[1]Hospital de Sabadell, Cardiology, Sabadell, Spain; [2]Hospital Clinic, Infectious Diseases, Barcelona, Spain; [3]Hospital Clinico San Carlos, Cardiology, Madrid, Spain; [4]Hospital La Princesa, Cardiology, Madrid, Spain; [5]Policlínica Miramar, Cardiology, Palma de Mallorca, Spain; [6]Hospital De Valladolid, Cardiology, Valladolid, Spain; [7]Hospital Reina Sofía, Cardiology, Córdoba, Spain; [8]Hospital Virgen del Rocío, Internal Medicine, Sevilla, Spain*

Background: Spread of infection in infective endocarditis (IE) from valvular structures to the surrounding perivalvular tissue results in periannular complications, which may rupture internally with the subsequent development of aorto-cavitary fistulas.

Objective: To investigate the clinical, echocardiographic and microbiologic features and prognostic factors of in-hospital mortality in patients with IE and aorto-cavitary fistulization.

Methods: Retrospective and multicentre cohort study at 11 Spanish Hospitals. Patients with IE and aorto-cavitary fistula diagnosed by TTE or TEE were included. A descriptive analysis of clinical, echocardiographic, microbiologic and evolutive variables and an univariate analysis of prognostic factors of in-hospital mortality were performed.

Results: Fifty-six patients were identified since 1992, representing 2.2% of all cases of IE, 39 (69%) were male, mean age 50.3 years (range 18-77). Prosthetic valve endocarditis was present in 24 (42%) cases and native valve IE in 32 (57%). All patients had aortic valve involvement and 18 (32%) had multivalvular infection. Embolic phenomena and complete AV block previous to surgery were detected in 12 (21%) and 7(12%) cases. Congestive heart failure (CHF) was present in 34 (60%). Streptococci were detected in 18 (32%) cases, S. aureus in 12 (21%), S. epidermidis in 12, and other microorganisms in 9 (16%). No pathogen was isolated in 4 cases. Echocardiography detected grade III or IV valvular regurgitation (VR), vegetations >10 mm and periannular abscesses in 26 (46%), 25 (44%) and 44 (78%) cases. Fistula developed from the right, left and non-coronary sinuses of Valsalva in 20, 17 and 19 cases. Fistulas communicated with the right atrium in 15 (26%) cases, right ventricle in 14 (25%), left atrium in 12 (21%) and left ventricle in 14 (25)% patients. There were 7 multiple fistulas and a ventricular septal rupture was also present in 9 (16%) cases. Surgery was performed in 52 (93%) patients using different techniques (closure and valve replacement). Overall mortality was 39%. Mortality for native and prosthetic valve endocarditis was 34% and 45% respectively (p=NS). There was no relationship between the involved sinus of Valsalva and higher mortality. Mortality in patients with CHF and with severe VR was 47% and 38%, respectively.

Conclusions: Aorto-cavitary fistulization in complicated IE with periannular extension occurs in patients with high grade of local destruction. It is associated with severe complications, increased requirement of surgery and high in-hospital mortality.

278 Long-term prognosis of patients with prosthetic versus native valve infectious endocarditis after initial successful therapy

R. Moreno, J. Zamorano, C. Almería, J.L. Rodrigo, V. Serra, D. Herrera, L. Alvarez, L. Sánchez-Harguindey. *Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain*

It is well known that prosthetic valve endocarditis (PE) has a worse in-hospital prognosis than native valve endocarditis (NE). Our aim was to compare the long-term prognosis of patients with PE vs NE.

The study group is comprised by 151 patients with endocarditis. Of them, 46 (30%) had PE and 105 (70%) NE. The mean follow-up after discharge was 3.1 years. Patients with PE were older (60+11 vs 48+20 yr, p<0.01), and had a higher frequency of female gender (50% vs 27%, p<0.01), heart failure at admission (59% vs 33%, p<0.01) and S. epidermidis as etiological germen (24% vs 8%, p<0.01). Patients with NE were drug abusers more frequently (37% vs 4%, p<0.01) and had S. aureus as etiological germen more frequently (36% vs 20%, p=0.04). During hospitalization, no significant differences were found between PE vs EN in mortality (22% vs 14%, p=NS), but surgery was required more frequently in PE (65% vs 38%, p<0.01). Of interest, mortality during follow-up was higher in PE (see figure and table).

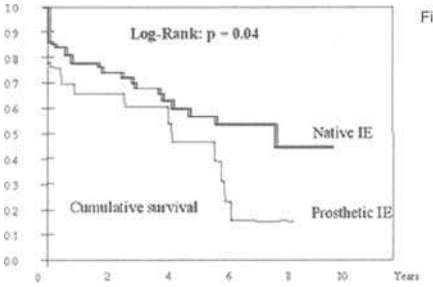


Fig. 1: Long-term outcome

Prosthetic vs Native valve IE	Prosthetic	Native
1 year	30%	22%
5 year	53%	40%
9 year	84%	55%

Thus, the higher mortality rate of PE is specially observed during follow-up rather than during hospitalization. This implies that a close follow-up of patients with PE is needed after discharge.

279 Incidence and characteristics of infective endocarditis in pacemaker recipients in France

C. Selton-Suty[1], X. Duval[2], F. Alla[3], B. Hoen[4], R. Ruimy[2], C. Leport[2], F. Vandenesch[5], F. Delahaye[5] on behalf of AEPEI study group. [1]*Chu Nancy-Brabois, Cardiology Dept., Nancy, France;* [2]*Hopital Bichat-Claude Bernard, Paris, France;* [3]*CHU Nancy, Nancy, France;* [4]*Hopital Jean Mermoz, Besançon, France;* [5]*Hopital Louis Pradel, Lyon, France*

Pacemaker (PM) infective endocarditis (IE) is a serious complication of permanent transvenous pacing. The aim of our study was to evaluate the incidence of definite PM-related IE and to compare characteristics of IE in pts with or without PM leads involvement. We therefore reviewed all the charts of PM recipients included in a cross-sectional prospective population-based survey on IE that was conducted in 7 French regions (17 million inhabitants) in 1999. Based on the results of echocardiographic and/or macroscopic and bacteriological data from extracted material, IE was classified as PM-related or valvular-related.
Among 559 pts included in the database, 45 (8%) had a permanent PM. Incidence of endocarditis was estimated at 460 cases/million of PM recipients/year. Among those 45 pts, 32 had PM-related IE (gr 1; 17 PM alone, 9 PM + tricuspid, 6 PM + left heart valves) and 13 had only valvular-related IE (gr 2; 5 mitral, 4 aortic, 2 both mitral and aortic, 1 tricuspid alone, 1 unknown). Mean age was 69±12 yrs, similar in both groups. A valvular prostheses was present in 3 gr1 and 8 gr2 pts. More than one previous surgical procedure on PM was recorded in 21/30 (70%) vs 3/13 (23%) pts (p=0.01). A procedure-related complication occurred in 8/30 vs 1/13 pts (p=0.23). For those 24 pts, mean delay between last procedure and diagnosis of IE was shorter in gr 1 than in gr 2 (2.0 ± 2.0 vs 5.0 ± 3.3 yrs, p<0.04). Staphylococcus aureus was the causative microorganism of IE in 25 (78%) gr1 pts and in 5 (38%) gr2 pts (p=0.02). A vegetation was seen at echo in 27 gr1 pts vs 9 gr2 pts (ns). An embolic event was noted in 12 gr1 (10 pulmonary, 3 others) vs 3 gr2 (3 others) pts (ns). PM was removed in 26 gr1 (81%) pts (19 surgically, 6 percutaneously, 1 unprecised) vs 2 gr2 (15%) pts (1 surgically, 1 percutaneously) (p=0.0001). A new PM was implanted in 17 gr1 (12 with epicardial electrodes) vs 2 gr2 pts (1 epicardial). In-hospital death occurred in 2 gr1 (6%) pts vs 3 gr2 (23%) pts (p=0.13).
Annual incidence of PM-related IE is intermediate between the incidence of IE in the general population and on prosthetic valves. One third of IE in PM recipients was considered as unrelated to PM and may not require PM removal. Multiple procedures on PM increases the risk of PM-related IE. Surgical or percutaneous PM removal remain the main procedure for treatment of PM-related IE.

SUCCESS OF CORONARY STENTING: IS IMAGING NEEDED?

280 Scintigraphic changes in myocardial perfusion after coronary stent implantation

S. Zalc[1], E.E. Martinez[2], J. Soares Jr[2], M.C. Pinto Giorgi[2], E. Ribeiro[2], A. Esteves[2], P.E. Horta[2], J.A. Franchini Ramires[2] on behalf of Heart Institute (InCor) University of São Paulo - Brazil. [1]*InCor, CATH Lab, Sao Paulo, Brazil;* [2]*Heart Institute (InCor) University of, São Paulo, Brazil*

Early ischaemic defects at Myocardial Perfusion Scintigraphy (MPS) occur in 30 to 50% of patients submitted to balloon angioplasty. A high proportion of these defects are not observed in scintigraphic studies performed after 3 months. There is very little information regarding the incidence and natural history of early ischaemic defects after coronary stent implantation.
Methods: 35 patients with reversible scintilographic perfusion abnormalities (demonstrated by either exercise or pharmacologically by dipyridamole or adenosine) were submitted to elective successful coronary angioplasty and stenting. Patients underwent MPS within 48 hours after coronary stenting and, again, after 3 months.
Results: In 9 patients (26%), MPS was normal early after stenting. Early mild to moderate reversible myocardial defects were detected in 26 patients (74%), of whom MPS findings were similar to pre-procedure in 8 (23%) and improved in 18 (51%). Before the first 3 months post-procedure 6 patients (17%) underwent new angioplastic studies preceded by MPS due to new onset angina. Of these 6 patients, 5 presented with in-stent restenosis and 1 with a new obstructive lesion in a vessel not treated in the index procedure. In 5 of these patients, the pre angio MPS revealed worsening of myocardial ischaemia. At 3 months, when compared to early MPS, 6 additional patients were shown to have worsening of the reversible perfusion defects. Control angiograms revealed stent restenosis in all. In 23 patients (66%), MPS at 3 months were similar to early MPS. Then, worsening of MPS when compared to early findings was observed in 10 of 11 patients with new obstructive coronary lesions. 3 months after stenting, MPS findings remained unchanged in 23 symptom free patients.
Conclusion: 1 - Early MPS was improved in 80% of patients when compared to pre stenting MPS; 2 - Late worsening of myocardial scintigraphic perfusion defects when compared to early MPS has a very high predictive value for in-stent restenosis.

281 Tl-201 redistribution patterns early after primary stenting for acute myocardial infarction predict variable degrees of contractility recovery

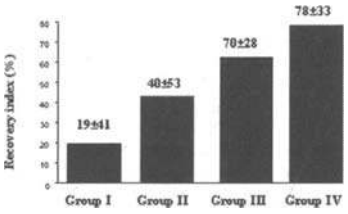
F. beygui[1], C. Le Feuvre[1], C. Maunoury[2], G. Helft[1], A. Vacheron[1], J.P. Metzger[1]. [1]*Necker Hospital, Adult Cardiology, Paris, France;* [2]*Necker Hospital, Nuclear Cardiology Dept., Paris, France*

We sought to study the relationship between different redistribution patterns observed on stress-redistribution Tl-201 scintigrams (SPECT), early after successful reperfusion therapy for acute myocardial infarction (AMI), and late regional contractility recovery.

Patient characteristics

	Group I (n=8)	Group II (n=7)	Group III (n=21)	Group IV (n=5)	p
Age (y)	57±8	53±7	58±10	54±4	NS
Symptom to reperfusion time (min)	209±102	253±129	207±108	178±19	NS
Peak creatin kinase (IU/l)	4390±2452	2241±2452	1945±1848	1718±1284	0.03

Methods: We studied 41 consecutive patients with successful primary stenting for a first AMI and single vessel disease. All patients underwent dipyridamole stress-redistribution SPECT 6-10 days after the AMI followed within 24 hours by coronary angiography, showing absence of residual stenosis, and contrast ventriculography. Coronary and left ventricular angiography were repeated at 6 months follow-up. Regional wall motion recovery was assessed by contrast ventriculography.
Results: Early SPECT showed fixed defects in 8 (Group I), stress defects with rest redistribution in 7 (Group II), reverse redistribution in 21 (group III) and absence of defect in 5 patients (Group IV). There was a significant stepwise decrease in infarct size and increase in contractility recovery from group I towards group IV.



Contractility recovery

Conclusions: Late regional contractility recovery, after successful primary stenting for AMI, is predicted in a stepwise fashion by the analysis of early Tl-201 redistribution patterns.

282 Incomplete revascularization with coronary stenting in multivessel coronary disease: value of exercise myocardial scintigraphy

A. R. Galassi, A. Tomaselli, C. Grasso, S. Moshiri, G. Rodi, M. Gulisano, C. Tamburino, G. Giuffrida. *Ferrarotto Hospital, Cardiology Division, Catania, Italy*

Objectives: The aim of this prospective study was to evaluate, in patients who undergo a planned strategy of staged percutaneous coronary revascularization for multivessel coronary artery disease once stenting of the "culprit lesion" is performed, if the execution of an exercise myocardial scintigraphy might be able to predict those subjects with adverse events or need for further revascularization procedures.
Methods and results: In 146 patients (mean age 60±9 years) with multivessel coronary artery disease who underwent incomplete revascularization with coronary stenting from March 1997 to December 1999, an exercise 99mTc-tetrofosmin SPECT scintigraphy was performed prospec-tively 4 to 6 months after the revascularization procedure. Follow-up defined how time from scanning until a cardiac event (cardiac death, non fatal myocardial infarction and revascularization procedure), or patient response, lasted up to 45 months (median 15 months). A summed stress score, which takes into account the extent and severity of perfusion defects, was calculated to estimate the severity of perfusion abnormalities. Patients with normal scan were at low risk of cardiac events as compared to patients with abnormal scan (yearly event rate 0.6% vs 6.9%, respectively, p<0.05). Conversely no significant difference in cardiac events was observed when negative and positive exercise tests were compared (yearly event rate 3.5% vs 4.1%, respectively, p=NS). Statistical analysis using the Kaplan-Meyer survival curves showed a significant difference in event-free survival between patients with normal and abnormal scan (p<0.05). With the use of Cox proportional-hazards analysis, nuclear data provided significant incremental prognostic value for cardiac events (chi-square = 34.85), as compared to clinical (chi-square = 14.60), angiographic (chi-square = 19.73), and exercise test (chi-square = 24.06).
Conclusions: In patients with incomplete revascularization procedures exercise myocardial scintigraphy provides significant independent information concerning the subsequent risk of cardiac events, with an annualized event rate <1% for patients with a normal scan. Myocardial scintigraphy is able to predict better than exercise test alone, the occurrence of cardiac events and to provide incremental prognostic information after adjusting for clinical, angiographic and exercise variables.

283 Haemodynamic significance of in-stent lesions compared to native coronary lesions. A myocardial perfusion imaging study

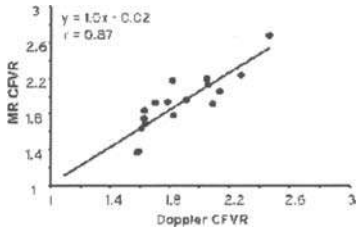
K.C. Koch[1], K. Ersahin[1], S. Krueger[1], W.M. Schaefer[2], B. Nowak[2], U. Buell[2], P. Hanrath[1], R. Hoffmann[1]. [1]*University Hospital Aachen, Cardiology, Aachen, Germany;* [2]*University Hospital, Nuclear Medicine, Aachen, Germany*

Background: Lesion complexity determines the hemodynamic relevance of a coronary lesion and in-stent lesions may be less complex than native lesions. This myocardial perfusion imaging study sought to determine whether the known relationship between severity of a native lesion determined by angiography and its hemodynamic impact can be translated to a in-stent lesion.
Methods: We identified 169 patients with single vessel disease and no wall motion abnormalities in the target vessel territory which underwent stress Tc-99m sestamibi single photon emission computed tomography within 2 months of angiography to determine the hemodynamic relevance of the lesion. 71 patients had a in-stent lesion and 98 patients had a native lesion. Coronary lesions were defined as hemodynamically relevant, if a reversible or partially reversible perfusion defect in the corresponding vessel territory was present on myocardial perfusion imaging.
Results: Reference diameters and lesion length were similar for stent and native lesions. The threshold diameter stenosis with the highest accuracy for detection of a hemodynamic relevant lesion was similar in both groups (stent: 58%, native: 59%). Receiver operator curve analysis yielded similar values for the area under the curve (0.87, 95% confidence interval (CI) 0.77-0.94 vs. 0.80, 95% CI 0.70-0.87, respectively). Considering the threshold values for the angiographic diameter stenosis the sensitivity and specificity to detect a hemodynamically significant stenosis was 91% and 85% for stent lesions versus 75% and 78% for native lesions. Multivariable analysis of lesion and stress imaging parameters yielded only diameter stenosis (odds ratio (OR) = 1.12, $p<0.001$) and lesion length (OR = 1.21, $p<0.01$) as independent predictors for ischemia during myocardial scintigraphy.
Conclusion: The threshold diameter stenosis of coronary lesions for reversible defects during stress myocardial perfusion imaging is similar for stent and native coronary lesions and is at least as accurate in stent lesions as in native lesions. Diameter stenosis and lesion length are the only predictors for hemodynamic relevance of a lesion while lesion type being native or in-stent is no independent predictor.

284 Magnetic resonance blood flow velocity after stent implantation

E. Nagel, T. Thouet, C. Klein, S. Schalla, J. Hug, E. Wellnhofer, E. Fleck. *German Heart Institute, Cardiology - CMR, Berlin, Germany*

In patients with coronary artery stents a noninvasive visualization of the coronary arteries is not possible with magnetic resonance. Flow measurements may be an alternative having the additional advantage to allow the determination of functional significance, rather than anatomical alterations of a stenosis. Aim of the study was to determine coronary flow velocity reserve (CFVR) with MR in patients after stent implantation.
Methods: In 38 patients after successful PTCA and stent implantation flow velocity was determined at rest and under adenosine stumulation 5 mm distal to the stent using a phase contrast technique (Philips, ACS NT, 1.5 Tesla, prospective navigator triggering, TE/TR/flip:6.9/11.5/40, spatial resolution 1 x 0.9 mm, temporal resolution 45 ms). Measurements were repeated after 3 months and compared to invasive coronary angiography. In 18 patients additional invasive Doppler flow measurements were obtained.
Results: In 29 patients CFVR could be determined. After 3 months significant differences were found between coronary arteries with and without restenoses. Using a threshold of 1.5 for >50% stenoses and 1.2 for >75% stenoses a sensitivity of 85% (83%), specificity of 89% (94%), and diagnostic accuracy of 86% (90%) was reached. MR CFVR correlated well with the Doppler measurements (r=0.87).



MR flow reserve vs Doppler flow reserve.

Conclusions: The determination of coronary artery flow and flow reserve after stent implantation is feasible with magnetic resonance, correlates well with invasive flow measurements and allows to detect restenosis with high diagnostic accuracy.

285 Visualisation and assessment of stent patency using multislice spiral computed tomography (MSCT)

M. Pasowicz[1], P. Klimeczek[1], T. Przewlocki[2], M. Konieczynska[2], A. Kozanecki[2], P. Pieniazek[2], K. Zmudka[2], W. Tracz[2]. [1]*The John Paul II Hospital, Cardiac and Vascular Diseases, Krakow, Poland;* [2]*The John Paul II Hospital, Institute of Cardiology, CM UJ, Krakow, Poland*

The present study aimed to assess the diagnostic value of MSCT in non-invasive evaluation of stent patency in comparison with conventional coronary angiography (CCA).
Material and Methods: We evaluated 49 patients (10 women, age 40 to 65 years, mean age 57 SD 10 years) with 51 stents in native coronary arteries. The patients were referred for CCA due to recurrent angina. One stent was implanted in the left main coronary artery, 28 in the left anterior descending artery (LAD), 15 in the right coronary artery, and 7 in the circumflex artery. MSCT scans (Somatom Plus 4 Volume Zoom, Siemens Erlangen) were obtained using Heart View software. Images were acquired throughout the entire cardiac cycle and then reconstructed at diastole with retrospective ECG gating. The stent was considered patent when contrast material was detected proximally and distally to the stent. MSCT scanning and coronary angiography were performed by two separate teams and were evaluated in a blinded fashion.
Results In 3 patients (6%) data acquisition with MSCT was not satisfactory (due to heart rate >65/min). In the remaining 46 patients (48 stents) - 3 stents (all in LAD) were identified as occluded, whereas 45 stents were found patent by MSCT. On angiography the same three stents were found occluded, and 45 stents were patent. The sensivity and specificity of MSCT in this group were 100%, respectively.

Stent in LAD 3D VRT.

Conclusion: As evidenced by our research MSCT may be a useful instrument in assessing the patency of coronary stents, although this technique should still be enhanced, with a view to facilitating an assessment of the inside of the stent (detection of in-stent restenosis). MSCT may be used efefctively for screening patients after stent implantation.

ADDING NEW DRUGS TO BASELINE TREATMENT IN HEART FAILURE

286 Acute haemodynamic effects of testosterone administration in men with heart failure

P.J. Pugh[1], T.H. Jones[2], K.S. Channer[1]. [1]*Royal Hallamshire Hospital, Department of Cardiology, Sheffield, United Kingdom;* [2]*University of Sheffield, Academic Unit of Endocrinology, Sheffield, United Kingdom*

Background: We have recently shown that testosterone administration may improve functional capacity in men with chronic congestive heart failure (CHF), in whom plasma testosterone levels may be relatively reduced. The mechanism of benefit is not clear but may include beneficial haemodynamic effects of testosterone. We have previously shown that testosterone acts as a vasodilator in-vitro in systemic, coronary and pulmonary arteries. The purpose of this study was to examine the acute effects of testosterone administration on central haemodynamics in men with CHF.
Methods: Nine male patients with stable CHF (mean age 61.9 ± 10.1years; ejection fraction 34.4 ± 12.6%) took part in a double-blind, placebo-controlled, cross-over study. In each subject, a balloon flotation catheter was passed into the pulmonary circulation and central pressures allowed to equilibrate for at least one hour. Subjects received 2 x 30mg tablets of testosterone or placebo via the buccal route. Heart rate, cardiac index and indices of left ventricular pre-load and after-load were recorded at t=0, 30, 60, 120, 180, 240, 300 and 360 minutes. Measurements were repeated the following day with the second test drug. The percentage change from baseline was determined at each time point. For each parameter, the mean of all changes from baseline in all patients was compared between active and placebo treatments, using paired t tests. Data are presented as % change from baseline (mean ± SD).
Results: At baseline, mean cardiac index was 2.98 ± 0.53L/min/m^2, mean pulmonary capillary wedge pressure (PCWP) was 12.3 ± 6.3mmHg, mean pulmonary artery pressure (PAP) was 23.4 ± 9.8mmHg. Active treatment produced a rapid rise in plasma testosterone from 11.4 ± 4.3nmol/L to a peak of 91.7 ± 39.1nmol/L. There was no apparent period effect, nor treatment-period interaction. There was no effect of testosterone on heart rate. Compared with placebo, there was a small reduction in both systolic and mean arterial blood pressure (-3.7 ± 9.7%, p=0.002; -3.5 ± 11.2%, p=0.01). In addition, there was a significant reduction in systemic vascular resistance (-9.8 ± 19.6%, p<0.001) and increase in cardiac index (+5.0 ± 12.9%, p=0.001). There was no effect of treatment on PCWP, PAP or pulmonary vascular resistance.
Conclusion: In male patients with CHF, acute administration of testosterone led to reduction in left ventricular after-load and augmentation of cardiac index, with no apparent effect on left ventricular pre-load. These haemodynamic effects may contribute to the clinical improvements seen in men with CHF treated with testosterone.

287 Effects of the addition of low dose of spironolactone on brain natriuretic peptide and cardiopulmonary function in patients with heart failure

M. Feola[1], A. Vado[1], A. Deorsola[1], E. Menardi[1], G. Visconti[2], U. Milanese[1], E. Uslenghi[1]. [1]*Santa Croce Hospital, Cardiology Dept., Cuneo, Italy;* [2]*Ospedale S. Croce, Radiochemical Labo. Dept., Cuneo, Italy*

Low dose of spironolactone, in addition to standard therapy, reduces the cardiac mortality in patients (pts) with congestive heart failure (CHF).The objectives of this study were the evaluation if a low dose of spironolactone, in addition to standard therapy, might modify the plasma level of brain natriuretic peptide (BNP), the NYHA class and the cardiopulmonary (CP) function at CP test in pts with CHF.
Sixty-one CHF pts (39 males, mean age 59.7) underwent echocardiography, CP test and blood sample for BNP at the time of enrolment and after 6 months of spironolactone therapy. Pts were in NYHA I-III and left ventricular ejection fraction (LVEF) <40%. Plasma BNP concentration was determined by a use of a specific immunoradiometric assay (Shionora). The peak oxygen consumption (VO2) and the oxygen pulse (PO2) at CP test were analysed. The causes of CHF were due to: 23 (37.7%) coronary artery disease; 19 (31.1%) dilatative; 18 (29.5%) hypertension; and 1 other. Fifty-two (85.2%) subjects were treated with Angiotensin-converting-enzyme (ACE) inhibitor, 9 (14.8%) with blocking Angiotensin-II receptor, 27 (44.3%) with digoxin. All subjects had a loop of diuretic and 35 (57.3%) assumed carvedilol. The therapy was maintained stable during the study. The average dose of spironolactone was 30 mg/die. During the six months period 7 pts interrupted the study: 1 pt died a cardiac death, 1 pt had a myocardial revascularization and 5 pts for adverse effects. The results of BNP, LVEF, NYHA class, VO2 and PO2 are depicted in the table.
In conclusion low dose of spironolactone in addition to standard therapy reduced the BNP level in CHF pts (p=0.01) and improved LVEF (p=0.001). This therapy ameliorated the NYHA class (p=0.0001) without increasing the functional parameters (VO2 and PO2) at CP. test.

	Baseline	6-month follow-up	p
BNP (pg/ml)	45.7±57.3	18.6±26.8	0.014
LVEF (%)	28.8±7.6	36±10.8	0.001
NYHA class	2.2±0.58	1.7±0.5	0.0001
VO2 (ml/kg/min)	17±5.8	17.4±5.3	0.64
PO2 (ml/b)	9.1±4.4	9.7±3.6	0.36

288 Long-term, dose-dependent effects of spironolactone on left ventricular function and exercise tolerance in chronic heart failure patients

M. Cicoira[1], L. Zanolla[2], A. Rossi[2], G. Golia[2], L. Franceschini[2], G. Brighetti[2], P.N. Marino[2], P. Zardini[2]. [1]*Divisione Clinicizzata di Cardiologia, Dip scienze biomediche e chirurgiche, Verona, Italy;* [2]*Divisione Clinicizzata di Cardiologia, Verona, Italy*

Background: in severe chronic heart failure (CHF) spironolactone administration(SP) improves survival, but the underlying mechanisms are still not fully understood. We aimed to assess whether SP may affect left ventricular (LV) function and exercise tolerance in CHF patients. Methods: we prospectively studied 106 outpatients with CHF. Patients were randomized to treatment with SP, titrated up to 50 mg/die (group 1) or control group (group 2). A complete echocardiography and a cardiopulmonary exercise testing with measurement of peak oxygen consumption (VO2) were performed at baseline and 12 months after randomization. Results: LV end-systolic volume at baseline and at follow-up was 188±94 mL and 171±97 mL in group 1 and 173±71 mL and 168±79 mL in group 2,respectively, p=0.03 for treatment group-by-time interaction). LV ejection fraction at baseline and at follow-up was 33±7% and 36±9% in group 1 and 34±7 and 34±9 in group 2,respectively, p=0.02 for treatment group-by-time interaction). At baseline, 9 patients in group 1 and 3 in group 2 had a restrictive mitral filling pattern,a marker of severe diastolic dysfunction; at follow-up, three patients in group 1 and no patient in group 2 improved the pattern; no patient in group 1 and four patients in group 2 worsened the pattern (chi-square test, p =0.02). Peak VO2 significantly increased in patients treated with 50 mg of spironolactone and decreased in group 2 (17.7±5.2 vs. 18.5±5.9 and 19.1±5.6 vs. 17.9±5.3, respectively; ANOVA: p=0.01). Conclusions: SP administration in chronic heart failure patients decreases LV volumes and improves LV systolic and diastolic function; furthermore, it improves exercise tolerance at the highest administered dose. Our data might help to explain the reduction in mortality observed during aldosterone antagonism in CHF patients.

289 Hyperkalemia and impaired renal function during treatment with spironolactone in patients with heart failure: figures from a real world scenario

M. Svensson, F. Gustafsson, D. Atar, S. Galatius, P. Hildebrandt. *Frederiksberg University Hospital, Div. of Cardiology E, Frederiksberg-Copenhagen, Denmark*

Background: Treatment with Spironolactone (SPL) is beneficial in patients with severe congestive heart failure (CHF). In the RALES-trial SPL was well tolerated, particularly with regard to renal function and serum-K$^+$ levels.
Aim: To investigate whether the reported low frequency of adverse effects during SPL treatment in a heart failure population could be confirmed in an unselected heart failure outpatient cohort.
Methods: We investigated 125 consecutive patients with CHF recruited from our heart failure clinic. Inclusion criteria were LVEF <45% and treatment with SPL. Mean age was 72.9 yrs (range 46.5-90.6), 27.4% were women. NYHA-class distribution was: I: 5.7%; II: 43.9%; III: 46.3% and IV: 4.1%. Mean EF was 28.8±4.5%. Other medications included ACE-I in 64.0% and betablockers in 32.8%. Blood tests were performed bimonthly or more frequently if necessary.
Results: At baseline (BL) creatinine levels were 117.4±6.5 (mean±SD; μmol/l, normal <130) and serum-K$^+$ was 4.1±0.3 mmol/l. The mean follow-up period was 11 months, and the cumulative observation period was 73 SPL treatment yrs. Mean peak s-creatinin was 160.2 μmol/l (36.5% incr. from BL) and mean peak s-K$^+$ was 4.89 (16.2% incr. from BL). 60 pts. were already on SPL when admitted to the CHF clinic, with >30% receiving >25 mg/d. The remainder were initiated on SPL, with 9% receiving a dose >25 mg/d. During the follow-up period a total of 30.4% of the pts. developed hyperkalemia (>5 mmol/l), with 4.8% having serum-K$^+$ >6 mmol/l. 46.4% of all patients had an increase of s-creatinine of >20%, and 17.6% increased >50%. These alterations in s-creatinine and serum-K$^+$ were not significantly more frequent in patients treated with ACE-I or betablokkers or high-dose SPL (>100 mg/d).
Conclusion: SPL adverse effects (impaired renal function, increase in s-K$^+$) are much more prevalent in our elderly CHF patient population than previously reported. Care should be given to the continuous monitoring of electrolytes and renal parameters.

290 Effects of pentoxifylline in severe heart failure

K. Sliwa[1], A. Woodiwiss[2], G. Norton[2], D. Badenhorst[2], A. Kibirigi[3], D. Skudicky[3], C. Libhaber[3], P. Sareli[3]. *[1]Baragwanth Hospital, Cardiology, Johannesburg, South Africa; [2]University of the Witwatersrand, Physiology Dept., Johannesburg, South Africa; [3]Baragwanath Hospital, Cardiology Dept., Johannesburg, South Africa*

Background: Patients with severe (NYHA FC IV) heart failure have a more than two-fold increase in cytokine concentrations in comparison to patients with moderate heart failure. Whether pentoxifylline (a drug known to modulate cytokines as TNF-alpha, IL-6, IL-10 and Fas/Apo-1) modifies the marked changes in cytokines that occur in severe heart failure has to be determined.
Methods: In a prospective, randomised, double blind, placebo controlled study we enrolled 18 consecutive patients with idiopathic dilated cardiomyopathy in FC IV. All patients required admission to intensive care unit for at least 7 days and intravenous inotropic support. Patients were randomised to pentoxifylline (400 mg TDS) or placebo in addition to diuretics, digoxin and ACE-inhibitors. Echocardiograms, radionuclide studies, TNF-alpha (in pg/ml) and Fas/Apo-1 (an apoptosis signalling receptor; in U/ml) plasma concentrations were determined on admission and after 1 month of treatment.
Results: There were no differences in baseline characteristics between the 2 study groups. Baseline ejection fraction of the study population was 16.8±8%, and baseline plasma levels of TNF-alpha and Fas/Apo-1 were 19.0±12pg/ml and 17.0±8U/ml. These levels were significantly higher compared to the concentrations we found previously in patients in FC II-III ($p<0.001$ for both). After one month 3 patients died (2 in the placebo group). There was a significant reduction in the TNF-alpha (16.7±3 to 8.0±2pg/ml, $p<0.05$) and Fas/Apo-1 (15.2±1 to 9.6±2 U/ml, $p<0.05$) plasma levels in the patients treated with pentoxifylline with no significant changes in the placebo group. This was associated with a significant increase in ejection fraction in the pentoxifylline group (16.6±6 to 24.4±4, $p<0.05$).
Conclusion: In patients with severe heart failure treatment with pentoxifylline is associated with a decrease in TNF-alpha and Fas/Apo-1 plasma levels and improvement in systolic performance compared to placebo. However, higher dose of pentoxifylline may be required to fully suppress the TNF-alpha and Fas/Apo-1 plasma levels.

291 Beneficial effects of short-term inotropic support on clinical status and on adrenergic drive in patients with severe congestive heart failure

M. White, R. Ibrahim, H. Gosselin, M.C. Guertin, L. Whittom, A. Calderone, N. Racine, A. Ducharme. *Montreal Heart Institute, Research Center, Montreal QC, Canada*

Background: Short-term administration of inotropic support decreases symptoms and signs of congestion in patients with decompensated congestive heart failure (CHF). It is unknown how these agents affect norepinephrine (NE) and functional capacity early (3 days) and late (30 days) after treatment. The objective of this study was to investigate the effects of milrinone (M) or dobutamine (D) on clinical status, functional capacity measured by a 6-minute walking test, plasma NE and troponin T (TnT) levels in patients with CHF and class IIIb or IV symptoms requiring inotropic support.
Methods: Forty patients with decompensated heart failure for a mean duration of 12±12 days [median=10 days, NYHA class 3.8±1.2 (mean ± SD); LVEF=24±8% were randomly assigned to receive M [0.6±1.0 μg/kg/min] or D [9±2 μg/kg/min] for 72±29 hours. All patients received triple therapy (digitalis/ACE inhibitor/diuretics) and 6 (15%) received a beta-blocker. Plasma NE and TnT levels were measured before the initiation of inotrope, 24 hours post-inotropic support, and 30 days later. A 6-minute walk-test was performed 24 hours post-treatment with M or D and at 30 days.
Results: Both M and D improve NYHA class at 3 days (2.5±7) and 30 days (2.7±0.7); ($p<0.05$ versus baseline). Six-minute distance walked improved significantly from 3 days (237±96 meters) to 30 days (309±91 meters); $p<0.001$. There was a trend in favor of M ($p=0.09$). Plasma NE decreased from 749±349 (BSL) to 659±432 (3 days), and 594±487 (30 days); $p<0.001$. The changes in NE overtime was similar for M and D. TnT were slightly elevated at baseline [0.2±0.3 mcg/L] but did not change significantly at 3 and 30 days in response to inotropes.
Conclusion: Short-term administration of D or M provides clinical, functional, and neurohumoral benefits which persist and even increase at 30 days. M and D appear equally efficacious in this cohort of patients with low use of beta-blockers and severe disease.

CURRENT INITIATIVES IN CARDIAC SURGERY IN THE MANAGEMENT OF HEART FAILURE

292 Partial left ventriculectomy has favourable effects on myocardial morphology one-year postoperatively: a semiquantitative morphometric study

J.D. Vasiljevic[1], P. Otasevic[2], Z.V. Popovic[1], S. Gradinac[3], Z.B. Popovic[3], R. Vidakovic[3], M. Miric[3], A.N. Neskovic[3]. *[1]Institute of Pathology, Belgrade, Yugoslavia; [2]Dedinje Cardiovascular Institute, Cardiovascular Research Center, Belgrade, Yugoslavia; [3]Dedinje Cardiovascular Institute, Cardiovascular Research Center, Belgrade, Yugoslavia*

In order to assess histological changes of the LV myocardium one-year following partial left ventriculectomy (PLV) we compared, in semiquantitative fashion, major morphometric parameters in the LV specimens taken during surgery and endomyocardial biopsies (EMB) one-year postoperatively. The study group consisted of 12 consecutive PLV survivors, who were predominantly male (10/12), aged 46+12 years. Surgical operative specimens were taken from the infero- and/or posterolateral wall of the LV, processed routinely and stained with Masson-trichrome for better contrast. Postoperative LV EMB, 3-5 per patient, were taken 12 months later and processed in exactly the same manner. The following morphometric parameters were assessed: (1) degree of hypertrophy and. attenuation of myocardial fibres (diameter); (2) nuclear evidence of hypertrophy (diameter); (3) myofibrilar volume fraction; (4) degree of degenerative, vacuolar changes in cardiomyocites, and (5) fibrosis volume fraction. These parameters were assessed semiquantitatively and graded in usual fashion (0-none, 1-mild, 2-moderate, and 3-severe). Myofibrilar hypertrophy and attenuation, as well as fibrosis and myofibrilar volume fraction, were interexclusive (mutual score was maximum 4).
Results: Both NYHA class and EF were improved 12 months following operation as compared to preoperative values (2.25±0.45 vs. 3.33±0.69, $p<0.001$, and 34±10% vs. 21±9%, $p<0.001$, respectively). Semiquantitative morphometric analysis demonstrated postoperative decrease in the degree of myofibrilar attenuation as compared to preoperative values (1.50±0.52 vs. 2.42±0.67, $p<0.01$), as well as postoperative decrease in fibrosis volume fraction (2.08±0.79 vs. 2.67±0.49, $p<0.01$) and consequent increase in myofibrilar volume fraction (1.92±0.77 vs. 1.33±0.49, $p<0.01$). There was no difference in post- and preoperative degree of myofibrilar hypertrophy, nuclear evidence of hypertrophy, and degenerative changes in myocardial fibres (1.17±0.39 vs. 1.25±0.45, 1.33±0.49 vs. 1.67±0.65, and 1.50±0.52 vs. 1.83±0.83, respectively).
Conclusions: One-year postoperatively, PLV has favourable effects on myocardial morphology, that parallels improvement in patient's functional status and LV systolic function. Histological remodelling is mainly due to the decrease of attenuation (reduced LV dilatation), increase of the relative myofibrilar volume fraction, and decrease of the fibrosis volume fraction.

293 Effects of surgical reduction in left ventricular size on left ventricular systolic and diastolic function

A. Guarneri, E. Gagliardi, N. Adragna, G. Giarratana, P. Nieddu, P. Vaccaro, M. Pilato, M. Traina. *Villa Maria Eleonora, Cardiologia, Palermo, Italy*

Reduction in left ventricular size by excluding the noncontracting dyskinetic or akinetic segments, combined with coronary artery bypass grafting (CABG), is a surgical technique that can be utilized in the treatment of patients (pts) with a remodeled dilated ventricle after anterior myocardial infarction (AMI). The aim of this study was to evaluate the effects of this technique on the preoperative and postoperative NYHA functional class, left ventricular ejection fraction (LVEF), left ventricular end-diastolic volume (LVEDV) and early filling/atrial filling wave peak velocity (E/A) ratio in pts with postinfarction dilated cardiomyopathy. We studied 55 pts (51 men, 4 women), mean age 64 years (range 39-82) with previous AMI and dilated cardiomyopathy who underwent operation (Guilmet's procedure in 44 pts and Dor's procedure in 11 pts) between September 1998 and September 2001, and were followed for 18 months. Mitral repair was used in 4 pts and mitral replacement in 3 pts. The parameters of ventricular function were determined through two-dimensional and pulsed Doppler echocardiography before operation, at disharge, at 6 months in 71% of pts and at 18 months in 51% of pts. For the statistical analysis of the data Student's t test for paired data was used. Overall hospital mortality among 55 pts was 3.6% (2 deaths). Follow-up at 18 months revealed 8 late deaths (5 sudden deaths and 3 deaths from progressive pump failure); overall survival at 18 months was 81.8%. In 15 pts (33%) an improvement of the NYHA class was observed at follow-up (2 pts from NYHA III to NYHA I, 3 pts from NYHA III to NYHA II; 10 pts from NYHA II to NYHA I). A significant increase in the LVEF was observed in the evaluation at disharge, at 6 months and at 18 months (from the preoperative LVEF 33+8% to 38+8% at disharge, $p<0.001$; 39+9% at 6 months, $p<0.001$; and 39+9% at 18 months, $p<0.005$, respectively). A significant reduction in the LVEDV was observed in the evaluation at disharge, at 6 months and at 18 months (from the preoperative LVEDV 143+30 ml to 96+18 ml at disharge, $p<0,001$; 104+23 ml, $p<0,001$ at 6 months; and106+31 ml at 18 months, $p<0,001$, respectively) without any E/A ratio change. In conclusion, our data demonstrate that a surgical reduction in left ventricular size, combined with CABG, determines a significant improvement in LVEF without any left ventricular diastolic function change and is associated with low operative mortality. The high incidence of sudden death at late follow-up indicates the need for the identification and treatment of high risk patients.

294 Surgical revascularisation in patients with ejection fraction lower than 30%: experience in over 2000 patients

B. Mihajlovic, L.J. Petrovic, S. Nicin, P. Kovacevic, Z. Potic, N. Radovanovic. *Institute of CVD, Clinic for Cardiovascular Surgery, Sremska Kamenica, Yugoslavia*

Material and methods: During the past 18 years 2007 patients (19%) with ejection fraction lower than 30% underwent myocardial revascularization. There were 1795 male and 212 female patients with the average age of 54.8 years. The majority of the patients (56%) had previous myocardial infarction on anterior wall, 28% on the posteroinferior, and 15% on both walls.
Results: The postoperative 30-day mortality in the whole group of 2007 pts was 3.8%.The majority of them died due to cardiac causes. There were 1044 pts (52%) who underwent coronary arteries endarterectomy (E) due to poor distal coronary bed. E was performed on one vessel in 688 pts (66%), on two coronary arteries in 288 pts (27%) and on 3 vessels in 68 pts (6%). Postoperative mortality in this group of 1044 pts was 4.5%. In order to prevent early thrombosis after coronary endarterectomy, we introduced in 1988 Prostacyclin as anticoagulant, antiaggregation therapy and bridge to heparinisation. Using Prostacyclin we reduced the perioperative infarction rate to 7.5%.
Conclusion: Contrary to certain authors' opinions, we believe that poor distal coronary bed is not a contraindication for myocardial revascularisation, even in patients with failing left ventricle (ejection fraction lower than 30%). However, we think that this technique enables a new chance for helping this group of patients and extends indications for myocardial revascularisation.

295 The extent of akinetic myocardium predicts in-hospital mortality after left ventricular endoaneurysmorrhaphy

J.F.M. Bechtel[1], R. Toelg[2], G. Richardt[2], H.H. Sievers[1], C. Bartels[1]. [1]*Cardiac Surgery,* [2]*Medical Clinic II, University of Luebeck, Luebeck, Germany*

Introduction: Endoaneurysmorrhaphy [EAR] has become an important therapeutic strategy in the treatment of patients with left ventricular [LV] aneurysm and congestive heart failure. However, little is known about risk factors for early mortality.
Material and Methods: We reviewed our experience with 147 patients with antero-septal LV aneurysms undergoing EAR. 70% of the patients were male; mean age was 62±9 years. The 30° RAO view of the preoperative LV cineangiograms was analyzed using software that allows manual tracing of the LV outlines. Data on regional LV function were derived using the centerline method. Absolute ventricular volumes were obtained using the Area Length method and then normalized for body-surface area. Demographic, hemodynamic, angiographic and surgical variables were analyzed in order to determine risk factors for in-hospital mortality.
Results: 133 patients had additional bypass surgery, 1 had additional mitral valve replacement. In-hospital mortality was 4.1% (n=6). Risk factors for in-hospital mortality were: the extent of akinetic myocardium (given in percent of the total LV-circumference; p=.027) and the duration of cardiopulmonary bypass (p=.0068) which was itself dependent on the LV-ejection fraction (p=.001), the number of stenosed coronary arteries (p=.004), and the extent of akinesis (p=.023).
Conclusion: Endoaneurysmorrhaphy can be performed with acceptable perioperative results. The risk of perioperative mortality was higher among patients with a larger extent of akinesis. Akinesis may increase in many patients over time; thus,our finding highlights the importance of optimal timing of the surgical intervention.

296 Autologous skeletal myoblast transplantation in treatment of postinfarction heart failure – phase I clinical trial feasibility study

T. Siminiak[1], R. Kalawski[2], D. Fiszer[3], O. Jerzykowska[1], N. Rozwadowska[3], J. Rzezniczak[2], M. Kurpisz[3]. [1]*District Hospital, Department of Cardiology, Poznan, Poland;* [2]*J. Strus Hospital, Cardiosurgery Dept., Poznan, Poland;* [3]*Polish Academy of Sciences, Institute of Human Genetics, Poznan, Poland*

Congestive heart failure secondary to myocardial infarction (MI) continues to be a major complication, despite advances in its treatment in the acute phase. The loss of cardiomyocytes is inversely related to the cardiac output and pressure-generating activity and subsequently leads to ventricular remodeling. The cardiomyocytes lost during MI cannot be regenerated and this affects the quality of life and survival. Experimental data suggest that myogenic cell grafting into area of postinfarction injury is a promising approach to the treatment of heart failure but transplantation of fetal cardiomyocytes raises availability and ethical issues. Transplantation of autologous skeletal myoblasts (ASM) has been evidenced by experimental data and suggested by initial clinical observations to improve both systolic and diastolic function after MI. Therefore we have established a Phase I clinical trial to evaluate the use of ASM transplantation performed during coronary artery bypass grafting (CABG) by non-profit research and academic institutions. Survivors from MI scheduled for CABG, with an akinetic area of the left ventricle, were screened by means of dobutamine stress echocardiography and included into the study when no viable myocardium was detected. In seven patients up to date, the skeletal myocardial biopsy was obtained from vastus lateralis. After isolation the cells were cultured for three weeks and up to 2x107 myoblasts per patients were grown. Myoblast injection into the akinetic area was done after constriction of the anastomoses during CABG procedure. No major perioperative complications were observed and an increase in segmental contractility was seen during initial 4 and 8 weeks visits. We conclude that ASM transplantation for treatment of postinfarction heart failure is feasible and initial observations justify further research to validate the method and define its role in clinical practice.

297 Medium-term prognostic evaluation of patients with symptomatic left ventricular aneurysms after endoventricular reconstructive surgery

C. Bartels[1], F.M. Bechtel[1], R. Toelg[2], B. Graf[3], G. Richardt[2], E.G. Kraatz[1], H.H. Sievers[1]. [1]*University of Luebeck, Cardiac Surgery, Luebeck, Germany;* [2]*Medical Clinic II, University of Luebeck, Luebeck, Germany;* [3]*Section Cardiology, Klinikum Schwerin, Schwerin, Germany*

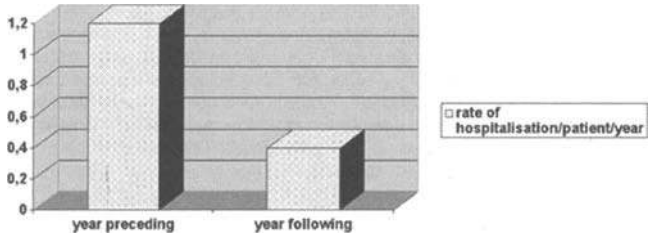
Objective: Endoventricular reconstructive surgery (EVRS) for treatment of postinfarct ventricular aneurysms leads to excellent short-term results. However, only sparse data of medium-term response after EVRS are currently available.
Methods: EVRS was performed in 171 patients (62 ± 9 years) with symptomatic ventricular aneurysms (median NYHA functional class III, EF mean 36±5%). Clinical and surgical variables influencing cardiac mortality and morbidity during follow-up were determined by univariate and multivariable analysis.
Results: Perioperative mortality was 5.7%. Mortality during follow-up was 3.8% per year, resulting in a 5-year survival rate of 78%. The NYHA status improved significantly during the follow-up period (median NYHA II; $p<0.001$, EF 46±9; $p<0.05$). Multivariable analysis only identified preexisting peripheral arterial occlusive disease ($p= 0.048$) as a significant factor influencing medium-term mortality.
Conclusions: Endoventricular reconstructive surgery entails low perioperative mortality, results in significant clinical improvement and is associated with low medium-term cardiac mortality and morbidity. The extent of generalized arterial occlusive disease should influence the therapeutic strategy for patients with symptomatic ventricular aneurysms.

PROGNOSIS IN HEART FAILURE: PREDICTORS OF OUTCOME

303 Optimisation of medical treatment in severe heart failure patients in tertiary care centers: benefit on hospitalisation rate

J.F. Morisson Castagnet[1], R. Dorent[2], O. Dubourg[1], I. Gandjbakhch[2], G. Jondeau[1]. [1]*Hôpital A Paré AP-HP, Cardiologie, Boulogne, France;* [2]*Hopital Pitié Salpétrière, Cardiolovascular Surgery, Paris, France*

Background: congestive heart failure (CHF) is responsible for multiple hospitalisations. The aim of this study was to evaluate the benefit of optimisation of therapy by tertiary centers on hospitalisation rate in severe CHF patients addressed for heart transplantation (HT).
Methods: 62 patients were referred for HT from 1/1992 to 1/2000. All had been managed by at least 3 cardiologists (in and out hospital) who felt that therapy was optimal.
During hospitalisation in our center, modification of therapy included adaptation of diuretic dosage, increase in ACE inhibition and beta-blockade according to ESC recommendations. Besides, all patients benefited from an individualized dietetic information and information on their disease.
We compared the number of hospitalisations during the year before and after modification of treatment.
Results: Patients were 50±11 y.o.(22-69), LVEF was 24±12%, cardiac index 2.2±0.6 l/min/m^2, VO2 was 16.4±5.2 ml/kg/min, i.e. 53±17% of theoretical value, and hyponatremia was present in 34% of the patients.
ACEI could be introduced in 7 (11%) deemed intolerant, and dosage was increased from 44 to 63% of the recommended dose in the others. 37% instead of 13% received full dose at the end of the stay ($p<0.001$). Beta-blockers were introduced in 7 (11%) patients, mean dose was 37% of recommended dose. Furosemide was decreased from 98 to 88 mg/d and spironolactone from 64 mg to 35mg (the number of patients receiving 25mg increased from 23% to 53%).
The rate of hospitalisation per year per patient decreased from 1.2 to 0.4 ($p<0.001$ fig).



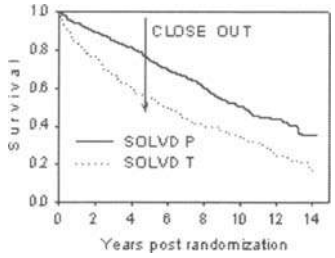
Rate of hospitalisations.

Conclusion: Optimisation of heart failure treatment significantly decreases the rate of hospitalisation. However, in severe patients this appears to be possible only in highly trained centers.

304 Mortality in left ventricular dysfunction treated with angiotensin-converting enzyme inhibitors. Ten-years follow-up post SOLVD close out

S.A. Ahn[1], P. Jong[2], S.I. Bangdiwala[3], S. Yusuf[2], H. Pouleur[1], M.F. Rousseau[1]. [1]*University of Louvain, Division of Cardiology, Brussels, Belgium;* [2]*Mcmaster University, Hamilton, Canada;* [3]*University of North Carolina, Biostatistics, Chapel Hill, United States of America*

To evaluate the impact of ACE-Inhibitor (ACE-I) therapy on the cause of death in patients with left ventricular dysfunction (LVD), 433 patients of the Belgian cohort were treated with open label ACE-I after the close out of the Studies Of Left Ventricular Dysfunction (SOLVD). 97 and 336 survivors respectively included in the Treatment (T, NYHA II-III, mean EF:24%) and Prevention (P, NYHA I-II, mean EF:29%) arms of the SOLVD were followed up during 10 years (from Feb 91 to Feb 01). The etiology of LVD was ischemic heart disease in 79%, idiopathic cardiomyopathy in 14% and other, such as valvular disease, in 7%. No patients were lost to follow-up. By Feb 01, 237 patients (55%) had died, 64 in the T group (66%) and 173 in the P group (51%). The causes of death were classified based on ICD-9 codes. 82% of patients (195/237) died from cardiovascular (CV) causes. The mode of CV death was: pump failure, n=82, sudden death/arrhythmia, n=78, myocardial infarction, n=13, cerebrovascular accident, n=15, following cardiac surgery, n=6 and pulmonary embolism, n=1. In addition, 12 had heart transplant. The primary cause of non-CV death was cancer (n=27) particularly lung (n=10), digestive tract cancers (n=6), urinary cancer (n=3) and breast cancer (n=2). At the end of the SOLVD follow-up, the treatment received included ACE-I (78%) or AII receptor blockers (6%), beta-blockers (27%), aspirin (58%), diuretics (31%) and antiarrhythmics (24%).
In conclusion, our data indicate that serious CV events still drive mortality in



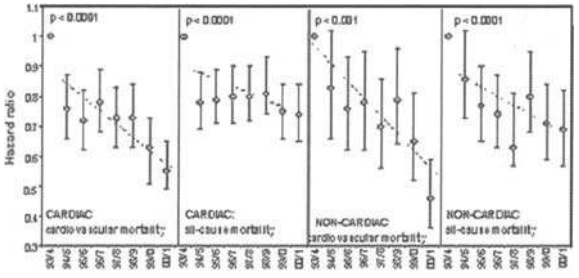
SOLVD follow-up.

patients with LVD treated with ACE-I. More research, targeting specific mechanisms of death, particularly sudden death, is needed to improve the prognosis particularly in patients with asymptomatic systolic LVD.

305 Survival following first hospitalisation with heart failure in Leicestershire 1993–2001

I.B. Squire[1], J. Tomlinson[2], H.M. Blackledge[2]. [1]*University of Leicester, Medicine & Therapeutics, Leicester, United Kingdom;* [2]*Leicestershire Health Authority, Public Health Medicine, Leicester, United Kingdom*

Rates of first hospitalisation for heart failure increased steadily in the 1980's-early 1990's. We used record-linked data to study temporal trends in incidence of and survival following first hospitalisation with heart failure in Leicestershire (population 1 million),1993-2001.The influence on survival of demographic factors and comorbidity were studied. From March 1993-April 2001, 12,200 individuals had first hospitalisation with heart failure. In these the primary diagnosis was cardiac in 8,302, non-cardiac in 3,918. Annual numbers rose from 1,100 (29/10,000 population) in 93/4 to 1,920 (47/10,000) in 2000/1. Only 27% had been hospitalised previously with a recognised precursor of heart failure.Mean follow-up was 507 (range 0-3,072 days). 4,971(60%) of the cardiac cohort died by the end of follow-up, 3,643 from cardiovascular causes. Hazard of death increased by 45% for each 10 years of age and was 15% greater for males. Concomitant MI was linked to lower survival. There was no association of social deprivation or diabetes with outcome. From 1993-2001 overall in-hospital mortality did not change (25-21%,p=0.15), but a trend to improvement was seen in the cardiac cohort (23-15%, p=0.05). From 1993/4 -2000/1, post-discharge survival by 50% improved in the cardiac cohort(X^2=13,$p<0.001$ all cause; X^2=32, $p<0.0001$ cardiovascular mortality) with similar trends in the non-cardiac cohort (Fig). We observed no improvement in survival for patients (n=1195) with concomitant MI (X^2=1.2, p=0.28).



In the modern treatment era, rates of and mortality after first hospitalisation with heart failure remain high. However clear trends to improving survival are apparent over the period 1993-2001.Improving survival and high incidence has implications for the prevalence of heart failure.

306 BMI as independent predictor of increased mortality in patients with multiple coronary risk factors: 3-year follow-up

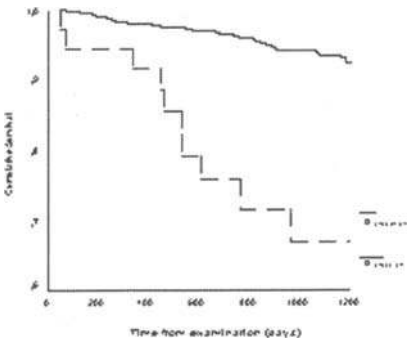
G. Kamensky[1], E. Piknova[2], E. Polak[3], I. Ondrus[4], R. Sidlo[5]. [1]*Ruzinov University Hospital, Dept. Noninvasive Cardiovasc. Diagnost, Bratislava, Slovakia;* [2]*Ruzinov University Hospital, Dept. Noninvasive Cardiovasc. Diagnost, Bratislava, Slovakia;* [3]*Ruzinov University Hospital, Department of Internal Medicine1, Bratislava, Slovakia;* [4]*Ruzinov University Hospital, Department of Internal Medicine2, Bratislava, Slovakia;* [5]*University of Economy, Department of Statistics, Bratislava, Slovakia*

Objectives: Nowadays, recent studies have shown that obesity is not associated with increased mortality in pts with CHF, and may confer a more favorable prognosis. Similar findings have been reported recently in older pts with hypertension and without CHF. This study aimed to evaluate the role of body mass index (BMI) in the prognosis of 203 consecutive patients with multiple risk factors, but without signs of congestive heart failure. Methods: From January 1997 to January 2001 we prospectively studied 203 consecutive pts (105 males, 97 females, mean age 68.7±8.8y) examined in an outpatient cardiology unit. The pts were subclassified into four categories of BMI defined as: B-1 (BMI 19-25 kg/m^2), n=55, mean BMI 22.2 ± 1.26; B-2 (BMI > 25 and < 29 kg/m^2), n= 65, mean BMI 26.6 ± 0.9; B-3 (BMI = or > 29 and < 32 kg/m^2), n = 46, mean BMI = 29.9 ± 1.0 and B-4 (BMI = or > 32 kg/m^2), n=36, mean BMI = 34.7 ± 2.7. Univariate and multivariate analyses were performed to test the association between body mass index and 3-year mortality and morbidity. Results: The four groups had similar profiles in terms of risk factors (hypertension, diabetes mellitus, serum cholesterol), the presence of CAD, stroke and atrial fibrillation. Lean pts were significantly younger compared to overweight and obese pts (p=0.05). During follow-up 62 (30%) pts died: 27 (13%) pts in B-1, 15 (7%) pts in B-2, 8 (4%) pts in B-3, 10 (5%) pts in B-4, (p=0.005). Using a Kaplan-Meier survival curve model there was a 40% increase of total mortality in group B-1 compared to group B-3 and 34% increase in group B-1 compared to group B-2 (log rank=17.8, p=0.005). After adjusted multivariate Cox proportional-hazard analysis, age (OR 1.12, p=0.0001, 95% CI 1.08-1.16) and BMI category (B-1 compared to B-3: OR 2.8, p=0.01, 95% CI 1.15-2.56), B-1 compared to B-2: OR 2.6, p=0.05, 95% CI 1.03-2.32) and B-1 compared to B-4: OR 2.5, p=0.05, 95% CI 1.40-3.45) were the only independent predictors of increased mortality. Conclusion: Among pts with multiple risk coronary factors, overweight status was associated with decreased total mortality compared with lean subjects. Further studies are needed to clarify this seemingly unexpected finding.

307 Prognosis of congestive heart failure in the middle-aged and elderly population in a urban population segment of Copenhagen

I.E. Raymond, F. Pedersen, J. Dimsits, P.R. Hildebrandt. *HS: Frederiksberg Hospital, Cardiology and Endocrnology, Frederiksberg, Denmark*

Background: The purpose of the study was to determine the prognosis, total mortality and cardiac morbidity, of patients with LV systolic dysfunction and heart failure (CHF) in the general population.
Methods: A total of 764 subjects(56,5% female), aged 50-89 years participated in the study recruited from GP's. Each participant filled in a CHF questionnaire, ECG, blood tests and echocardiography were performed.
Results: Median follow-up was 1145(range:51-1197) days. Survival first and second year after the examination was 91.7%, and 76.5% in subjects with LVEF≤40%[age controlled mortality rate 4.6(95% C.I.=1.6-13.2)] compared to 97.9%, respectively 96.8% of those with LVEF>40%.
In Cox proportional hazards analyses age, gender, history of hypertension, history of IHD, diabetes, dyspnoea, ankle edema, heart rate, systolic and diastolic blood pressures, abnormal ECG, LVEF≤40% were evaluated as potential prognostic factors for mortality and admission for CHF. LVEF≤40%(hazard ratio (HR)=3.72, p=0.0004), admission for ankle edema(HR=3.81, p=0.0006), male gender(HR=2.55, p=0.002) and age(HR=1.08 per year, p<0.0001) were independent predictors of total mortality. LVEF≤40%(HR=4.14, p<0.009), admission for pulmonary congestion(HR=7.80, p=0.0001), CAD(HR=4.93, p=0.002) and age (HR=1.11 per year, p=0.0004) were independent markers for CHF admissions. All-cause mortality (27.8% vs. 5.6% deaths, p<0.0001), first CHF admissions (25.0% vs. 1.9%, p<0.0001), and for other cardiac causes (25.0% vs. 6.3%, p<0.0001) were significantly higher in subjects with LVEF≤40% than in subjects with LVEF>40%.
Conclusion: In this large sample of the general population, patients with LV systolic dysfunction had a poor prognosis for total mortality as well as for cardiac morbidity.



Kaplan-Meier plot of cumulative survival.

308 Prognosis of heart failure in the general population – results from the London heart failure studies

M. Cowie[1], K. Fox[2], D.A. Wood[2], T. Collier[3], B. DeStavola[3], A.J.S. Coats[1], P.A. Poole-Wilson[1], G.C. Sutton[1]. [1]*National heart & Lung Institute, Cardiac Medicine, London, United Kingdom;* [2]*Imperial College, Cardiology Dept Charing Cross Hospital, London, United Kingdom;* [3]*London Schl of Hygiene & Tropical Med, Department of Epidemiology, London, United Kingdom*

The prognosis of incident (new) cases of heart failure arising from the general population in the modern era is not well described. We report the results of follow-up of a large cohort of incident cases of heart failure in London, UK.
Methods: Between April 1995 and March 1998, 552 incident cases of heart failure were identified in the Hillingdon and Bromley Heart Failure Studies from populations of 150 000 and 195 000, respectively. The design of both studies was identical. Cases were identified from acute admissions to the hospitals serving the two areas, and from a rpaid access clinic to which suspected cases of heart failure were referred by the primary care physicians recruited to the study. The clinical assessement, ECG, chest radiograph and echocardiograpm of all cases were reviewed by a panel of 3 cardiologists (DAW, AJSC, GCS) working to a pre-set definition of heart failure according to the European Society of Cardiology guidelines. The combined cohort of 552 cases has now been observed for a minimum of 3.5 years (90% range 3.6 to 6.1 years) with automatic notification of death from the Office of National Statistics.
Results: The combined cohort included 196 men and 256 women, with a median age of 76 years. During the follow-up period 324 (59%) subjects have died. Survival was 84% at 1 month, 74% at 6 months, 69% at 1 year, 60% at 2 years, 51% at 3 years and 43% at 4 years (Kaplan-Meier method) Age, smoking status, NYHA class, systolic blood pressure, serum creatinine and LV systolic function were associated with survival on Cox univariate analysis. Cases in whom coronary artery disease was the aetiology had a poorer survival than the remainder (Hazard Ratio 0.79 [95% Confidence Interval 0.63-0.99] P=0.04). Cases identified as inpatients had approximately twice the mortality risk of those identified in the clinic (HR 2.18, 95% CI 1.66-2.86 P<0.001).
Conclusions: The average life expectancy of a new case of heart failure arising in the general population is 3 years, with the highest risk of death in the first 3 months. Simple clinical features can be used to identify those with the poorest prognosis.

REFINED DOPPLER INDICES FOR ASSESSING DIASTOLIC FUNCTION

324 Non-invasive estimation of left ventricular end-diastolic pressure by pulmonary venous flow deceleration time

E. Wellnhofer[1], A. Olariu[1], M. Gräfe[1], D. Bedeleanu[2], E. Fleck[1]. [1]*Deutsches Herzzentrum Berlin, Cardiology, Berlin, Germany;* [2]*Institutul Inimii, Cardiology, Cluj-Napoca, Romania*

Aims: The scope of this study was to assess the potential value of pulmonary venous flow diastolic deceleration time (PVFd-dt) to predict end-diastolic pressure and stratify patients with regard to elevation of left ventricular end-diastolic pressures (LV-EDP).
Methods and results In 176 consecutive patients without mitral valve disease or atrial fibrillation PVFd-dt was determined by transthoracic Doppler and compared to LV-EDP measured invasively during cardiac catheterization. The sample was randomly divided into two subgroups of equal size for modelling of prediction and independent testing of the model.
Results: Predicted LV-EDP calculated from PVFd-dt (LV-EDP =-10.87+5261/PVFd-dt) agreed well with measured LV-EDP (mean difference: -1.3±3.4 mmHg). The correlation of LV-EDP with PVFd-dt is fair (r=0.73989). A value of PVFd-dt <220 ms is suggestive of elevated LV-EDP and should be monitored. A value of PVFd-dt <190 ms predicts elevated LV-EDP. A value of PVFd-dt <165 ms predicts severely elevated LV-EDP. With 190 ms as a cut-off value for elevated and 165 ms for severely elevated LV-EDP cross-table analysis classifies all patients with normal LV-EDP correctly. No patient with severe elevation (<18 mmHg) of LV-EDP is classified as normal (Chi^2=102, P<0.0001).
Conclusion: PVFd-dt is an appropriate non-invasive measurement to stratify patients with respect to potential elevation of LV-EDP.

325 The importance of late left ventricular diastolic filling wave propagation in assessment of diastolic dysfunction

A.P. Patrianakos[1], F.I. Parthenakis[1], G.F. Diakakis[1], S.I. Chrysostomakis[1], C. Tsoutsoumanou[1], P.E. Vardas[2]. [1]*Heraklion University Hospital, Cardiology Dept., Heraklion, Crete, Greece;* [2]*Heraklion University Hospital, Cardiology, Heraklion, Greece*

Background: Pulsed Doppler indices of both transmitral and Pulmonary vein flow present a parabolic distribution during progression from normal to advanced diastolic dysfunction (DD). Color M-Mode Doppler displays velocities data along a scan line and early transmitral velocity propagation (Ep) throughout the left ventricle (LV) has been proposed as a useful non-invasive index for assessing LV relaxation. However, there is no data concerning the importance of late transmitral velocity propagation (Ap).
Methods: We investigated 100 patients aged 58,5 ± 10 years who presented to our laboratory with echocardiographic evidence of LV diastolic dysfunction. Fifty pts had delayed relaxation (Group I) and 50 patients (pts) pseudonormal pattern (Group II). Forty age-matched, healthy persons served as a control group (Group III). An echocardiography study and colour M-Mode Doppler from the apical 4-chamber view in LV inflow, was performed and delayed relaxation pattern was defined if early (E) to late filling wave (A) was <1, isovolumetric relaxation time (IVRT) was >100msec, deceleration time of E (DTE) was >220 msec and atrial component (AR) of the pulmonary vein flow was <35 cm/sec. Pseudonormal pattern was recognized if E/A=1-2, DTE=150-200msec, IVRT=60-100 msec and AR>35 cm/sec.
Results: In pts with DD, the Ap slope was steeper than Ep compared to the normal group. The table shows the differences between the three groups.

	LVEF(%)	LA(mm)	E/A	AR(m/sec)	Ep(m/sec)	Ap(m/sec)
Group I	49±14	39,1±5,0	0,6±0,1	0,32±0,02°	0,40±0,09°	1,05±0,27°
Group II	43±15°©;	42±5,5°†	1,6±0,5	0,4±0,03°©;	0,32±0,07°	1,11±0,49°
Group III	52±10	37,8±3,8	1,11±0,4	0,20±0,03	1,09±0,27	0,67±0,1

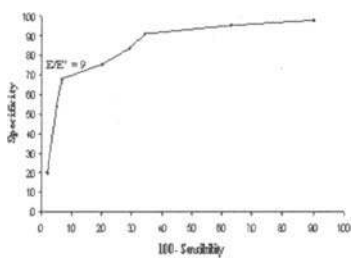
° = p<0,05 vs Gr.III † = p<0.05 vs Gr I

Conclusions: Pts with DD reveal a reverse relationship between early and late filing propagation through the LV with the slope of Ap showing more oblique angle, compared with normal pts. Estimation of Ep and Ap slopes may help to diagnose the existence of diastolic dysfunction, especially in the presence of pseudonormal pattern were there are difficulties in the clinical setting to ungroup from normal.

326 Value of Doppler tissue imaging to predict left ventricular filling pressure in patients with CAD

N. Mansencal, E. Bouvier, T. Joseph, F. Digne, M. Rigaud, P. Lacombe, G. Jondeau, O. Dubourg. *Hôpital Ambroise Paré, Service de Cardiologie, Boulogne Cedex, France*

Background: Doppler Tissue Imaging (DTI) has been proposed to assess left ventricular (LV) filling pressure. The aim of this prospective study was to investigate reliability of this method in patients with CAD in clinical practice.
Methods: We studied 32 consecutive CAD-patients, mean age 64 ± 12 years, in sinus rhythm. All patients underwent cardiac catheterization and echocardiography in the same hour. Cardiac catheterization was performed with ventriculography and measurement of pre-A-wave pressure. The following Doppler echocardiographic parameters were assessed: 1) Pulsed wave Doppler signals from the mitral inflow (E), 2) Pulsed wave DTI of the mitral annulus (E'), thus allowing to obtain the ratio of mitral velocity to early diastolic velocity of the mitral annulus (E/E').
Results: The correlation between pre-A-wave pressure and E/E' was significant (r=0.60, p<0.01). In patients with LVEF >50% (n=20), no correlation was found (r=0.18, p=0.44), even when in patients with LVEF <50% (n=12), the correlation between pre-A-wave pressure and E/E' was very good (r=0.76, p<0.01). By ROC curve analysis, we identified an E/E' >9 to be the best cut-off value to fit with a pre-A-wave pressure >15 mmHg.



ROC curve.

Conclusion: In CAD-patients, DTI may allow to determine LV filling pressure >15 mmHg only for patients with LV ejection fraction <50%, with a E/E' cut-off value of 9.

327 Prognostic insights from combined pulmonary venous and mitral flow in acute myocardial infarction

F.L. Dini[1], G. Micheli[2], S.M. De Tommasi[1]. [1]*Santa Chiara Hospital, Cardiovascular Diseases Unit 2, Pisa, Italy;* [2]*Villamarina Hospital, Cardiology Unit, Piombino, Italy*

We have previously shown that the duration of pulmonary venous versus mitral flow velocity curves at atrial contraction provided an added value to the risk stratification of patients with left ventricular (LV) dysfunction. Recent data have shown that restrictive filling is associated with a poor outcome in patients with a recent acute myocardial infarction (AMI), but it is not known whether the assessment of the difference in duration of pulmonary venous flow (PVF) and mitral flow A waves can provide additional prognostic information.
To assess the prognostic value of the difference in duration of pulmonary venous and mitral flow at atrial contraction in patients with a recent AMI.
A Doppler echocardiographic examination was carried out in 148 patients (mean age 70±10 years) with a recent AMI (within two weeks) and LV ejection fraction <45% in sinus rhythm. Patients were categorized according to their mitral E wave deceleration time (EDT) and pulmonary venous flow (PVF) curves in: restrictive mitral flow pattern (characterized by an EDT <130 msec), 2) non-restrictive mitral flow pattern with the difference in pulmonary venous and mitral flow velocity duration at atrial contraction >30 msec, 3) non-restrictive mitral flow pattern with the difference in pulmonary venous and mitral flow velocity duration at atrial contraction <30 msec. All patients were subsequently followed-up for a mean period of 22±9 months.
During the follow-up, 38 patients died from cardiac causes and 29 were hospitalized for worsening heart failure. Multivariate Cox analysis revealed that PVF reversal exceeding in duration by >30 msec mitral atrial wave was the most important independent predictor of the combined end-point. Probabilities of survival free from cardiac events at Kaplan-Meier analysis were 75% in nonrestrictive patients with a <30 msec difference in duration of pulmonary venous and mitral atrial flow, 32% in nonrestrictive patients with a >30 msec difference in duration of pulmonary venous and mitral atrial flow and 22% in the restrictive group (p<0.0001 by Log-rank).
In patients with a recent AMI and LV dysfunction, an increased duration of pulmonary venous and mitral flow at atrial contraction can predict the prognosis for the combined end point of cardiac mortality and hospitalization for worsening heart failure. Patients with nonrestrictive filling and a greater difference in atrial wave durations had an intermediate event-free survival at follow-up with respect to the group with non-restrictive filling and a shorter difference in duration of the two waves and to the restrictive group.

328 Study of patients with coronary artery disease using the TEI – Tissue Doppler Imaging Index

A. Kranidis[1], J. Lekatsas[1], S. Koulouris[1], G. Filippatos[2], K. Kappos[1], E. Karabinos[1], J. Pirros[1], N. Exadaktylos[1]. [1]*Evangelismos Hospital, 1st Department of Cardiology, Athens, Greece;* [2]*ATHENS, Greece*

The TEI index has been used for the assessment of left ventricular (LV) function. The aim of this study was the evaluation of this index, based on a standard calculation, but also using TEI calculated from pulsed Tissue Doppler Imaging (TEI-TDI), in patients with coronary artery disease (CAD).

Methods: We studied 50 patients (mean age 60.9±9.8 years) with CAD and in sinus rhythm, compared with 15 healthy controls with similar age and sex distribution. All underwent SPECT thallium-201, coronary angiography (EF 42± 8.1) and a complete echocardiographic Doppler study. TEI was calculated using the equation TEI = ICT+IRT/ET, where ICT = isovolumic contraction time, IRT = isovolumic relaxation time and ET = ejection time. TEI-TDI was calculated in the same way after recording of tissue velocities in the left atrioventricular plane measured by pulsed TDI in the segments (septal, lateral, anterior, inferior, posterior) from the apical views. The mean TI-TDI was also calculated. Of the 50 patients, 33 (Group A) had segmental wall motion abnormalities (SWMA) and 19 (Group B) did not.

Results: The TEI did not differ significantly between CAD patients and controls (0.702±0.208 vs. 0.578±0.148, p = 0.079), but mean TEI-TDI was significantly greater in the former group (1.248±0.507 vs. 0.893±0.380, p = 0.04). Mean TEI-TDI differed significantly between Group A and controls but not between Group B and controls (1.454±0.514 vs. 0.893±0.388, p = 0.003 and 0.915±0.255 vs. 0.893 ± 0.388, p = 0.859, respectively). Mean TEI-TDI differed significantly between patients with only akinesia or dyskinesia and those with hypokinesia or without SWMA at the 5 sites of the left ventricle (1.648±0.413 vs. 1.148±0.482, p = 0.004). There was a significant correlation between mean TI-TDI and the wall motion score index (r=0.69). In Group B, the TEI-TDI of segments in the region of the left anterior descending (LAD) artery (anterior and septal) was significantly different from the control group ($p < 0.01$). In Group B patients a TEI-TDI > 1.2 had sensitivity 63% and specificity 76% for the detection of LAD artery disease, compared to 50% and 53%, respectively, for SPECT thallium-201.

Conclusions: 1) In CAD patients mean TEI-TDI seems to be better than TEI for the evaluation of LV function. 2) TEI-TDI is less useful a) in the presence of SWMA, depending on its severity; b) in the absence of SWMA, but when there is ischaemia in segments in the LAD region. 3) The precision of TEI- TDI in detecting LAD artery disease in patients without SWMA is at least comparable to that of SPECT thallium-201.

329 Myocardial regions supplied by stenosed coronary arteries have impaired resting diastolic function

B.S. Wasan[1], N. Patel[1], R. Lane[1], S.A. Thom[2], R.A. Foale[1], J. Mayet[1]. [1]*Imperial College - St. Mary's Hospital, Waller Cardiac Department, London, United Kingdom;* [2]*Imperial College - St. Mary's Hospital, Clinical Pharmacology, London, United Kingdom*

Background: It is recognised that areas of myocardium subtended by chronically stenosed coronary arteries have impaired diastolic properties with preserved systolic function. Tissue Doppler Echocardiography (TDE) allows us to regionalise abnormalities in an objective and non-invasive manner. Diastolic function, on both a global and regional scale, is impaired with increasing age.

Methods: 50 patients with angiographically documented coronary artery disease were aged and sex matched with normal volunteers. Pulsed wave TDE images were taken from the apex and systolic and early diastolic velocities measured at the septal (sep), lateral (lat) and inferior (inf) aspects of the mitral valve annulus and the free wall of the tricuspid valve annulus (RV). Direct comparison was then made between segments supplied by stenosed arteries (greater than 70% on angiography) and equivalent segments from the normal group.

Results: 147 myocardial segments were analysed per group. There was no significant difference in systolic velocities. Diastolic velocities are shown in the table. Diastolic abnormalities existed in myocardial territories supplied by stenosed coronary arteries when compared with both normally perfused myocardial segments from the same patient and also age-matched normal controls.

Regional early diastolic velocities

Age	Group	Inf	95% CI	Lat	95% CI	Sep	95% CI	RV	95% CI
40-49	Normal	12.3	11.7-12.9	13.2	12.5-13.9	9.5	9.0-9.9	12.0	11.2-12.7
40-49	Ischaemic	8.1**	6.5-9.7	9.8**	7.4-12.0	7.6*	6.0-9.2	7.8**	6.0-9.6
50-59	Normal	10.7	10.1-11.3	11.8	11.1-12.4	8.4	7.9-8.9	11.3	10.5-12.0
50-59	Ischaemic	7.6*	6.6-8.7	9.2*	7.7-10.7	6.9*	5.9-8.0	8.0*	6.9-9.1
60-69	Normal	9.1	8.3-9.8	10.3	9.4-11.1	7.3	6.7-7.9	10.7	9.7-11.6
60-69	Ischaemic	7.1*	6.4-7.8	8.6**	7.6-9.5	6.3	5.6-6.9	8.2*	7.5-9.0
>70	Normal	6.5	4.5-8.4	8.0	5.9-10.0	5.6	4.1-7.0	9.4	7.6-11.0
>70	Ischaemic	6.2	4.9-7.5	7.4	5.8-8.9	5.0	3.7-6.4	8.6	7.1-10.2

Velocities in cm/s. **p<0.01 *p<0.05

Conclusion: There is minimal overlap in early diastolic velocities in segments supplied by tightly stenosed coronary arteries and age-matched normally perfused areas in patients under 70. This technique shows promise as a non-invasive, non-stress tool for the investigation of possible coronary artery disease and now requires prospective evaluation.

EUROPEAN SOCIETY OF CARDIOLOGY LECTURE ON CLINICAL CARDIOLOGY

331 Aspirin improves not only the endothelium-dependent but also the β-adrenoceptor-related vasodilatation in patients with essential hypertension

S. Liaghat, R. Koll, D. Bulut, C. Hanefeld, A. Mügge. *St. Josef-Hospital, Medical Department II, Bochum, Germany*

Patients with essential hypertension (eHYP) and hypercholesterolemia show an abnormal endothelium-dependent vasodilation which may be a risk factor for coronary heart disease. The benefit of treatment with acetylsalicylate (ASS) in prevention of coronary heart disease (CHD) is usually explained by inhibition of platelet-aggregation. It has been suggested in a preliminary report that ASS may improve endothelial dysfunction in patients with hypercholesterolemia. The mechanism may be related to an inhibition of synthesis/release of constrictive eicosanoid-metabolites.

Aim of our study is to examine the effect of ASS (500 mg) on endothelium-dependent and -independent regulation of vessel tone in patients with eHYP

Patients with eHYP as a single risk factor (n=24) (age 54.2 + 8.5 years, mean + SD) were included. Blood flow was measured in the forearm circulation by venous occlusion plethysmography during i.a. infusions of acetylcholine (15-40 μg/min), the β1/β2-non-selctive agonist orciprenaline (100-250 ng/min), and sodium-nitroprussid (1.6-3.2 μg/min). The measurements were repeated 15 minutes after an intravenous application of ASS-Lysin. The table summarizes the maximal increases in blood flow (D% of baseline,*p< 0.05 vs. before ASS).

	before ASS	after ASS
Acetylcholine max.	67.2 ± 26.3%	99.2 ± 27.2%*
Sodium-Nitroprussid max.	202.4 ± 31.5%	198.7 ± 30.1%
Orciprenaline max.	49.9 ± 17.9%	89.0 ± 15.8%*

Conclusion: ASS improved endothelial-dependent vasodilation in patients with eHYP. Furthermore, the β-adrenoceptor-mediated, but not the endothelium-independent vasodilatation using nitroprusside was improved. These results suggest that a cyclooxygenase-dependent, contractile co-factor may participate to NO- and β-adrenoceptor-signal-transduction pathway in eHYP patients.

332 Left ventricular functional characteristics in renovascular hypertension and in primary aldosteronism

M. Muiesan, M. Salvetti, C. Monteduro, S. Viola, D. Rizzoni, P. Poisa, A. Paini, E. Agabiti-Rosei. *University of Brescia, Medical and Surgical Sciences, Brescia, Italy*

Objective A high prevalence of left ventricular hypertrophy (LVH) and concentric remodeling has been reported in patients with secondary forms of hypertension. Very few data are available on LV systolic and diastolic (Diast) performance in these patients. Aim of this study is to evaluate LV structural and functional characteristics in patients with renovascular hypertension (RVH) and primary aldosteronism (PA) in comparison with a control population.
Design and methods Eighty-two consecutive patients with secondary hypertension (30 RVH, 52 PA) and 196 age and sex matched, never treated, essential hypertensive controls (HT) were submitted to an echo-doppler study for evaluation of LV anatomy and function. LV mass index (LVMI) and relative wall thickness (RWT) were calculated; endocardial (end) and midwall fractional shortening (mid FS) were calculated to assess systolic performance. In addition transmitral E and A flow velocities, E wave deceleration time and isovolumic relaxation time were measured for diastolic filling evaluation.
Results are shown in the table:

	Controls	RVH	PA	ANOVA
BP mmHg	150(13)/93(8)	168(20)*/102(15)*	158(25)*/99(12)*	<0.001
RWT	0.38(0.08)	0.44(0.08)*	0.42(0.06)*	< 0.0001
LVMI g/m^2.7	45 (14)	56 (16)*	53(15)*	<0.001
LVH %	34	60*	58*	<0.05
FS end %	41 (8)	39 (7)	40(8)	ns
FS mid %	18 (3.5)	15 (2.7)*	16 (2.7)*	< 0.001
Dec E msec	151 (38)	149(91)	178 (55)*°	<0.005
Diast dysf %	28	37	45*	<0.05

* p < 0.05vs HT; ° vs RVH

All differences were confirmed after adjusting for clinic and 24hrs BP differences (ANCOVA).
Conclusion This is by far the largest study evaluating cardiac structure and function in RVH and PA, compared to age and sex matched never treated HT, indicating that neurohumoral factors may influence the development of structural and functional changes in the left ventricle.

333 Eight-year coronary risk in relation to baseline rule-of-halves blood pressure status: the Scottish heart health study

R. Chen, H. Tunstall-Pedoe. *Ninewells Hospital and Medical School, Cardiovascular Epidemiology Unit, Dundee, United Kingdom*

Introduction A large cohort of men and women aged 40-59 sampled randomly from across Scotland were examined in 1984-87 in the Scottish Heart Health Study. Cross-sectional analysis showed that the population followed the "rule of halves" - half of hypertensives being undetected, half of those previously detected untreated, and half of those treated uncontrolled. Participants were followed for subsequent death, myocardial infarction and coronary artery surgery. We have examined eight-year coronary risk in relation to baseline blood pressure and rule-of-halves status.
Methods Subjects completed a questionnaire on medical history and medication. The mean of two random-zero sphygmomanometer readings was used to categorize their blood pressure. Risk factor levels including blood pressure were reported back to general practitioners. We have used the cut-point of ≥160/95 for hypertension and classified normotensives <120/80 as optimal, 120-129/80-84 normal, 130-139/85-89 high normal, and 140-159/90-94 high blood pressure. Hazard ratios were adjusted for age and multiple risk factors.
Results 5 754 men had 461 coronary events during follow-up, 5 875 women had 188 events. Compared to those with optimal blood pressure (RR=1.0) multiple adjusted RR with 95%CI in men were as follows: normal 1.43(0.95-2.16), high normal 1.66(1.12-2.47), high blood pressure 1.25(0.83-1.90),undetected 1.94(1.27-2.95),untreated 3.21(1.98-5.23),uncontrolled 3.22(1.97-5.29), controlled 2.58(1.61-4.15).
Equivalent adjusted RR with 95%CI in women (with fewer events)were:normal 0.94(0.49-1.83), high normal 1.55(0.86-2.81), high blood pressure 1.81(1.02-3.20),undetected 1.81(0.93-3.52),untreated 3.12(1.50-6.47),uncontrolled 2.63(1.24-5.57), controlled 2.69(1.39-5.23). These results included everyone at baseline - sub-group analysis excluding any evidence of coronary heart disease from symptoms, history or electrocardiogram at that time produced similar results.
Conclusions Findings from a single baseline survey clinic are very powerfully predictive of coronary risk over the next eight years. Rigorous attention is needed to detection, treatment and control of hypertension in the community along with management of accompanying risk factors. Our extended follow-up, now in progress, will show whether these risk differences have widened or narrowed during the later 1990s when newer drugs and attitudes to coronary risk factors were more prevalent.

ADDED VALUE OF STRESS ECHO IN PATIENTS WITH CHEST PAIN

334 Comparison of early dobutamine stress echo, exercise testing, and hospital admission in patients presenting to the emergency room with chest pain

L. P. Badano[1], N. Sarraf-Zadegan[2], G. Pettinati[2], A. Karavidas[2], V. Vysniauskas[2], B. Ilerigelen[2], C. Astarita[2], G. Scaffidi[2] on behalf of the ASSENCE Investigators. [1]*A.O.S Maria della Misericordia, Cardiovascular Science Dpt., Udine, Italy;* [2]*Udine, Italy*

Management of pts presenting to Emergency Department (ED) with chest pain (CP) suggestive of acute coronary syndrome remains a continuing challenge, and these pts are often admitted to rule out acute myocardial infarction (AMI). To shorten in-hospital length-of -stay, maintain pt safety, and enhance cost-effectiveness, several startegies have been applied to the management of pts with CP. However, efficacy and safety of these strategies have never been compared in a randomized study.
To address this issue, a total of 290 pts (57% males, 54±11 years) with no ischemic EKG changes, negative serial CK-MB and cardiac troponin at 6 hours from ED presentation, and who were to be admitted, were enrolled in 10 participating centers and randomized to dobutamine stress echo (DSE, n= 109), or exercise test testing (ETT, n= 89), or hospital admission (H, n= 92). Eighty-seven (80%) pts were discharged after DSE, and 75 (84%) were discharged after ETT (p= NS). Pts with negative DSE or ETT were discharged with no or unchanged ischemic medications. All pts were followed for at least 2 month. The 3 pt groups were similar for age, gender distribution, clinical characteristics of CP and risk factors prevalence. No significant adverse event was observed during DSE or ETT. In pts in the H group there were 4 in-hospital events (4%): 3 AMIs, and 1 urgent coronary revascularization. Ischemic origin of the CP was diagnosed in 38% of the study pts. None of the pts discharged after DSE or ETT suffered a late major adverse cardiac event. During follow-up, 4 pts in the ETT group were readmitted to ED for CP, 25 pts underwent additional noninvasive diagnostic tests, and 2 underwent coronary angiography. Conversely, only 8 pts in the DSE group underwent additional noninvasive tests and there was no readmission (p<0.0001 vs ETT pts for both). In-hospital length-of-stay was 26±4 hours in the ETT pts, 26±8 hours in the DSE pts, and 72±11 hours in the H pts who were found not having an ischemic origin of CP (p<0.0001).
Thus, early DSE or ETT in ED pts with CP, normal serial biochemical markers of myocardial injury and EKG tracings at 6 hours from ED admission are safe and effective tools for early risk stratification. Accelerated diagnostic protocols incorporating DSE or ETT tests show an equivalent high negative predictive value for major adverse cardiac events during follow-up, and are less resource-consuming than usual hospital admission.

335 Stress echo in chest pain unit: the SPEED (Stress Pharmacological Echocardiography in Emergency Department) trial

E. Pasanisi[1], G. Bedetti[2], L. Fonseca[3], S. Tresoldi[1], C. Minneci[1], A. Orlandini[1], R. Bugiardini[2], E. Picano[1]. [1]*Institute of Clinical Physiology, PISA, Italy;* [2]*Imola Hospital, Cardiology Division, Imola, Italy;* [3]*Brasilia Hospital, Cardiology Division, Brasilia, Brazil*

Background: emergency room (ER) evaluation of patients with acute chest pain and non diagnostic electrocardiography (ECG) remains a frequent and difficult problem. Aim: to assess the safety and prognostic implication of stress echocardiography in the ER chest pain unit (CPU).
Methods: 540 patients (326 males/age 58±12 years) with acute chest pain and negative serial cardiac markers, and ECG recordings and normal/unchanged resting left ventricular function, underwent stress echo (dipyridamole n= 520, dobutamine n=20) within 12-48 hours after admission. Six echo labs quality-controlled for stress echo reading entered the study. Follow-up was obtained in all patients after 12 ± 6 months.
Results: feasibility was 97%, no major side effects occurred during tests. Stress echocardiography was negative in 491 and positive in 49 patients. Patients with negative stress echocardiography were discharged with no or unchanged anti-ischemic medication. Patients with positive stress echo were admitted to coronary care unit. In 42 of them coronary angiography was performed and showed significant coronary artery disease in 40. There were 42 events in the follow-up: four (two acute myocardial infarction and two unstable angina requiring revascularization) in the 491 pts with negative and 38 (37 unstable angina requiring revascularization and one acute myocardial infarction) in the 49 patients with positive stress echo (0.81% vs 77.5%, p<.001). The negative predictive value of stress echocardiography for subsequent events was >99%.
Conclusion: Stress echocardiography is feasible, safe and effective tool for early stratification of patients with acute chest pain and non-diagnostic ECG, cardiac markers and resting echo admitted to the ER.

336 The incremental prognostic value of dobutamine stress echocardiography in chest pain unit patients with negative troponin levels

M S. Dolan[1], S. Puri[2], T. Huckin[2], D. Kumar[2], A. El Shafei[2], J. St Vrain[2], A. Maniet[2], A J. Labovitz[2]. [1]Saint Louis University Hospital, Internal Medicine/Cardiology, St. Louis; [2]Saint Louis University School of Medic, Internal Medicine/Cardiology, St. Louis, United States of America

Background: The prognostic value of elevated troponin (TnI) in acute coronary syndrome is well established. However, little is known about patients with chest pain but normal troponin (TnI) levels and their risk stratification with stress echocardiography in predicting future cardiac events.
Methods: We therefore prospectively studied 125 consecutive patients who were admitted with chest pain. Serial troponin determinations and echocardiographic images were prospectively evaluated. In 99 of the patients with negative troponin levels, stress echocardiography was performed. A positive event was defined as cardiac event (unstable angina, coronary artery revascularization, congestive heart failure or death) occurring during hospitalization or 3-month follow up.
Results:

The incremental prognostic value of dobutamine stress echocardiography in chest pain unit patients with negative troponin levels in predicting in hospital and short term cardiac events

	Positive Predictive Value	Negative Predictive Value
Troponin	75%	81%
Troponin and Stress Test	69%	98%
Fisher's Exact:	P=NS	P=0.01

Conclusion: Stress echocardiography increased significantly the negative predictive valve of patients with normal troponin. Stress echocardiography adds incremental prognostic information in predicting future cardiac events in low risk patient population. In addition, combination of stress echocardiogram result with negative troponin levels allows 98% confidence level when discharging the patient for three month follow up.

337 Ischaemia-induced interleukin-6 and tissue factor are related to persistent left ventricular dysfunction after dobutamine stress echocardiography

I. Ikonomidis[1], G. Athanassopoulos[2], J. Lekakis[3], K. Venetsanou[3], M. Marinou[2], P. Nihoyannopoulos[4], D.F. Cokkinos[2], S. Stamatelopoulos[3]. [1]Alexandra Hospital, Univ. of Athens, Dep. of Clinical Therapeutics, Athens; [2]Onassis Cardiac Surgery Center, 1st Cardiology Department, Athens; [3]Alexandra General Hospital, Clinical Therapeutics Dept., Athens, Greece; [4]Hammersmith Hosp, Cardiology Dept., London, United Kingdom

Interleukin 6 (IL6) and macrophage colony stimulating factor (MCSF) plasma levels are elevated after acute myocardial infarction. IL6 has an inherent negative inotropic action and mediates the ischemia-reperfusion myocardial injury. We investigated whether ischemia induces cytokine production leading to a) increased tissue factor (TF) expression and b) persistence of regional wall motion abnormalities (RWMA) during recovery after dobutamine stress echocardiography (DSE) in patients with stable angina(SA).
Methods: 80 patients with SA were studied by DSE. Blood samples were obtained at rest, at peak stress and 20min after cessation of dobutamine infusion (rec) for measurement (median, 25th-75th percentile) of MCSF, IL6 and TF plasma levels (pg/ml). Patients had angiograpically documented CAD. New or worsening RWMA at peak stress and their duration in the rec were noted.
Results: Forty five patients presented ischemia during DSE. Patients with and without ischemia achieved similar heart-rate product at peak stress. IL6 and TF levels increased at peak stress and at rec compared to rest in ischemic but not in non-ischemic patients (Table, $p<0.05$). MCSF levels were similar at rest, at peak stress and rec in all patients. The time to recovery of RWMA was related with IL-6 plasma levels at peak stress and rec ($r=0.51$ and $r=0.39$ $p<0.05$). Patients with RWMA lasting>5 min in rec (n=20) had higher IL6 at peak stress and rec than those with RWMA lasting <5 min (peak stress: 3.3 (2.4-4.6) vs 2.0 (1.5-2.7), rec: 2.7 (2.3-4.3) vs 1.9 (1.4-2.7), $p<0.01$). High MCSF was related with high TF only in ischemic patients in rec ($r=0.61$, $p<0.01$).

DSE	IL-6			TF		
Patients(n=80)	Rest	Stress	Rec	Rest	Stress	Rec
Ischemic* (n=45)	2.1 (1.5-2.8)	2.5 (1.7-3.3)	2.4 (1.6-3.4)	266 (132-405)	310 (243-553)	385 (141-577)
Non-ischemic (n=35)	2.1 (1.3-3.2)	2.1 (1.4-3.5)	2.2 (1.4-3.6)	371 (142-576)	312 (210-590)	328 (265-600)

*$p<0.01$ stress and recovery vs rest in ischemic patients

Conclusion: Reversible ischemia induces an increase of IL-6 and TF plasma levels that is sustained in recovery after DSE. MSCF is related to TF plasma levels during the post ischemic period. Ischemia-induced increase of IL6 persisting throughout recovery may explain the persistent left ventricular dysfunction observed in the post-ischemic period after DSE since this cytokine has an inherent negative inotropic action.

338 Dobutamine-stressechocardiography: means to reduce investigation time to detect ischaemia

M. Zuber, F. Cuculoski, P. Erne. *consultant in cardiology, Kantonsspital Luzern, Othmarsingen, Switzerland*

Aim: Dobutamine- stressechocardiography (DSE) is a well accepted but time-consuming test to define myocardial ischemia. The purpose of the study was to evaluate means to reduce investigation time to document myocardial ischemia.
Patients and methods: DSE wer performed in 102 patients (pat) for localizing or proving ischemia with a standardized protocol (group A: stepwise increase of dobutamine-infusion with 5,10,20,30,40 gamma/kg/min with addition of atropine if necessary to reach submaximal heart rate). For comparison we performed DSE in 100 pat with adding physical exercise (handgrip, leg elevation) to the same protocol (group B) and DSE in another 62 pat with constant infusion of 50 gamma dobutamine/kg/min during the whole test together with handgrip (group C). Pat were 60±11 years old (187 male/ 77 female), had a bodymass-index (BMI) of 27kg/m^2, were on betablockade in 53% and had myocardial scars in 33%. None of the investigation was terminated due to side effects.
Results: 41% of pat had an ischemic response (50% of those with and 39% of those without chest pain in pat history). Groups did not differ in age, sex, BMI, use of betablockers, maximal ST-segment depression, localisation and existing ischemia, scars, resting and maximal heart rate, ejection fraction and enddiastolic volume. However maximal double-product was higher and use of atropine was lower in group C than in group A ($p<0.03$). Duration of the test (stimulation and recovery time without time to prepare the test or interpretation) in group A/B/C were 1026±192, 919±204 and 654±216sec ($p<0.006$) with a mean difference of -107sec between A/B and -265sec between B/C. Total reduction for the stimulation time for high-dose dobutamine/ handgrip to standard protocol was -30% for pat with and -49% for pat without betablockade without difference in provoked arrythmias ($p<0.0001$).
Conclusions: Adding simple dynamic stress with handgrip and changing from a standard stepwise increase DSE to a constant high-dose DSE with 50gamma dobutamine- infusion has the potential to reduce atropine-dosage significantly and total stress/recovery time of 36% without provoking more side effects, although producing even higher pressure-heart-rate-double product. This simple change of protocol could be of importance for DSE in clinical practice.

339 Comparison of peak and postexercise treadmill echocardiography for the detection of multivessel coronary artery disease

R. Perez, J. Peteiro, L. Monserrat, J.A. Rodriguez, N. Vazquez, A. Castro-Beiras. *Juan Canalejo Hospital, Cardiology, A Coruña, Spain*

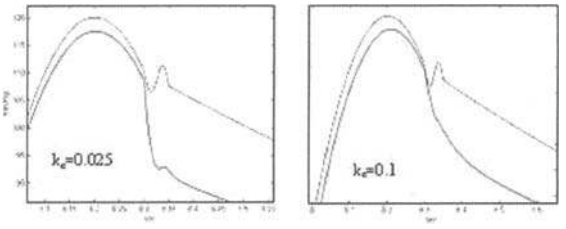
Objectives: We sought to compare the feasibility and accuracy of peak (Pk) treadmill exercise echocardiography (EE) versus postexercise echocardiography (PE) for identification of multivessel (MV) coronary artery disease (CAD) and to assess its incremental value when combined with clinical and exercise test variables.
Background: Although peak exercise echocardiography has been reported for both bicycle and treadmill exercise and has shown higher sensitivity than postexercise imaging, little is known about its utility for identifying multivessel CAD.
Methods: The study group included 335 patients (228 men; mean (±SD) age 60±11). Two hundred seventy nine patients were included on the basis of having had an EE between 1998 and 2000 and a coronary angiography (CA) within 4 months of the EE. To avoid bias to CA a subgroup of 56 consecutive non-diabetic patients referred for EE with pretest probability of CAD <10% that had atypical chest pain or were asymptomatics were also included. These latter patients were considered as having no CAD. MV CAD (> 49% diameter stenosis in >1 coronary artery, major branch, or by-pass graft) was confirmed in 170 patients, whereas 165 patients were considered to have 1-vessel CAD or no CAD. Positive EE was defined as ischemia or necrosis in at least 2 coronary territories.
Results: PE images were acquired within 125 seconds after exercise (49±15). Mean heart rate (bpm) was 139±19 at Pk versus 117±22 at PE ($p<.001$). Interpretable Pk and PE images were obtained for all patients. Sensitivity for detecting MV disease was higher with Pk than with PE imaging (79% vs. 55%, $p < 0.001$), with lower specificity (79% vs. 88%, $p< 0.05$). Predictive positive value was similar (80% vs. 83%). Negative predictive value was again higher with peak imaging (78% vs. 66%, $p< 0.01$). Total accuracy was not different (79% vs. 72%). A stepwise logistic regression analysis identified Pk EE positivity for MV CAD as the strongest independent predictor of MV disease (OR: 7.36); also significant were male gender (OR: 4.22), diabetes mellitus (OR: 4.28), previous myocardial infarction (OR: 3.12) and increment of product heart rate x blood pressure (OR: 1.00).
Conclusions: Pk treadmill EE is technically feasible and has higher sensitivity and negative predictive value for MV disease than PE echocardiography. This method adds independent and incremental value to clinical and exercise variables for the diagnosis of MV CAD. Therefore in the clinical setting Pk EE should be performed to diagnose MV CAD.

COMPUTER DEMONSTRATION

345 Computerized simulator for study of coronary artery physiology

E. Shalman, M. Ortenberg, V. Erenburg, O. Herzenstein. *Florence Medical, Research, Kfar Sava, Israel*

Introduction: Recognized shortcomings in angiographic imaging, has led to increasing interest in the assessment of real time physiology in the catheterization laboratory. Among the parameters currently being used clinically are CFR, FFR, rCFR, Pulse Transmission Coefficient (PTC), and Collateral Flow Index (CFI). Interrelationships between these parameters yield information that can be lesion and/or vascular bed specific. To better understand the interrelationships between varying hemodynamic parameters we have created a computer model of the coronary circulation.
Methods: The simple hydraulic model of coronary stenosis is used together with the windkessel model of the vascular bed. The compliance of the vascular bed is assumed to be inverse to its resistance. The systolic/diastolic change in resistance is described by step-wise functions of time. Input parameters are: aortic pressure signal, number of stenosis, length of each stenosis, MLD of each stenosis, reference diameter, rCFR, systolic/diastolic velocity ratio, CFI, and a constant Kc representing the ratio of vascular bed compliance to vascular bed resistance. The output of the model is coronary flow and the pressure signal distal to each stenosis at rest and at hyperemia.
Results: Fig 1 illustrates the simulated effect of changes in vascular bed compliance on the shape of distal pressure waves. Comparable analysis on the interrelationships of reference CFR, collateral flows and multiple lesions on CFR and FFR will also be demonstrated.



Conclusion: The demonstrated computer model allows for the estimation of the physiologic changes. It can be used for the design of clinical and animal studies. It is also valuable for demonstrating the usefulness of physiologic study to interventionists.

346 Psychological distress versus quality of life in chronic heart failure: validation of a new dedicated software

G.P. Carboni, C. Goffredo, R. Botti, Y. Brignardelli. *Universita Campus Bio-Medico, Cardiology Dept., Roma, Italy*

Quality of life (QOL) of patients (pts) with chronic heart failure (CHF) is associated with severe reduction in functional capacity (FC), limitations in social life (SL), alterations of the emotional (E) status and therapy compliance (TC). All such conditions are generally accompanied by a deep state of psychological distress. An objective measure of all such conditions is however still undefined. The alterations in FC, SL, E and TC of 69 pts with CHF were then calculated with a score from an interview consisting in 32 graded questions on QOL. The same method was carried out in other 50 pts but without CHF (control group). The alterations in FC, SL, E and TC were then expressed as percentage reduction from the values observed in control pts.
All pts were invited to self-rating in a visual graded scale (0 = normal, 100 = maximal values) their psychological distress burden. The amount of psychological distress was also evaluated by a pt close relative by using the same method. A modified Maastricht Questionnaire, self-ratings and ratings by a close relative was also submitted to all pts. Major determinants of psychological distress were assessed by the Life Events Assessment, the Social Support Questionnaire and the Ways of Coping Checklist. Browsing on the computer screen, the software provides informations on the clinical status of the 69 pts under study: mean age of 69±11 years,37±12% mean ejection fraction (EF) on echocardiography, 3±1 mean New York Heart Association (NYHA) class. This software also automatically illustrates with graphics that, in pts under study, the percentage reduction in FC, SL,E and TC was of 61±13%, 46±15%, 36±32%and 23±17%, respectively. The self and relatives ratings of psycological distress showed, on an other separate graphic, a percentage increase of 58±27% and 54±29%, respectively. These values were significantly correlated (Pearson r> 4,P < 0.001) with the Modified Maastricht Questionnaire results. These data indicate that a high level of psychological distress is detectable in pts with CHF and that it parallels the reduction of QOL. The use of this validated software is rapid (it takes less than 10 min to complete it) and objective and it may facilitate counseling and treatment in pts with CHF.

POSTER DISPLAY I

MODERATED POSTER SESSION I

P347 Absence of correlation between stress SPECT imaging and angiography at 6 months after direct angioplasty for acute myocardial infarction

K. Isaaz, A. Cerisier, E. Faure, M. Lamaud, S. Schouvey, M. Hassan-Sabri, A. Da Costa, C. Gerenton. *Hôpital Nord-CHU de Saint Etienne, Service de cardiologie, Saint Etienne, France*

Background: Restenosis of the infarct-related artery after direct angioplasty (d-PTCA) for acute myocardial infarction (AMI) is often silent. The value of stress SPECT imaging performed systematically at 6 months-follow-up (FU) for detecting myocardial ischemia due to restenosis in asymptomatic patients (pts) who underwent d-PTCA with stenting (d-S-PTCA) for AMI has not been well evaluated.
Methods: Among a cohort of 440 consecutive AMI pts successfully treated by d-S-PTCA for AMI in our institution from 01/99 to 08/01, 75 pts with no symptom during the F-U systematically underwent both rest thallium 201/stress Tc-99m setamibi myocardial perfusion (SPECT) and coronary angiogram (CA) at 6 months.
Results: Binary angiographic restenosis rate was 32%. Reversible ischemia at SPECT in the territory of the infarct related artery was observed in 34 of the 75 patients (45%); among these 34 patients with positive SPECT, only 10 had angiographic restenosis. Among the 41 patients without reversible ischemia at SPECT, 14 had restenosis. Specificity, sensitivity and positive predictive value of SPECT for detecting restenosis were 32%, 53% and 30%, respectively. Patients with SPECT reversible ischemia at 6 months-FU did not differ from those without SPECT reversible ischemia regarding restenosis, initial angiographic LVEF, diabetes, hypertension, exercise peak workload. Patients with SPECT reversible ischemia had a higher LV ejection fraction at 6 months than those without reversible ischemia (67±8% vs 61±13%, p=0.03).
Conclusion: These data suggest a poor correlation between stress SPECT imaging and angiographic restenosis at 6 months in patients treated by direct angioplasty for AMI and who remain asymptomatic at follow-up. These findings should be taken into account in the strategy of the clinical follow-up of this population.

P348 Relationship between electrocardiogram and electrophysiological findings and the extension of DNA mutation in patients with Steinert myotonic dystrophy

A. Dello Russo[1], G. De Martino[1], G. Pelargonio[1], T. Sanna[1], L. Messano[1], F. Mangiola[2], P. Zecchi[1], F. Bellocci[1]. [1]*Università Cattolica del Sacro Cuore, Cardiologia Dipt., Rome, Italy;* [2]*UILDM, Centro per le Malattie Neuromuscolari, Rome, Italy*

Background: Myotonic dystrophy (MD) is the most frequent autosomal dominant muscular dystrophy in adult life. MD is caused by an amplified and unstable trinucleotide cytosine-thymine-guanine (CTG) repeat on chromosome 19. Cardiac conduction disorders and arrhythmias are common in MD, but a correlation between length of CTG expansion and severity of cardiac involvement is debated.
Methods: In order to assess whether CTG repeat length is correlated to cardiac involvement, we studied 90 pts (age 43±15 years, 49 women) with a genetic diagnosis of MD. All pts underwent 12-lead ECG and 24-hour ECG Holter monitoring (HM). 21 pts with an AHA class 1 or 2 indication underwent also electrophysiological study (EP).
Results: The number of CTG repeats was positively correlated to heart rate (HR), (r= 0.29, p= 0.032) and inversely correlated to QT (r=-0.34, p=0.012) and QTc (r=-0.33, p=0.014) intervals. In contrast, CTG repeats were not correlated with P-R interval and their number was not different in patients with (n=21, 810.1±513.0) or without (n=69, 743.6±440.2) intraventricular conduction defects (p=0.57). HM data revealed that CTG number was similar in patients with (n=8, 918.7±511) or without (n=82, 876±456) ventricular pauses (p=0.42) but tended to be significantly increased in those with (n=9, 1059.3±572.6) compared to those without (n=81, 751.9±434.0) frequent and/or repetitive ventricular arrhythmias (VA), (p=0.056). Finally, among pts who underwent EP, CTG number was not significantly different in those who developed (n=8) and in those who did not develop (n=13) sustained VA (1093.2±431.9 vs. 769.8±462.7; p= 0.24).
Conclusions: CTG repeat length in MD pts is (1) positively correlated with with HR and spontaneous VA (2) inversely correlated with QT/QTc intervals (3) is not correlated with impairment of cardiac conduction and to inducibility of sustained ventricular arrhythmias. Mechanisms underlying these correlations need to be clarified to discriminate whether our observation are explained by a primary alteration of cardiac function caused by CTG repeat lenght in cardiomyocytes or merely represent the cardiac effects of neurohormonal changes caused by extracardiac manifestations of MD.

P349 Determination of the accessory pathway location by the QRS polarity in the electrocardiogram of children with Wolff Parkinson White's syndrome

L.V.A Boersma[1], E. Garcia-Moran[2], L. Mont[2], J. Brugada[2]. [1]*St. Antonius Hospital/HLCU, Cardiology Department, Nieuwegein, Netherlands;* [2]*Cardiovascular Institute, Arrhythmia Unit Hospital Clínic, Barcelona, Spain*

Introduction: The QRS polarity (QRSP) in the ECG has been used to predict the accessory pathway (AP) location in adults with WPW syndrome. In children this may fail due to electro-anatomic differences and we therefore sought to verify or improve the existing algorithm.
Methods: The ECGs of 173 symptomatic children with WPW syndrome were collected, blinded, and evaluated by 2 experienced electrophysiologists. The QRSP was designated as mainly positive (+), intermediate(=), or negative (-) for the 12 individual ECG leads. A previously validated algorithm for adults (d'Avila, PACE 1995) was used to predict the AP location by the QRSP pattern in leads V1, III, aVL, II, and V2. The AP location had been established fluoroscopically during electrophysiological study and radiofrequency ablation. The AP locations were designated as LL, LPS, PS, RPS, RL, AS, MS, or Parahisian (PH).
Results: The ECGs of 157 patients with sufficient pre-excitation were included in the study. The age of the children was 13±3 yrs, 55 were female and 102 were male. With the existing QRSP algorithm for adults, the 2 observers predicted only 55% to 58% of AP locations correctly and a new algorithm had to be devised. Based on a + or = QRSP in V1 as a first step, the 61 left sided APs were all detected but an additional 10 ECGs were of PS, MS, or RPS APs. The 47 LL APs could all be distinguished by a + QRSP in III and a - or = QRSP in I. The 18 LPS and PS APs had a - or = QRSP in III but could not be further separated from the 6 MS and RPS APs. For ECGs with a - QRSP in V1 the existing adult algorithm using leads III, II, and V2 failed significantly. Instead, the introduction of a + QRSP in V3 and + or = QRSP in aVF was found to differentiate most PH (7 of 12) and AS (4 of 8) from most RPS (21 of 26) and MS (8 of 13) APs that showed a + QRSP in V3 but a - or = QRSP in aVF. The majority of RL (25 of 31) but also some AS (4 of 8) an PH (4 of 12)AP were characterized by a - or = QRSP in V3. Especially the AS, but also MS and Parahisian AP, showed heterogeneous ECG patterns and were difficult to classify. The use of additional ECG leads provided no contribution for further classification. There did not seem to be a clear relationship between age and electrocardiographic expression of APs.
Conclusions: In children with WPW the ECG manifestation of the AP is more heterogeneous than in adults. AS and Parahisian AP are most difficult to diagnose. The new QRSP algorithm based on leads III, aVF, V1 and V3 has a 90% overall reliability to predict the AP location in five regions of the heart.

P350 Internal cardioversion of atrial fibrillation: which role in the era of external biphasic shock?

G.L. Botto, A. Politi, A. Sagone, M. Luzi, R. Lombardi, R. Bonatti, G. Ferrari. *Sant' Anna Hospital, Cardiology Dept, Como, Italy*

Background: Internal cardioversion (IC) of atrial fibrillation (AF) has been indicated for converting atrial arrhythmias mainly refractory to external cardioversion (EC) delivering monophasic shock (MS).
Aim of the present study was to evaluate the role of IC in the era of external biphasic shock (BS)
Methods: The study population consisted in 135 patients (pts), mean aged 69±8 years, with their first episode of AF lasting 3 days to 12 months (mean arrhyhmia duration 150±97 days), NYHA functional class I-II, who received anticoagulation 3 weeks before and 4 weeks after external cardioversion. Pts received MS-EC using a step-up protocol (3 J/Kg anterior-posterior (AP), 4 J/Kg AP, 4 J/Kg anterior-lateral (AL), maximum 360 joules), if arhhythmia persisted a BS-AP-EC at the maximun energy previously delivered was administrated. Pts still refractory to BS-EC underwent IC. No additional antiarrhythmic drugs were given. End-point of the study was resumption of sinus rhythm (SR).
Results: Sixteen (12%) pts were excluded because of spontanous reversion to SR before EC. The main results are reported in the table.

Efficacy	3 J/Kg MS-AP	4 J/Kg MS-AP	4 J/Kg MS-AL	4 J/Kg BS-AP	IC
Pro-step	57/119 (47,9%)	26/62 (41,9%)	18/36 (50%)	17/18 (94,4%)	1/1 (100%)
Total	57/119 (48%)	83/119 (70%)	101/119 (85%)	118/119 (99%)	119/119 (100%)

Arrhythmia duration predicts only MS-EC failure (182±86 days in non-responder vs 132±94 in responder pts; p=0.038).
Conclusions: The use of biphasic shock for external cardioversion rises the success rate of the procedure very close to 100%. The need for internal cardioversion in patients with their first episode of atrial fibrillation lasting < 1 year, is less than 1%, therefore the use of the invasive procedure in this clinical setting must be very limited.

P351 Thromboembolic complications after direct current cardioversion in patients with atrial fibrillation and ineffective anticoagulation

K. Seidl, M. Rameken, M. Vater, H. Schwacke, A. Brandt, C. Kilkowski, R. Zahn, J. Senges. *Klinikum Ludwigshafen, Cardiology Dept., Ludwigshafen, Germany*

The Ludwigshafen atrial fibrillation (AF) study is a prospective single center observatinal study on an intention to cardiovert basis, including 1269 consecutive unselected patients (pts) with AF. Aim of the substudy was to evaluate the embolic event rate in pts with AF and ineffective anticoagulation (IA), in whom electrical cardioversion (CV) was intended. IA was defined, if warfarin was given, however INR was < 2, or if no anticoagulation was performed. Reasons for performing CV in pts with IA were AF of < 48 h, hemodynamic instable AF, or contraindication for anticoagulation. After cardioversion an overlap of warfarin therapy and intravenous heparin was given to maintain adequate anticoagulation after CV in pts without contraindications for anticoagulation.
Results: In 193 pts (15%) anticoagulation therapy was ineffective at the time of the intended CV. Transesophageal echocardiography (TEE) was performed in 126 pts, in the remaining 67 pts transthoracic echo was performed. A thrombus was found in 10 pts (7.9%) of the 126 pts with AF and ineffective anticoagulation. In 53 of the 126 pts (42%) TEE revealed spontaneous echo contrast. The grade of spontaneous echo contrast was mild in 74%, moderate in 19% and severe in 9%. In 150 of the 196 pts (78%) CV was performed, in the remaining 43 pts no CV was performed. In 2 of 150 pts (1.3%) with AF and IA a transient ischemic attack occurred in the first 4 weeks after CV. In both pts TEE was performed before CV, none of the pts had evidence of left atrial thrombus. In none of the 43 pts without CV a thromboembolic complication occurred. In comparison the rate of thromboembolic complications in the first 4 weeks after CV was 0.8% (9/1076 pts) in pts with AF and effective anticoagulation at least 3 weeks prior to CV.
Conclusion: 1) In our AF outpatient clinic 15% of the pts with AF had ineffective anticoagulation prior to CV. 2) The rate of embolic events in first 4 weeks after the intended CV was 1.3 in pts with ineffective anticoagulation compared to 0.8 in pts with effective anticoagulation.

P352 Influence of reciprocating tachycardia on development of atrial cardiomyopathy in WPW patients

Z. Kalarus, R. Lenarczyk, O. Kowalski, J. Prokopczuk, H. Krupa, B. Oeredniawa, A. Sokal, T. Zielińska. *Silesian Center of Heart Diseases, Ist Dpt of Cardiology, Zabrze, Poland*

Background Stretch of cardiac tissues resulting from pressure-overload is a confirmed trigger for atrial fibrillation (AF). Atrial strech during atrio-ventricular reentry tachycardia (AVRT) is suspected source of AF in WPW patients
Objective was to evaluate influence of AVRT on atrial pressures during tachycardia and presence of AF in WPW syndrome
Methods Study population consisted of 88 consecutive patients with left-sided accessory pathway (AP) and stimulated AVRT during electrophysiologic study (EPS). Studied group (Gr-I, n=32, 36.36%) consisted of patients with sustained episodes of AF during EPS, control group (Gr-II, n=56, 63.64%) PTS without AF. Mean and maximal pressure during AVRT in both atria were evaluated using transseptal approach (LAP mean, LAP max, RAP mean, RAP max). Relation between atrial pressures and electrophysiological parameters of AVRT: A-V, V-A conduction time, indexes A-V/V-V, V-A/V-V were calculated in the entire population
Results We found significantly higher values of atrial pressures in Gr-I compared with Gr-II: LAP max 32.0 mm Hg versus 20.8, LAP mean 21.6 versus 13.2, RAP max 15.2 versus 11.5, RAP mean 8.2 versus 6.17 respectively ($p<0.001$). Analysis of the influence of AVRT on atrial pressures showed significant ($p<0.001$) negative correlation between A-V-conduction times, A-V/V-V indexes and LAP max, LAP mean and positive($p<0.05$) correlation between V-A conduction times, V-A/V-V-indexes and LAP max LAP mean. Similar effect of AVRT was found analyzing right atrial pressures.The most significant correlations were found between LAP max and A-V conduction time (r=-0.64), A-V/V-V, V-A/V-V indexes (r=-0.60, r=0.60 respectively).

	LAPmax	LAPmean	RAPmax	RAPmean
A-V	r=-0.64	r=-0.57	r=-0.25	r=-0.26
V-A	r=0.36	r=0.32	r=0.23	r=0.11
A-V/V-V	r=-0.60	r=-0.54	r=-0.30	r=-0.20
V-A/V-V	r=0.60	r=0.54	r=0.30	r=0.20

Conclusions 1.Electrophysiological parameters of AVRT have an influence on atrial pressures and presence of AF in WPW patients.
2.Earlier ventricle and later atrial activation during AVRT increase atrial pressures.

P353 Electrophysiological effects of novel Kv1.5 channel blockers on left versus right pig atrium in comparison with IKr-blockade

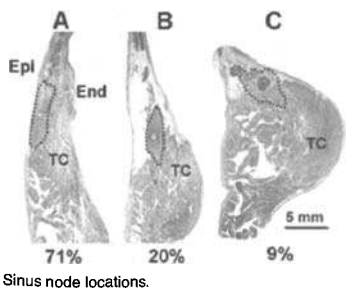
K.J. Wirth, J. Brendel, A.E. Busch, K. Knobloch. *Aventis Pharma, DG Cardiovascular Diseases, Frankfurt am Main, Germany*

Objectives: Inhibition of the cardiac Kv1.5-channel, the molecular base for the human cardiac ultrarapid delayed rectifier potassium current (IKur), is considered a new promising atrial selective antiarrhythmic concept since this channel is presumed to contribute to atrial but not ventricular repolarization in the human heart. In a previous study in pigs we found clear baseline differences in refractoriness between left and right atrium with shorter effective refractory periods (ERP) of the left atrium associated with a high vulnerability for tachyarrhythmias of the left, not the right atrium. In this newly established model we compared atrial and ventricular effects of three novel Kv1.5-blockers, S9947, S20951 and S1185, with the IKr-blockers dofetilide, azimilide, ibutilide and d,l-sotalol.
Methods: In pentobarbital anesthetized pigs (n=40) we determined ERPs in the free walls of both atria with the S1-S2-stimulus method at three basic cycle lengths (BCL 240/300/400ms)and the QTc-intervals. The incidence of atrial tachyarrhythmias triggered by the S2-extrastimulus of the left atrium was evaluated (left atrial vulnerability).
Results: In contrast to IKr-blockade, Kv1-5-blockade had no effect on the QTc-interval, but prolonged the atrial ERP. The Kv1.5-blockers were significantly stronger on left atrial ERP, Ikr-blockers on right atrial ERP ($p<0.05$ for all compounds tested). A 240 ms BCL the Kv1.5-blocker S9947,1mg/kg, prolonged left vs. right atrial ERP by 20±2% vs. 12±3%; S20951, 3mg/kg, by 29±7% vs. 9±2% and S1185, 1mg/kg, by 54±7% vs. 23±7%. By contrast the effect of dofetilide,10μg/kg, was stronger on the right than left atrium (36±4% vs. 23±2%), a profile also found with azimilide (5mg/kg, 33±2% vs. 17±3, ibutilide (15μg/kg, 40±9% vs. 23±5%) and d,l-sotalol (1.5mg/kg, 41±5% vs. 30±4%). The Kv1.5-blockers, S9947, S20951 and S1185, significantly decreased left atrial vulnerability (-62, -75 and -100%, respectively, $p<0.01$) in contrast to the selective IKr-blocker dofetilide(-14%, n.s.).
Conclusion: Kv1.5- and IKr-blockers showed substantial differences in their atrial and ventricular actions in pigs. IKr-blockers were stronger on right atrial ERP, Kv1.5-blokckers on left atrial ERP suggesting interatrial differences in the expression of potassium channels. In contrast to selective IKr-blockade, Kv1.5-blockade inhibited left atrial vulnerability and had no effect on the QT-interval. Based on the atrial selective prolongation of refractoriness and the inhibition of left atrial vulnerability Kv1.5 channel blockade seems a promising atrial antiarrhythmic concept.

P354 Topographic location of the human sinus node: implications in radiofrequency catheter ablation of inappropriate sinus node tachycardia

D. Sanchez-Quintana[1], J.A. Cabrera[2], V. Climent[1], J. Saenz de Santamaria[1], F. Cabestrero[2], M. Orejas[2], J.M. Rubio[2], J. Farre[2]. *[1]Extremadura University, Human Anatomy, Badajoz, Spain; [2]Fundación Jiménez Díaz, Cardiology, Madrid, Spain*

Treatment of inappropriate sinus tachycardia with radiofrequency (RF) catheter ablation has lower success rates than those attained in other atrial tachycardias. No systematic investigation has been made on the anatomic relations of the sinus node (SN) and the endocardial and epicardial aspects of the right atrium (RA), and the terminal crest (TC) in the human heart.
Methods: In 45 autopsied normal human heart specimens (49±20 years; 31 male), we examined by longitudinal sections the location of the SN body within the TC and the distance to the RA epicardium and endocardium.
Results: The SN body, constantly formed around a central sinus node artery, had a variable shape structure, which extended along the TC in lateral position, gradually passing through the middle of the crest to reach the endocardium at variable distances. Its location in relation to the RA epicardium and endocardium could be assigned to 3 different patterns (figure). In 32 specimens (71%) the SN was subepicardial at the junction of the superior caval vein and the RA (type A). The distance SN-epicardium was 0.5±0.2 mm and SN-endocardium 4.0±0.4 mm. In 9 hearts (20%) the SN was located in the middle between the epicardium (epi) and endocardium (end) (type B). In 4 specimens (9%) the SN was subendocardial and the distance SN-endocardium was 0.8±0.3 mm (type C).
Conclusions: In 71% normal human hearts the SN body has a subepicardial location. This combined with the presence of a central sinus artery and a thick muscular TC between the SN tissue and the RA endocardium probably accounts for the difficulties in ablating with RF inappropriate sinus tachycardia.



Sinus node locations.

P355 Left atrial macroreentry tachycardia after mitral valve surgery: complete conduction block across the critical isthmuses can prevent recurrence

T. Vogtmann, F. Ouyang, M. Antz, S. Ernst, M. Goya, M. Volkmer, K.-H. Kuck. *AK St. Georg Hamburg, Cardiology Dept., Hamburg, Germany*

The reentry circuit of left atrial macroreentry tachycardias (LAMRT) after mitral valve (MV) surgery are complex and data about results of RF ablation are limited. We investigated 9 pts. (3 f; age 18-70 y) with LAMRT after MV surgery with CARTO. Mapping in LAMRT was possible in 7 pts. In 2 pts we performed substrate mapping in sinus rhythm. Ablation endpoint was complete conduction block across all identified critical isthmuses CIs and non-inducibility.
Results: In addition to an electrical silent area (ESA) or line of double potentials (LDP) anterior of the right pulmonary veins (PV) representing the atriotomy in 8/9 pts acquired electrical barriers were identified. 17 tachycardias were mapped in 7 pts (1-3/pt, CL 250 - 440 ms). In 12/17 dual loop mechanism was suspected with the CI between a posterior ESA/LDP and a PV (6), between 2 posterior ESAs (3) or a posterior ESA and the atriotomy (3). An additional 5 were single loops around the mitral annulus (3 counter-clockwise, 2 clockwise) with isthmus at the lateral (3) or anterior (2) mitral annulus (MA). Finally all CIs could be blocked by delivering 4.0±0.8 RF pulses at sites with a maximal bipolar amplitude of 0.08 - 3.24 mV. 2 CIs located between the lateral MA and a posterior ESA with amplitudes of 3.24 and 1.89 mV and a widths of 26.6 and 31.4 mm (average widths of all CIs: 14.0 ± 8.8 mm) required cooled ablation after recurrence.
During a follow up of 14 ± 9 mon no LAMRT occurred. 7/9 pts were completely arrhythmia free, 2 were symptomatic with intermittent AF.
Conclusion: Electroanatomical mapping in LAMRT pts after mitral valve surgery reveals ESAs or LDPs due to atriotomy, additional ESAs, and allows identification of the critical isthmus and mechanism of tachycardia. Complete conduction block across the critical isthmuses prevents recurrence of LAMRT.

P356 The post-pulse sodium spike as a marker of cardiac capture: from modelling to clinical evidence

A P. Ravazzi[1], M. Sassara[2], P. Diotallevi[1], S. Ficili[2], C. Militello[3], J. Meier[3], L. Brandolisio[4], R. Audoglio[5]. *[1]Osp. SS Antonio e Biagio, Cardiology Div., Alessandria, Italy; [2]Osp. Belcolle, Cardiology Div., Viterbo, Italy; [3]Biotronik GmbH, Erlangen, Germany; [4]Biotronik-Seda, Trezzano S/N, Italy; [5]Linarolo (PV), Italy*

Introduction: A pacemaker assuring myocardial capture, through automatic output adjustments, would improve patient safety, extent battery life and speedup follow-ups. At the upstroke of action potential the impedance of cell membrane strongly decreases due to the opening of sodium channels (NaCh). During this phase lasting 2-4 ms, myocardial impedance decreases accordingly. Theoretical models of membrane kinetics show that a short living negative dip in intracardiac impedance is expected soon after a captured pacing pulse (within 20 ms).
Aim of this preliminary clinical investigation was to verify whether right ventricular capture can be recognized from intracardiac impedance changes resulting from NaCh opening.
Material and methods: Six patients implanted with an Inos2 CLS pacemaker (Biotronik, Germany)and low-polarization leads, were paced in DDD mode at pulse amplitudes below and above the threshold value. The bipolar intracardiac impedance was DC measured in right ventricle by the pacemaker and downloaded via telemetry in a laptop PC for post-processing.
Results: In all pts, a small (mean 2.9 ± 0.8 Ohms) and fast (< 6ms) intracardiac impedance dip could be detected 10-18 ms after the ventricular capture. This dip was not observed after non-captured events. The mean DC intracardiac impedance was 542 ± 50 Ohms.
In conclusion, an ultra-fast (within 20 ms) detection of capture is feasible by an impedance-based method. Since impedance measurement is slightly affected by polarization artifacts, such method is expected to work with any lead.

LONG-TERM BIVENTRICULAR PACING RESULTS

P357 Effects of biventricular pacing on morbidity and mortality in patients affected with severe congestive heart failure

G. Mascioli, T. Bordonali, L. Bontempi, F. Costa, L.M. Culot, R. Marconi, A. D'Aloia, A. Curnis. *Division of Cardiology, Brescia, Italy*

Biventricular pacing is a new treatment for severe congestive heart failure that has proven to be effective in several studies.
Since October 1998 to December 2001, we have implanted 82 patients with a biventricular device. 54 patients have until today at least 1 year of follow-up. 6 died during the first year after the implant, so that the mortality rate at 1 year is 11.1%. 3 patients died for sudden cardiac death, 2 for congestive heart failure and 1 for non cardiac death.
For the morbidity analysis, we have studied in the year before and in the year after implant: days to first recurrence of CHF, number of acute episode of CHF, number of hospitalisation in the Cardiology Division and in the ICU, length of hospital stay in the Cardiology Division and in the ICU.
The table shows the results, expressed ase mean±1 standard deviation.

Morbidity parameters

	DFR	NAC	NHC	NHI	LHSC	LHSI
1 year pre	124+134	2.8+1.4	2.6+1.5	0.7+1.0	36.5+31.7	1.9+2.9
1 year post	298+108	0.4+0.7	0.5+1.4	0.06+0.24	4.4+12.3	0.08+0.35

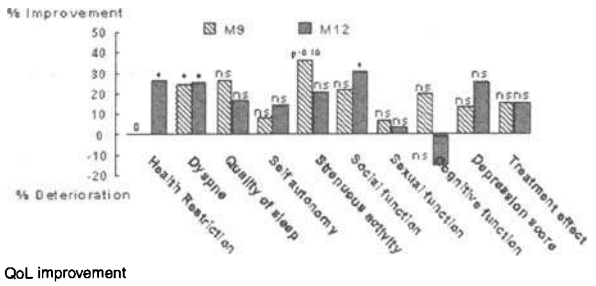
DFR = Days to first recurrence, NAC = Number of acute episode of CHF, NHC = Number of hospitalisation in Cardiology Dept., NHI= Number of hospitalisation in ICU, LHSC=Length of stay in Cardiology Dept, LHSI = Length of stay in ICU

All differences are statistically significant.
If the particular severity of our patients is considered (mean NYHA class 3.1±0.3, mean ejection fraction 22±7%)our results on mortality are satisfying. Furthermore, our data demonstrate that biventricular pacing not only is hemodinamically and clinically efficacious, but it is also related to a significant decrease in morbidity rate.

P358 Long-term benefit in quality of life by biventricular pacing in patients with chronic heart failure and atrial fibrillation in the MUSTIC study

C. Linde[1], F. Braunschweig[1], F. Gadler[1], C. Bailleul[2], J.C. Daubert[3]. [1]*Karolinska Hospital, Dept of Cardiology, Stockholm, Sweden;* [2]*ELA Recherche, Le Plessis-Robinson, France;* [3]*Centre Cardio-Pneumologique CHU, Rennes, France*

The MUltisite STimulation In Cardiomyopathy (MUSTIC) study is a controlled multicentre trial, to assess the clinical efficacy of biventricular pacing (BIV) in patients with chronic NYHA III heart failure and intrinsic QRS>150 or RV paced QRS>200 ms. We have reported symptomatic relief from the crossover phase (CO) with sustained results over one year. The aim of this study was to assess quality of life (QoL) over time in the group of patients with atrial fibrillation (AF) and slow ventricular rate either due to spontaneous rhythm or His-ablation.
Methods: The 6 month CO single blind comparison of BIV and no-BIV was completed in 41 of 64 included. Of these, 35 preferred and were programmed to BIV. Quality of life was evaluated by one disease specific and one generic form - the Minnesota Living with Heart Failure questionnaire and the Karolinska questionnaire - in 30/35 patients with BiV at 9 (M9) and 12 months (M12) compared to Start CO.
Results: Significant and sustained benefits regarding the Minnesota form were seen at M9 and M12 compared to start CO. Results from selected dimensions of the Karolinska form are given in the figure.



QoL improvement

In conclusion: In parallel with a maintained clinical improvement, quality of life benefits were sustained over one year by biventricular pacing in these patients with severe heart failure, atrial fibrillation and intraventricular conduction delay.

P359 Long-term biventricular pacing decreases inducibility of ventricular arrhythmia in congestive heart failure

S G. Molhoek, J J. Bax, L. van Erven, M. Bootsma, P. Steendijk, E.E. van der Wall, M.J. Schalij. *Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Background: Biventricular (BV) pacing may improve systolic left ventricula function, functional status and well-being of patients with depressed left ver tricular function and interventricular conduction delay. These patients with cor gestive heart failure often have an indication for ICD implantation as well. Th aim of the present study was to evaluate whether long term BV pacing de creases inducibility of ventricular arrhythmias in these patients.
Methods: 10 patients treated with a combined BV-ICD device for dilated cai diomyopathy and at risk for ventricular arrhythmia were included. All patient underwent an electrophysiological (EP) study with ventricular programme electrical stimulation (PES), both before implantation of the BV-ICD device an after a period of at least 6 months of BV pacing. PES protocol was 8 beat driv train with basic cycle length 600, 500 and 400 ms and up to 3 extrastimuli wit minimal cycle length 200 ms.
Results: The patients included (7 M, age 64±12y) had dilated cardiomyopath (5 ischemic, 5 idiopatic) and interventricular conduction disturbances. Indica tions for ICD device were out of hospital cardiac arrest (n=6) or ventricula tachyarrhythmia (n=4). Antiarrhythmic drugs before BV-ICD (sotalol n=3, amio darone n=4) was not significantly changed at long term follow-up (sotalol n=4 amiodarone n= 3). Before BV-ICD implantation, sustained VT could be induce in 8 patients and nonsustained VT in one. After a period of 9.9 ± 4.1 months c BV pacing, VT was inducible in only 4 patients.
Conclusion: Long term BV resynchronisation therapy decreases the inducibil ity of VT from 90% to 40% ($p<0.05$). Resynchronisation therapy may have a antiarrhythmic effect.

P360 Long-term (2 years) clinical effects of permanent biventricular pacing in chronic atrial fibrillation. Results from the MUSTIC trial

C. Leclercq[1], C. Linde[2], S. Cazeau[3], L. Kappenberger[4], R. Sutton[5], C. Bailleul[6], C. Daubert[1] on behalf of the MUSTIC Study Group. [1]*University Hospital, Cardiology, Rennes, France;* [2]*Karolinska Hospital, Stockholm, Sweden;* [3]*St Cloud, France;* [4]*Lausanne, Switzerland;* [5]*London, United Kingdom;* [6]*Le Plessis Robinson, France*

Background: Previous controlled and randomized studies have shown tha biventricular pacing improved functional status in patients with advanced hear failure, intraventricular conduction delay and left ventricular (LV) systolic dys function and stable sinus rhythm. However, results of permanent biventricula pacing in atrial fibrillation patients remain controversial.
The aim of the present study was to evaluate the long term clinical benefit o permanent biventricular pacing (follow up = 2 years) in atrial fibrillation patient included in the MUSTIC trial.
Method: The MUSTIC trial was a cross-over (2 x 3 months) designed study t assess the effect of biventricular pacing. After the two cross-over phases, the patient were followed every 3 months in the pacing mode selected according t their preference (biventricular or uni-right ventricular pacing).
43 patients in permanent atrial fibrillation (66 ± 9 years), all in NYHA class III with a mean LV ejection fraction (LVEF) of 25 ± 10% were included in this study. Baseline data were recorded after a 3 month period of heart rate control in most cases by radiofrequency AV node ablation, and uni-right ventricula pacing. After the completion of the cross-over phases, all patients but 4 were programmed in biventricular pacing mode.
Results:

	Baseline	1 year	2 years
Heart rate (bpm)	75±15	76±7	71±12
NYHA class	3±0	2.2±0.5*	2.2±0.5
6 min walk (m)	325±82	370±87*	362±99
Peak VO2 (ml/min/kg)	13±4	14±3.5	NA
QOL questionnaire	45±23	31±17*	32±20*
LVEF radionuclides (%)	26±7.7	30±8*	NA

* $p<0.01$ vs baseline, NA = not available

To date, 26 patients completed the 2-years follow-up.
Conclusion: These data suggest that biventricular pacing significantly im proves the quality of life and exercise tolerance over a 2 years follow-up ir advanced heart failure patients with permanent atrial fibrillation.

P361 Benefits of cardiac resynchronization therapy – results of the InSync and InSync ICD trials

W. Abraham[1], J. Young[2], A. Leon[3], L. Liem[4]. [1]University of Kentucky, Section of Heart Failure, Lexington, United States of America; [2]Cleveland, United States of America; [3]Crawford Long Hospital, Atlanta, United States of America; [4]Stanford University Medical Center, Stanford, United States of America

Background: The InSync & InSync ICD trials were each designed as a multicenter, randomized, double-blind controlled study to evaluate the safety and effectiveness of CRT in a large number of patients with advanced systolic heart failure, ventricular dysynchrony and, in the case of InSync ICD, an indication for an ICD.
Methods: 815 NYHA Class III and IV patients were successfully implanted with the InSync (n=453) or InSync ICD (n=362) systemand randomized to either the CRT OFF (control, n=401) or the CRT ON (treatment, n=414) group. Primary effectiveness endpoints in both studies were quality of life (QOL, as measured by the Minnesota Living with Heart Failure questionnaire), NYHA class and 6-minute hall walk distance (6MW). Key secondary endpoints included peak VO2/kg, exercise time, and LVEF.
Results: Effectiveness results comparing the median paired differences at baseline and 6 months are summarized in the table below.

	CRT ON	CRT OFF	P-value
QOL*	-18	-9.5	<0.0001
NYHA Class*	-1	0	<0.0001
6MW (meters)*	46	28	0.01
Peak VO2/kg (ml/kg/min.)	1.1	0.2	0.006
Exercise Time (sec.)	68.5	13	<0.0001
LVEF (%)	4.0	0.6	<0.0001

*Median paired difference

Conclusions: In patients with moderate to severe heart failure and LV dysynchrony, the InSync and InSync ICD trials have demonstrated that cardiac resynchronization is safe and improves functional status.

ARRHYTHMIAS MECHANISMS: CELLULAR ELECTROPHYSIOLOGY AND PATHOPHYSIOLOGY

P362 Pharmacological modulation of the pacemaker current (IF) in human atrial myocytes

G. Lonardo[1], E. Cerbai[1], G. Giunti[2], S. Casini[1], M. Bonacchi[2], G. Sani[3], A. Mugelli[1]. [1]University of Firenze, Dept. Pharmacology, Firenze, Italy; [2]Azienda Ospedaliera Careggi, Cardiosurgery Unit, Florence, Italy; [3]University of Florence, Cardiosurgery Unit, Florence, Italy

IF is an inward Na/K current, activated by hyperpolarization and responsible for the phase 4 of action potential; IF is constitutively expressed in human atrial myocytes (HuAM), where it is modulated by beta-adrenergic (βAR) and serotonin (5-HT4) receptors. Modulation of IF may play a relevant role in triggering human atrial arrhythmias. Recent data obtained by heterologous re-expression of human F-channels and 5-HT receptors suggest that differences exist in the pharmacological modulation depending on channel and receptor isoforms. In particular, 1) HCN1 isoform of the F-channel seems to be insensitive to cAMP and 2) 5-HT(4b), but not 5-HT(4a), isoform is coupled to both inhibitory (Gi) and stimulatory (Gs) G-proteins. However, the functional relevance of this different coupling has never been tested on native F-channels in human cells. The aim of this study was to investigate the pharmacological properties of IF in HuAM, by evaluating its modulation by cAMP cascade through β1AR, β2AR and 5-HT4 receptor stimulation.
Methods: Coupling of receptor subtypes with Gi was tested by incubating HuAM in 0.5 μg/ml pertussis toxin [PTX] (which inactivates Gi) for 3 hours at 33°C. Myocytes were isolated from specimens of right atrial appendages, collected during cardiac surgery procedures. All patients were in sinus rhythm. Myocytes were freshly utilised for patch clamp recording of IF in whole cell configuration.
Results: IF was recorded in 62 cells: its density was 28.1±2.8 pS/pF and midpoint activation voltage ($V\frac{1}{2}$) was -93±2 mV. β1AR stimulation was carried out by superfusing cells with isoprenaline (ISO, 1 μM) in the presence of the selective β2AR antagonist ICI 118,551 (50 nM); β2AR stimulation was obtained with 1 μM ISO plus the selective β1AR antagonist CGP 20712A (100 nM); 5-HT4 stimulation was obtained with 1 μM serotonin. All stimuli were able to cause a positive shift ($DV\frac{1}{2}$) of IF activation curve (β1AR $DV\frac{1}{2}$=16.3±2.2 mV n=13; β2AR $DV\frac{1}{2}$=11.5±1.6 mV n=13; 5-HT4 $DV\frac{1}{2}$=16±2 mV n= 15) ($p<0.0001$ versus corresponding controls), resulting in an increase of active current at voltage near to the physiological diastolic potential. All receptor subtypes also speeded up the rate of IF activation. Pre-incubation with PTX did not alter the pharmacological response of F-channel to β1AR ($DV\frac{1}{2}$[PTX]=14.4±2.5 mV), β2AR ($DV\frac{1}{2}$[PTX]=12.1±2.0 mV) and 5-HT4 stimulation ($DV\frac{1}{2}$[PTX]=16.8±1.8 mV) (NS versus no-PTX conditions for all).
Conclusions: IF is positively modulated by cAMP-coupled receptors, whose effect is unchanged by Gi blockade.

P363 S100A1 enhances the L-type Ca^{2+} current in murine cardiomyocytes

M. Reppel[1], A. Remppis[1], P. Sasse[2], W. Roell[2], P. Most[1], J. Hescheler[2], H.A. Katus[1], B.K. Fleischmann[2]. [1]Med. University of Luebeck, Med. Clinic II, Luebeck, Germany; [2]Neurophysiology, University of Cologne, Cologne, Germany

Background: S100A1 is a Ca^{2+} binding protein of the EF hand-type with a muscle specific expression pattern. It displays highest protein levels in cardiomyocytes and has been found to be expressed as early as on day eight in the embryonic heart. Since S100A1 is known to be involved in the regulation of Ca^{2+} homeostasis we tested whether S100A1 also plays a role in regulating the L-type Ca^{2+} current (ICa) in murine cardiomyocytes. Methods and Results: Murine embryonic (E16.5) ventricular cardiomyocytes were coincubated with S100A1 (0.001-10μM) for 2 to 48h. The amplitude of peak ICa was significantly increased as early as 2h (+33.1±16.%, n=6, $P<0.05$) after the addition of S100A1, while current-voltage relationship and inactivation characteristics remained unchanged. Fluorescence- and capacitance measurements evidenced a fast translocation of rhodamine coupled S100A1 from the extracellular space into cardiomyocytes. S100A1 treatment did neither affect the functional expression of L-type Ca^{2+} channels (VDCC) nor cAMP levels. However, protein kinase inhibitor (PKI), a selective blocker of the cAMP-dependent protein kinase A (PKA), abolished the S100A1-mediated enhancement of ICa and measurements of PKA activity yielded a significant increase in S100A1-treated cardiomyocytes (53.7±7.4%, n=6). Conclusion: The Ca^{2+} binding protein S100A1 enhances ICa via increase of PKA activity. Thus, S100A1 enhances myocardial inotropy by augmenting transsarcolemmal Ca^{2+} influx.

P364 The human cardiac inwardly-rectifying K^+ channel Kir2.1b (hIRK) is inhibited by direct protein kinase C-dependent phosphorylation

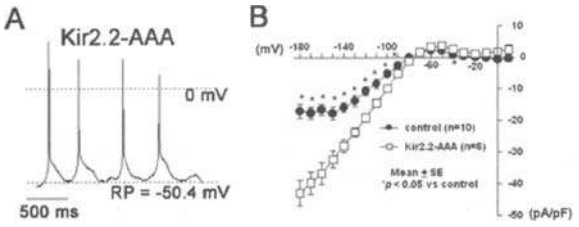
C. Karle, E. Zitron, W. Zhang, G. Wendt-Nordahl, S. Kathöfer, D. Thomas, J. Kiehn. Internal Medicine, Dept. of Cardiology, Heidelberg, Germany

Introduction: For the stabilization of the resting membrane potential and in arrhythmogenesis, the native inward rectifier potassium current IK1 plays a critical role. Protein kinases A (PKA) and C (PKC) are activated in coronary artery disease and heart failure accompanied by life-threatening ventricular arrhythmias.
Methods: This study investigates the functional relationship between PKA, PKC and IK1 or its cloned correlate Kir2.1b (hIRK) with techniques of molecular electrophysiology.
Results: In whole-cell patch-clamp experiments with isolated human atrial cardiomyocytes, the IK1 current was decreased by 41%, when the unspecific activator of PKC, phorbol 12 myristate 13-acetate (PMA, 100 nmol/L) was applied. To study the effects of PKA and PKC on a cloned channel underlying parts of the native IK1, we expressed Kir2.1b (hIRK) heterologously in Xenopus oocytes and measured currents with the double-electrode voltage-clamp technique. PMA (100 nmol/L) decreased the current by an average of 68%, with an IC50 of 0.68 nmol/L. The inactive compound 4-alpha-PMA was ineffective. Thymeleatoxin and OAG, two specific activators of PKC, produced similar effects as PMA. Inhibitors of PKC, i.e. staurosporine and chelerytrine, could inhibit the PMA-effect (1 nmol/L) significantly. After mutation of the PKC phosphorylation sites (especially S64A and T353A), PMA became ineffective. Pharmacological activation of PKA increased the current. Mutation of the single PKA phosphorylation site on Kir2.1b could not establish any significant results.
Conclusion: The human IK1 current in isolated atrial cardiomyocytes and one of its underlying clones, the Kir2.1b channel, is inhibited by PKC dependent signal transduction pathways, possibly contributing to heart arrhythmias in patients with structural heart disease.

P365 Modulation of spontaneous activity in mouse ventricular myocytes by adenovirus-mediated gene transfer of Kir2.2 channels

T. Hibino, J. Lee, K. Miwa, L. Zhang, I. Kodama. *Nagoya University, Res. Inst. of Environ. Med., Nagoya, Japan*

Purpose: To explore the feasibility of genetic modulation of intrinsic pacemaking activity of the ventricle, we investigated the effects of gene transfer of Kir2.2 channels to mouse ventricular myocytes.
Methods: wild-type Kir2.2 channels (Kir2.2-wt) and its dominant-negative mutant (Kir2.2-AAA: GYG motif of the ion selective filter was replaced by AAA) were incorporated into adenovirus vector. Cultured ventricular myocytes of neonatal mice were used for in-vitro transfection of Kir2.2-wt. Adult mice were used for in-vivo transfection of Kir2.2-AAA by a catheter-based method (Hajjar et al., 1998). Action potentials and IK1 were recorded using patch-clamp technique in a whole-cell mode.
Result: Regular spontaneous beating was observed in 12/20 (60%) control neonatal myocytes at 145 ± 10/min with resting membrane potential (RP) at -56.2 ± 3.2 mV. The Kir2.2-wt overexpressed myocytes showed less incidence of spontaneous beating (4/20 cells, 20%) at significantly slower rates (35 ± 2/min, n=4) and more negative RP (-72.3 ± 3.1 mV) (n=5, $p<0.05$). The ventricular myocytes isolated from control adult mice showed no spontaneous beating, whereas 30/100 (30%) myocytes from mice transfected with Kir2.2-AAA in-vivo showed spontaneous beating at 110 ± 10/min (Fig. 1A). The Kir2.2-AAA transfected myocytes had less negative RP (-53.8 ± 7.4 mV) and lower IK1 density (0.73 ± 0.36 pA/pF at -40 mV) than controls (-68.1 ± 0.8 mV, 2.54 ± 0.36 pA/pF) (n=8, $p<0.05$) (Fig. 1B).



Conclusion: The automaticity of ventricular myocytes can be regulated by adenovirus-mediated gene transfer of Kir2.2 channels, suggesting the feasibility of gene therapy for both brady- and tachyarrhythmias.

P366 Excitability restitution in fibrotic human myocardium depends on the architecture of fibrosis

R. Derksen[1], T. Kawara[2], J.R. de Groot[2], R. Coronel[1], R.N.W. Hauer[1], J.M.T. de Bakker[1]. [1]*Cardiology, Heart Lung Center Utrecht, Utrecht;* [2]*Experimental Cardiology, AMC, Amsterdam, Netherlands*

Progressive ventricular activation delay (PAD) starting at long coupling intervals of premature stimuli has been shown to correlate with sudden cardiac death in patients with heart disease. We studied PAD in 11 explanted hearts of patients undergoing heart transplantation and hypothesize that PAD depends on the amount and type of interstitial fibrosis.
Methods and results: Eleven hearts were studied (4 coronary artery disease, 1 hypertrophic cardiomyopathy and 6 dilated cardiomyopathy). Eight hearts were Langendorff-perfused, from the 3 remaining hearts superfused epicardial sheets (1 mm thickness) were taken and studied in a tissue bath. High resolution unipolar epicardial activation mapping (105 or 208 recording sites; interelectrode distance 0.8 or 0.5 mm, respectively) was carried out following premature stimulation in 11 hearts. Activation maps and conduction curves were constructed and correlated with histology. As a measure for PAD, the mean increase of delay (MID) was obtained from the conduction curves. Prominent increase of MID was associated with zones of patchy, dense fibrosis with long fibrotic strands and depended on the direction of propagation relative to fiber direction.. In contrast, MID was only marginally affected by short strands of fibrosis (diffuse fibrosis) with the same high density. The table shows the main results.

	Fibrosis(%)	MID(ms)	CVIIBCL(m/s)	CVIIS2(m/s)	CV=BCL(m/s)	CV=S2(m/s)
Patchy	21.8±13.8	18.4±5.8	0.28±0.07	0.05±0.01	0.57±0.13	0.31±0.12
Diffuse	20.7±13.7	5.0±1.3	0.24±0.04	0.17±0.06	0.58±0.15	0.41±0.22

Conduction velocity during BCL and after premature stimulation (S2) for different types of fibrosis. CVII and CV=: conduction velocity perpendicular (II) and parallel (=) to fiber direction during basic cycle length and S2

Conclusions: In chronically diseased human myocardium long fibrotic strands cause PAD starting at long coupling intervals of premature stimuli. MID depends strongly on the direction of the wave front with respect to fiber direction and on the architecture of fibrosis. These data suggest that patients with patchy fibrosis with long strands are more prone to develop VF than patients with diffuse fibrosis.

P367 Intercellular communication in connexin43 transfected skeletal myocytes

Y. Ma[1], O. Tolmachov[2], M. Themis[2], M. Poznansky[3], C. Coutelle[2], N S. Peters[1]. [1]*St. Mary's Hospital, ICSM, Cardiac Electrophysiology, London, United Kingdom;* [2]*Imperil College, Division of Biomedical Sciences, London, United Kingdom;* [3]*Harvard Medical School, Boston, United States of America*

Myocyte transplantation has been considered a potential therapy to repair damaged myocardium. In the attempt to create electrical coupling between cardiac and transplanted skeletal myocytes, we transfected Connexin43 cDNA (Cx43) into skeletal myocytes using a retroviral expression vector MLV-CX43-EGFP2, which produces 80% infection in these Cx43 transfected skeletal myocytes by FACS analysis of EGFP expression. We report here the results on the studies of the functional gap-junctional communication of Cx43 transfected skeletal myocytes.
2 skeletal myocyte preparations were studied: L6 cell line and primary rat skeletal myocytes. Cx43 transfected cells (Cx43) and the control cells (Cont.) were grown in culture dishes to confluence, and were placed on the stage of an epifluorescence microscope. Microelectrodes were filled with 5% fluorescence dye cascade blue. A 2-4nA current for 1min was applied to the electrode to deliver dye into the cell. Dye transfer to the adjacent cells was recorded using a DC 200 digital camera (Leica). The number of cells to which dye was transferred within 60 seconds with each injection was counted. Data were analysed statistically using T-test (two population t-test).
Four groups of experiments were carried out in this study: L6, non-transfected and transfected; Primary myocytes, non-transfected and transfected. Dye transfer occurred in 65.0% and 16.7% of L6 Cx43 and L6 Cont. respectively, and 64.7% and 13.3% of primary Cx43 and primary Cont. respectively. The number of cells to which dye was transferred with each injection ranged from 0-3 cells, and was significantly greater in the transfected culures (L6, P=0.001; primary P=0.026, table)

	L6 Cell Line N=18	Cx43 Cell Line N=20	Primary Cell N=17	Primary Cx43 Cell N=15
# Cells Dye Transferred (Mean ± SD)	0.17 ± 0.147	0.90 ± 0.621*	0.13 ± 0.124	0.70 ± 0.346*

* Compared with control, $P<0.05$

The results show Cx43 transfection induced gap junctional coupling and enhanced dye transfer in cultured skeletal myocytes, with the potential, therfore, of enhancing incorporation into the functional myocardial syncytium.

P368 Increased atrial tissue expression of angiotensin II type 1 receptor (AT-1) in an animal model of pacing induced atrial remodelling

J.A. Cabrera[1], F. Cabestrero[1], E. Garcia-Colis[1], C. Castilla[1], J.M. Rubio[1], D. Sánchez-Quintana[2], J. Farré[1], A. López-Farré[1]. [1]*Fundación Jiménez Díaz, Cardiology, Madrid, Spain;* [2]*Extremadura University, Human Anatomy, Badajoz, Spain*

Recent studies in animal models of sustained rapid atrial pacing showed that angiotensin II antagonist prevents electrical remodeling in atrial fibrillation. However no systematic investigation has been made of atrial tissue expression of angiotensin II type 1 receptor (AT-1) in this animal model. The present study was designed to assess atrial AT-1 receptor expression in the early stages of atrial remodeling in a canine model of prolongaded rapid atrial pacing.
Methods: Fifteen halothane-anesthetized adult beagle dogs underwent insertion of a transvenous lead at the right atrial appendage. Ten dogs were continuously paced at 400 bpm for 3 days and 5 dogs in sinus rhythm served as control. Right atrial effective refractory period (ERP) was measured at either baseline and after 3 days in both groups. Atrial tissue AT-1 receptor expression was determined in interatrial septum, lower right atrium, right and left atrial appendages by Western-blot and immunohistochemical staining. Additionaly fibrotic changes of the atrial myocardium were examined by conventional and electron-microscopy studies.
Results: At baseline study the right atrial ERP was similar in controls (136±15 msg) and paced dogs (120±20 msg). After 3 days of continuous pacing the ERP was significantly shorter than control (80±30 msg vs 140±10 msg; $p<0.03$). We found a basal AT-1 receptor expression in both right and left atrial myocardium. However atrial AT-1 receptor expressión increased almost 2-fold in dogs after three days of prolongaded rapid atrial pacing. This increasing was more manifested in the right than in the left atrium and more marked in the appendage and lower right atrium. These findings correlated with the expression levels of proteins detected by immunohistochemical stainig. In paced dogs, no evidence of increased extracelular fibrosis or connective tissue content was documented.
Conclusion: Rapid atrial pacing increases atrial tissue expression of angiotensin II type 1 receptor (AT-1) in early stages of atrial remodeling before appearance of fibrotic structural changes. The use of AT-1 receptor antagonist may be useful to prevent atrial fibrosis during structural remodeling of atrial fibrillation.

P369 Electrocardiographic evidence of Duchenne muscular dystrophy in a mouse model suggests a novel clinical diagnostic tool

I. Amende[1], A. Kale[2], V. Chu[1], J.M. Otero[2], T. Hampton[1] on behalf of The CuraVita Corporation. [1]*Harvard Medical School, Cardiology, Boston, United States of America;* [2]*The CuraVita Corporation, R&D, Boston, United States of America*

Objective: Record and analyze electrocardiograms (ECGs) in dystrophin-deficient (mdx) mice, a mouse model of Duchenne muscular dystrophy (DMD), to see whether they correspond to clinical observations in patients with DMD.
Methods: A new system for non-invasively recording ECGs in conscious mice (no anesthesia, no implants) and e-MOUSE ECG analyses software in male mdx (n=15) and C57 control (n=15) mice at baseline and in response to atropine (0.5 mg/kg, i.p.) and phenylephrine (3 mg/kg i.p.).
Results: We demonstrate that mdx mice have significant tachycardia, consistent with observations in Duchenne patients. Heart rate was nearly 15% faster in mdx mice (809 ± 5 bpm) than in control mice (706 ± 13 bpm, $P<0.01$). ECGs revealed significant shortening of the rate corrected QT interval duration (QTc) in mdx mice compared to control mice (55.5 ± 0.5 ms vs. 61.6 ± 1.5 ms, $P<0.05$). PR interval durations were shorter at baseline in mdx compared to control mice (27.2 ± 0.4 vs. 29.4 ± 0.5 ms, $P<0.05$). The muscarinic antagonist atropine significantly decreased heart rate and increased PR interval duration in all mdx mice but not in control mice. Compared to the effects in C57 mice, atropine administration in mdx mice led to significantly greater changes in HR (-90 ± 14 bpm vs. +21 ± 12 bpm, $P<0.05$) and significantly smaller changes in HRV (+0.1 ± 0.1 ms vs. -1.6 ± 0.7 ms, $P<0.05$). mdx mice administered phenylephrine demonstrated significantly smaller reductions in HR compared to C57 mice, (-132 ± 27 bpm vs. -312 ± 39 bpm, $P<0.05$). Pharmacological autonomic blockade and baroreflex sensitivity testing demonstrated an imbalance in autonomic nervous system modulation of heart rate, with decreased parasympathetic activity and increased sympathetic activity in mdx mice.
Conclusions: mdx mice have tachycardia and an autonomic nervous system imbalance affecting heart rate modulation, consistent with observations in Duchenne patients. The cholinomimetic effects of atropine in mdx mice but not in C57 control mice suggest a simple test that may be predictive of dystrophin-deficiency.

P370 A French hot spot in KCNQ1 at position 174 is associated with mild forms of congenital long QT syndrome

I. Denjoy[2], M. Imboden[1], M. Berthet[1], V. Fressart[3], D. Klug[4], G. Vaskmann[4], B. Hainque[3], P. Guicheney[1]. [1]*Hopital Pitié-Salpêtrière, INSERM U523, Paris, France;* [2]*Hopital Lariboisière, Service Cardiologie, Paris, France;* [3]*Hopital Pitié-Salpetrière, Service de Biochimie, Paris, France;* [4]*Hopital Cardiologique, Lille, France*

Background: Long QT syndrome (LQTS) is characterized by QT prolongation on the surface ECG and ventricular arrhythmias responsible for syncope and sudden death. It is a heritable ion channel disease caused by mutations in genes encoding sodium or potassium ion channel subunits. Genetic abnormalities are most frequently found in the potassium channel genes KCNQ1 (LQT1) and HERG (LQT2).
Methods: The genotyped LQTS population included 90 LQT1 families, 40 LQT2 families and 6 LQT3 families. The phenotype of each subject was ascertained by clinical history, ECG and Holter recording. We analyzed the phenotype of the most frequent mutation in LQT1.
Results: Sixty-four mutations were identified in KCNQ1 among the 90 LQT1 probands. Arginine at position 174 was the most frequently mutated aminoacid (8 families, 33 carriers). R174 was replaced either by a cysteine (R174C) in 5 families (n=20) or by a histidine (R174H) in 3 families (n = 13). In one patient with congenital deafness R174C was homozygous, and in another case the mutation was associated with a second LQT1 mutation (R293C). Two probands out of 5 were asymptomatic and were diagnosed by routine ECG testing before DNA testing.There was no history of sudden death in these families. The phenotypes of R174C carriers were found to be milder compared to R174H carriers with regards to both QTc duration (449 ± 49 ms, n = 20, versus 484 ± 31 ms, n = 13) and to syncopes (3/20 versus 6/13).
Conclusions: R174 was the most frequently mutated amino acid in the French LQT1 population. The R174C mutation was clearly associated with a mild phenotype, whereas R174H presented with a higher penetrance. Such mutations can be a precipitating factor for ventricular arrhythmias in the setting of QT prolonging drugs.

P371 Paced electrogram fractionation in symptomatic and asymptomatic long QT patients

M. Sterlinski[1], M. Pytkowski[1], H. Szwed[1], A. A. Grace[2], R. C. Saumarez[2]. [1]*National Institute of Cardiology, Ischaemic Heart Disease Dept., Wars, Poland;* [2]*Cambridge University, Papworth Hospital, Cambridge, United Kingdom*

Background: Paced ventricular electrogram fractionation (PEF), increased electrogram duration and number of potentials following premature paced extrastimuli related to inhomogenous conduction are strongly associated with VF in patients with hypertrophic cardiomyopathy. Aim of study was to analyse PEF in pts with long QT syndrome (LQTS). Material and methods: PEF was studied in 30 patients: 26 females and 4 males, aged 11-56 (mean 27), with LQTS. All pts had QTc > 440 ms, and no structural heart diseases. Group consisted of: 10 pts after aborted VF, 6 pts with syncopies and 14 asymptomatic patients. Controls (12 pts) were studied after diagnostic, normal EP. Stimulation protocol was S1S2 490 ms and S1S2 450-220 ms, shortening 1 ms every third beat. Potentials of each electrogram obtained from recording electrodes were plotted against S1S2. Characteristics of the pts were (average from all electrodes): value of S1S2 at which delay occurred and corresponding increase of duration of electrogram. Multivariate discrimination analysis and Fisher's exact test for statistics were used. Results: All LQTS patients had increased fractionation compared to controls (328,4+21,4ms/13,7+8,7ms vs. 270+11,4ms/3,1+3,7ms, $p<0,01$). Fractionation was higher in LQTS pts with VF than in all other LQTS pts (339+23,5ms/15,1+9,8ms vs. 322+19ms/13,2+8,9ms, $p<0,04$). Results showed increase in electrogram delay with an increased number of potentials in symptomatic, especially VF, pts. Conclusions: Patients with the LQTS demonstrated large intraventricular conduction delays, strongly visible with the symptoms aggravation, that is compatible with functional re-entrant substrate theory and suggests that PEF analysis may be useful in risk assessment in LQTS patients. Observed delays may be result of axial block due to local refactoriness and consequent slowed transverse and anisotropic activation.

P372 Gender-related proarrhythmia in a rabbit model of LQT2 and LQT3

P. Milberg, L. Eckardt, P. Kirchhof, L. Fabritz, N. Reinsch, S. Ramtin, G. Breithardt, W. Haverkamp. *Medizinische Klinik und Poliklinik C, Münster, Germany*

Recent clinical observations indicate that female gender is associated with a high risk of developing cardiac arrhythmias especially of the torsade de pointes (TdP)-type in humans. We therefore sought to investigate gender differences in a previously developed rabbit heart model of TdP. Methods and Results: In 40 Langendorff-perfused rabbit hearts, the IKr-blocker erythromycin (E; 150-300μM) as well as veratridine (V, 0.1-0.5μM), an inhibitor of sodium channel inactivation, led to significant increase in QT-interval and monophasic action potential (MAP) duration in male (E; n=13, V: n=9) as well as in female (E: n=11, V: n=7) hearts and thereby mimicked long QT (LQT)2 and LQT3 syndrome. In bradycardic (AV-blocked) hearts, up to eight simultaneous epi- and endocardial MAP demonstrated a significant increase in dispersion of repolarization in male and female hearts. There was no significant difference in QT-interval or mean APD50 or APD90 between female and male hearts at baseline or after infusion of E and V. In E-treated hearts 6 (46%), 9 (69%) and 10 (76%) of 13 male hearts showed early afterdepolarizations (EAD) and developed TdP at the three concentrations. In female hearts, 9 (82%) 11 and 11 of 11 hearts showed EAD and TdP (p=ns as compared to male). In V-treated-hearts, 1 (11%), 8 (89%) and 9 of 9 male hearts showed EAD and developed TdP at the three concentrations. In female hearts, 1 (14%) 7 and 7 of 7 hearts showed EAD and TdP (p=ns as compared to male). Conclusion: Rabbit hearts show a high incidence of proarrhythmia of the TdP-type in a model of LQT2 and LQT3 and are thereby an excellent model for drug screening. Due to the high incidence of proarrhythmia there is only a slight gender difference in this animal model.

P373 Efficacy of antiarrhythmic therapy in patients with effort polymorphic ventricular arrhythmias and ryanodine receptor gene (RyR2) mutations

B. Bauce[1], A. Rampazzo[2], C. Basso[3], A. Bagattin[2], L. Daliento[1], G.A. Danieli[2], G. Thiene[3], A. Nava[1]. [1]*University of Padua, Department of Cardiology, Padua, Italy;* [2]*University of Padua, Department of Biology, Padua, Italy;* [3]*University of Padua, Department of Pathology, Padua, Italy*

Background: effort induced polymorphic ventricular arrhythmias (PVA) have been recently proved to be linked to ryanodine receptor gene (RyR2) mutations. Beta-blocker therapy seems to play a role in avoiding or reducing the incidence of arrhythmias and to prevent sudden death (SD).
Aim of the study: to evaluate the efficacy of therapeutic strategies in the long term follow-up of patients with PVA associated with RyR2 mutations.
Materials and methods: in 1985 a family in which four cases of juvenile SD had occurred was studied. In all family members genetic study was carried out. The family consisted of 26 living subjects belonging to three generations (11 M, 15 F, mean age 32±15 yrs). Thirteen subjects (6M, 7F, mean age 30±16 yrs) showed effort induced PVA (non sustained ventricular tachycardia or premature ventricular beats); they all underwent beta-blocker therapy (acebutolol 200 to 600 mg daily) and were strongly advised to avoid strenuous physical exercise. Stress test was undertaken to evaluate the efficacy of therapy.
Results and follow-up: DNA testing proved the presence of RyR2 mutation N2386I in 14 subjects (6M, 8F, mean age 29±17 yrs), all with PVA except one (female, 10 yrs old). Five subjects had syncopal episodes and three experienced dizziness before the beginning of antiarrhythmic therapy. In four subjects who were younger than 12 at the time of the first visit, arrhythmias appeared during the follow-up (mean age 14±1 yrs). Beta-blocker therapy caused the disappearance of PVA in 20% of cases, while in the remaining subjects arrhythmias appeared at a higher level of load and consisted of isolated ventricular premature beats in the majority of cases. During follow-up (2 to 16 yrs, mean 9) no patient had syncopal episodes or died suddenly.
Conclusions: the long term follow-up of this family demonstrates the efficacy of beta-blocker therapy in reducing PVA and preventing SD. The therapeutic strategy in asymptomatic carriers of RyR2 mutations remains a challenge, since SD may be even the first manifestation of the disease.

P374 A deletion in the calsequestrin gene (CASQ2) causes the autosomal dominant form of catecholaminergic polymorphic ventricular tachycardia

C. Napolitano[1], M. Memmi[1], M. Gasparini[2], B. Colombi[1], R. Bloise[1], E. Ronchetti[1], S.G. Priori[1]. [1]*Salvatore Maugeri Fondation, Molecular Cardiology Dept., Pavia, Italy;* [2]*Humanitas Hospital, Cardiology Division, Rozzano, Italy*

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an inherited arrhythmogenic disease characterized by adrenergically (emotion and/or exercise) induced syncope and sudden death manifesting during childhood and adolescence in the absence of cardiac structural abnormalities. The disease is mainly transmitted with an autosomal dominant pattern even if a rare autosomal recessive form has been reported. We recently demonstrated that the cardiac ryanodine receptor gene (RyR2) is a gene involved in the autosomal dominant form of the disease, while Lahat et al identified mutations in the Calsequestrin gene (CASQ2) in the rare autosomal recessive variant. Calsequestrin is a component of the calcium release complex of the sarcoplasmic reticulum and is functionally linked to RyR2. Here we provide the first evidence of a link between the autosomal dominant form of CPVT and the CASQ2 gene. An eleven year old Caucasian female with history of syncope was referred for evaluation. Baseline ECG was unremarkable with normal QT interval and runs of fast non-sustained polymorphic ventricular tachycardia were elicited at exercise stress test. The 45 year old mother had experienced repeated syncopal episodes triggered by physical activity and she also presented ventricular arrhythmias at exercise stress test. No signs of structural heart disease were present in both patients. The diagnosis of autosomal dominant CPVT was established and molecular screening of the RyR2 gene was performed on genomic DNA. No mutations were identified in the open reading frame of RyR2 while molecular screening of the CASQ2 gene led to the identification of a 16 bp deletion creating a frameshift and a truncation of the distal 2/3 of the protein leading to haploinsufficiency. This mutation was present in the proband and her mother in the heterozygous state but not in the unaffected father and in 400 control individuals.
In summary present data suggest that CASQ2 is a novel gene responsible for the autosomal dominant variant of CPVT further supporting the concept that arrhythmias in CPVT are caused by abnormal intracellular calcium handling.

P375 QT dispersion in Arg 403 Gln missence point mutation of beta-myosin-heavy-chain in hypertrophic cardiomyopathy families

M. Ersanli, N. Gultekin, E. Kucukates, H. Mutlu. *Institue of cardiology, Istanbul, Turkey*

Backgraund: QT dispersion (QTD) is regarded as an important prognostic factor in hypertrophic cardiomyopathy (HCM). Prolongation of QTD may be variable in different HCM genotypes. The aim of this study is the examination of the degree of QTD in Arg 403 Gln missence point mutation of beta-myosin-heavy-chain (MHC) in HCM families.
Methods: The study was carried out on 17 HCM families with 28 cases of HCM (12 females, 16 males) and 90 phenotype-negative relatives (56 females, 34 males), thus on a total of 118 cases screened by history, physical examination, ECG, two-dimensional echocardiography and genetic examination. QT interval was measured in all leads from a standart 12-lead ECG. QTD was calculated as the maximal difference between QT intervals in any two leads, and corrected for heart rate (QTcD) with Bazett formula.
Results are shown in table.

	HCM Arg 403 Gln (+) n=7	HCM Arg 403 Gln (-) n=21	p value	Relatives Arg 403 Gln (+) n=13	Relatives Arg 403 Gln (-) n=77	p value
QTD (msec)	50±10	77±35	0.029	40±11	35±13	NS
QTcD (msec)	44±22	73±36	0.03	41±21	31±17	0.028

Conclusion: QTD and QTcD were significantly shorter in the patients with positive Arg 403 Gln missence point mutation of beta-MHC, although poor prognosis is frequently seen in this mutation. However, in the healthy relatives group, the QTcD value was significantly higher in those with positive mutation. As a result, we could not prove QTD as a significant indicator of Arg 403 Gln mutation.

P376 The role activation of sarcolemmal ATP-sensitive potassium channels play in ischaemic ST-segment changes and ventricular fibrillation

G.E. Billman[1], H.C. Englert[2], H. Goegelein[2], A.E. Busch[2]. [1]*The Ohio State University, Physiology, Columbus, Ohio, United States of America;* [2]*Aventis Pharma, Frankfurt, Germany*

It is well established that myocardial ischemia is accompanied by characteristic changes in the ST-segment of the ECG. However, the cellular events that are responsible for these ECG changes remain to be identified. The activation of sarcolemmal ATP-sensitive potassium (KATP) channels during myocardial ischemia has been shown to lead to potassium efflux with corresponding reductions in action potential duration. The resulting heterogeneity in repolarization could contribute to both the ECG changes and malignant arrhythmias induced by ischemia. To test this hypothesis, ischemia was induced a 2 min occlusion of the left circumflex coronary artery during the last min of exercise in dogs with healed myocardial infarctions. The exercise plus ischemia test provoked both significant (ANOVA, $P<0.01$) ST-segment depression (-6.5 ± 0.8 mm) and ventricular fibrillation in these animals (n=29). On subsequent days, the exercise plus ischemia test was repeated after pretreatment with one of the following KATP channel antagonists: sarcolemmal selective antagonists (HMR 1098, 3.0 mg/kg i.v., n=13) and HMR 1402 (3.0 mg/ kg i.v., n=4); mitochondrial selective antagonist 5-hydroxydecanoic (5-HD, 30 mg/kg i.v., n=5), or non-selective antagonist glibenclamide (1.0 mg/kg i.v n=7). Glibenclamide (-2.7 ± 1.5 mm), HMR 1098 (-3.1 ± 1.2 mm), HMR 1402 (-1.8 ± 1.9 mm), but not 5-HD (-4.5 ± 1.3 mm), significantly attenuated the ischemic ST segment changes and protected against ventrciular fibrillation (HMR 1098, 11 of 13; HMR 1402, 4 of 4; glibenclamide, 6 of 7; and 5-HD, 0 of 5 animals protected). In a similar manner, a 30 min occlusion of the left anterior descending artery occlusion followed by reperfusion in anesthetized (alpha-chloralose/urethane) dogs elicited significant reductions is the ST-segment throughout the ischemic period (-4.3 ± 0.9 mm, n=3) that were reduced by HMR 1098 (-1.6 ± 0.6 mm, n=5), HMR 1402 (-0.7 ± 0.7 mm, n=3) and glibenclamide (-1.0 ± 0.2 mm, n=3). In contrast to the lethal arrhythmias induced during ischemia, these drugs failed to prevent the ventricular fibrillation induced by reperfusion in any animal. These data suggest that the activation of cardiac sarcolemmal ATP-sensitive potassium channels may be responsible for the ST-segment changes induced by myocardial ischemia. These data further suggest that the activation of ATP-sensitive potassium channels plays a critical role in the induction of ventricular fibrillation during ischemia but not during reperfusion.

P377 Amiodarone-induced post-repolarization refractoriness prevents induction of ventricular fibrillation in the isolated rabbit heart

P. Kirchhof[1], H. Degen[2], M. R. Franz[3], L. Fabritz[2], L. Eckardt[2], G. Breithardt[2], W. Haverkamp[2]. *[1]University Hospital Münster, Cardiology and Angiology Dpt., Münster, Germany; [2]Cardiology and Angiology and IfA, Münster, Germany; [3]VA and Georgetown Univ.Medical Centers, Cardiology and Pharmacology, Washington DC, United States of America*

It is still incompletely understood why amiodarone is such a potent antiarrhythmic drug. Sodium channel blockers prevent induction of ventricular fibrillation by inducing post repolarization refractoriness (PRR), but this antiarrhythmic effect is offset by conduction slowing (Circulation 97: 2567-2574). We studied to which extent amiodarone induces PRR and conduction slowing and related these effects to induction of ventricular arrhythmias.

The hearts of 13 amiodarone-pretreated (50mg/kg po for 6 weeks) rabbits and 14 controls were isolated and 8 monophasic action potentials were simultaneously recorded from the epicardium and endocardium of both ventricles. Steady state action potential durations (APD), activation times, refractory periods (ERP), and dispersion of APD were determined and digitally analyzed during programmed stimulation. Burst stimuli (20ms burst cycle length (CL), 5s duration, 2-10 x stimulation threshold) were applied to induce ventricular fibrillation.

Amiodarone prolonged APD at 50, 70, and 90% repolarization by 12-15ms at CL from 200-600ms (all $p<0.01$), but did not significantly change activation times or dispersion of APD. During programmed stimulation, amiodarone prolonged the shortest S2-induced APD and prolonged ERP more than APD, resulting in PRR (APD90 minus ERP Amio: 14±10ms, $p<0.05$). During burst stimulation, amiodarone induced even more PRR (Amio: 40±15ms vs. Base: 22±13ms, $p<0.05$) and reduced the inducibility of ventricular arrhythmias by 40% ($p<0.05$ vs. base). At high burst strengths, monomorphic ventricular tachycardias were induced instead of ventricular fibrillation in 35% of bursts ($p<0.05$ vs. base). PRR during burst stimulation protected against induction of arrhythmias at baseline and with amiodarone, while lack of PRR was associated with induction of ventricular fibrillation ($p<0.05$).

Conclusions: Chronic amiodarone treatment causes post-repolarization refractoriness without relevant conduction slowing. This effect prevents the induction of ventricular fibrillation and, evenly important, converts induced arrhythmias from ventricular fibrillation to monomorphic ventricular arrhythmias.

P378 Comparison of the electrophysiological effect on atrial myocardium between Ic antiarrythmic drugs, pilsicainide and flecainide

H. Kakugawa, A. Shimizu, T. Yamagata, M. Esato, T. Ueyama, M. Ohmura, M. Kimura, M. Matsuzaki. *Yamaguchi University, 2nd Departiment of Internal Medicine, Ube, Japan*

The purpose of this study is to compare the effect of Ic-antiarrhythmic drugs on atrial electrophysiological characteristics. Pilsicanide is known as the pure Na channel blocker and flecanide is well known as class IC drug. Method: Subjects were 22 patients (51±13 years-old: P-group) in whom pilsicainide was administrated intravenously (1mg/kg/10min.) and 38 patients (49±15 years-old: F-group) in whom flecainide was administrated intravenously (2mg/kg/10min.). Atrial effective refractory periods (A-ERP), intra-atrial conduction time (CT), max intra-atrial conduction delay (max CD), repetitive atrial firing zone (RAFZ), fragmented atrial activity zone (FAZ), intra-atrial conduction delay zone (CDZ) were measured before and after drugs. CT was defined as the interval from the stimulus to the atrial deflection at the distal portion of the coronary sinus. Conduction delay (CD) was defined as the difference of CTs at between extrastimulus and basic cycle length. Positive conduction delay was defined as the increase in CT at extrastimulus $\geq$20 ms, comparing to CT at basic cycle length. The CDZ was defined as the range of the coupling interval, that shows positive conduction delay. RAF was defined as the occurrence of two or more premature atrial complexes. The presence of fragmented atrial activity (FAA) was defined as duration of A2/duration of A1 $\geq$150%. The FAZ was defined as the range of the coupling interval that resulted in FAA. Results: Pilsicainide and flecainide significantly prolonged A-ERP (210±27ms to 245±37ms; $p<0.001$, 217±32ms to 242±35ms;$p<0.001$, respectively) and CT (128±33ms to 160±40ms; $p<0.001$, 125±21ms to 154±28ms; $p<0.001$, respectively). The percentage of prolongation of A-ERP was 17±15% in P-group and 13±17% in F-group. The percentage of prolongation of CT was 26±15% in P-group and 24±13% in F-group. RAFZs were significantly improved in both group (22±25msec to 6±28msec;$p = 0.014$, 21±27msec to 11±22msec; $p = 0.039$, respectively). However, Max CD was shortened by pilsicainide, but not by flecainide (67±13msec to 52±33msec in P-group ($p = 0.027$) and 65±25msec to 61±28msec in F-group ($p = 0.383$)). FAZ and CDZ were improved in P-group (27±33ms to 12±33ms;$p = 0.011$, 54±28ms to 43±35ms, $p = 0.075$, respectively), but not in F-group. Conclusions: These data may indicate the possibility that the effect of pilsicainide on atrial vulnerability is stronger than that of flecainide.

P379 Effects of K (ATP) channel blocker on monophasic action potential and coronary flow in Langendorff-perfused guinea pig hearts under hypoxia

A. Weyermann[1], M. Bleich[1], A E. Busch[1], H.C. Englert[1], H. Goegelein[2]. *[1]Aventis Pharma Deutschland GmbH, Cardiovascular Agents, Frankfurt/Main, Germany; [2]Aventis Pharma Deutschland GmbH, Cardiovascular Agents, Frankfurt am Main, Germany*

ATP-sensitive potassium (K(ATP)) channels are present in the sarcolemmal membrane of cardiac muscle as well as in smooth muscle cells of coronary arteries. The channels are activated under hypoxic and ischemic conditions. In coronary arteries there is some residual activity during normoxia. Selective blockade of K(ATP) channels in the sarcolemmal membrane of cardiac myocytes was shown to prevent ventricular fibrillation in a dog model of sudden cardiac death (Billman et al. 1998 J. Pharmacol. Exp. Ther. 286:1465-1473). Blockade of K(ATP) channels in coronary arteries reduces the coronary flow and consequently, the supply with oxygen and substrates. Therefore, the aim is to develop selective blockers for the sarcK(ATP) with little effect on coronary flow as novel antiarrhythmic drugs.

We used a Langendorff-model of isolated perfused guinea pig hearts in which both effects could be compared. For sarcK(ATP)channels, the duration of the monophasic action potential at 90% repolarisation (MAPD) was recorded during low flow ischemia (1.2 ml/min, oxygen-free). The effects on the coronary flow were tested by perfusion at constant pressure (55 mmHg) with hypoxic buffer solution (gassed with 20% instead of 95% oxygen).

Results: For glibenclamide, repaglinide, HMR 1402 and HMR 1098 the half-maximal inhibition of the ischemia-induced shortening of the MAPD was 95 nM, 74 nM, 110 nM and 550 nM, respectively, whereas half-maximal inhibition of the hypoxia-induced increase in coronary flow was 25 nM, 220 nM, 9.7 μM and > 10 μM, respectively. The sulfonylureas glibenclamide as well as the carboxylic acid repaglinide are potent blocker both of the sarcK(ATP) channel, and the vascular K(ATP) channel. In contrast, the sulfonylthiourea HMR 1402 is nearly as effective as glibenclamide on inhibition of MAPD shortening, but for reduction of the coronary flow a 88fold higher concentration of HMR 1402 is necessary. The sulfonylthiourea HMR 1098 is somewhat less effective on the sarcK(ATP) channel but has no significant effect on K(ATP) channels in coronary arteries at concentrations up to 10 μM.

In conclusion, the Langendorff-perfused guinea pig heart is a good model to study the effects of K(ATP) channel blocker on the cardiac monophasic action potential and on the coronary vascular system. It could be confirmed that glibenclamide and repaglinide are potent, but unselective blocker. HMR 1098 and HMR 1402 show good selectivity to the cardiac K(ATP) channel, and therefore, are considered as novel drugs for the development against ischemically induced sudden cardiac death.

P380 Conduction delay within the coronary sinus in humans: implications for atrial arrhythmias

D. Katritsis[1], J.P.A. Ioannidis[2], E. Giazitzoglou[1], S. Korovesis[1], A. Papadopoulos[1], N. Chrysomalis[1], C.E. Anagnostopoulos[1], A.J. Camm[3]. *[1]Athens EUROCLINIC, Cardiology, Athens, Greece; [2]University of Ioannina, Epidemiology, Ioannina, Greece; [3]St George's Hospital Medical School, Cardiological Sciences, London, United Kingdom*

Myocardial connections between coronary sinus and left atrium have been described in humans. Their conduction properties and potential arrhythmogenicity in patients with and without paroxysmal atrial fibrillation (PAF) are unknown.

Methods: Twenty-one patients (pts) with PAF, 32 pts with other arrhythmias, and 25 pts without arrhythmia, underwent catheter mapping of the CS from the distal, superoposterior part to the ostium during sinus rhythm, CS pacing, and right atrial pacing.

Results: Discrete double potentials or fractionated electrograms, indicative of delayed conduction, were recorded during proximal coronary sinus or right atrial pacing in 14 (66.7%), 11 (34.4%), and 5 (20.0%) pts, respectively ($P=0.004$). In 29 pts, double potentials were recorded at the distal, superoposterior CS, in 3 at mid-CS and in 4 at the ostium. Spontaneous or induced atrial tachyarrhythmias were recorded in 18 (85.7%), 12 (37.5%), and 2 (8.0%) pts in the three groups, respectively ($P<0.001$) and were originating from the CS in 6, 3, and 0 patients, respectively ($P=0.010$).

Conclusions: Recording of double potentials is possible within the CS, particularly at its distal, superoposterior part, near the left superior pulmonary vein. Their prevalence is higher in patients with PAF than in subjects with other or no arrhythmias and their presence denotes possible delayed conduction and substrate for atrial arrhythmias.

P381 A prospective study of atrial fibrillation after acute myocardial infarction: multivariate risk analysis using P-wave duration on SAECG, P-wave dispersion and clinical variables

M. Rosiak, H. Bolinska, J. Ruta. *Lodz, Poland*

Purpose: P-wave duration on SAECG (PWD) and P-wave dispersion on standard ECG (Pd) are markers of intra-atrial conduction disturbances. Purpose of this study: to evaluate prospectively whether PWD and Pd can predict development of AF in patients (pts) with AMI.
Methods. Study population: 130 pts with AMI (100 men, 30 women, aged 56,9±12,3). Assesed parameters: Pd=Pmax-Pmin in the surface ECG; pts during first 24-hours in hospital underwent SAECG from XYZ leads, PWD signals at noise < 0,4mV analysed.
Results: 22 (16,9%) pts developed AF. Pd was more prolonged in the pts with AF than in those without AF (34,47 vs 19,68ms, p<0,05). PWD was longer (131,94 vs 116,24ms; p<0,05) in pts with AF. PWD>125ms and Pd>25ms defined pts at high risk of AF in optimal spec/sens ratio.

	sensivity	specifity	ppa	npa	OR(95%CI),p<0,05
PWD>125ms	74%	77%	40%	92%	6,2(1,4-26,5)
Pd>25ms	81%	82%	53%	96%	23,5(5,5-100,6)

*ppa/npa = positive/negative predictive accurancy; OR = odds ratio; CI = confidence interval

Univariate anlysis variables associated with development of AF: age>65, Killip class III-IV, PWD>125ms, and Pd>25ms. Stepwise logistic regression analysis showed that age>65, PWD>125ms and Pd>25ms were independently associated with AF.Conclusions: PWD and Pd both measured in a very early period of AMI are useful in predicting AF.®

P382 Study of initiation and perpetuation of atrial fibrillation in a computer model of human atria based on magnetic resonance images

V. Jacquemet[1], N. Virag[2], C. Henriquez[3], O. Blanc[1], J-M. Vesin[1], E. Pruvot[3], L. Kappenberger[3]. *[1]EPFL, Signal Processing Institute, Lausanne, Switzerland; [2]Medtronic Europe SA, Tolochenaz, Switzerland; [3]CHUV, Division of Cardiology, Lausanne, Switzerland*

While different mapping techniques have provided significant information on the electrophysiological processes associated with atrial fibrillation (AF), the mechanisms underlying its initiation and perpetuation remain unclear. Hence its treatment is sometimes based on empirical considerations. A computer model of atrial fibrillation offers the advantage of providing reproducible information at multiple biological scales. Furthermore, it is possible with such a model to study separately the parameters leading to the initiation and perpetuation of AF.
Methods: An electro-anatomical model of human atria has been developed using an ionic-based membrane model and geometry derived from segmented MR images of human atria. The three-dimensional surface includes obstacles corresponding to the location of major vessels and valves. The main advantage of this model is its ability to simulate several seconds of AF in a tissue with realistic size and membrane kinetics. Clinically relevant protocols, such as single-site burst pacing, were used to initiate AF (defined as multiple reentrant wavelets). The model outputs both transmembrane potential maps and electrograms at any location, facilitating comparisons of simulation results to experimental clinical data. The dynamics of AF was investigated for different action potential durations (APD) and restitution properties.
Results: In our baseline model with normal conduction velocity and APD, AF was inducible but non sustained. Initiation was dependent on the restitution properties. The first wavebreaks tend to occur in regions where the curvature varies rapidely (righ and left appendages for example). However, AF converted to sinus rhythm after a few seconds, usually preceded by a gradual reorganization and a decrease in the number of wavelets. Time to self-termination was difficult to predict from potential maps or indices of organization such as the number of wavelets. However, significant longer runs of AF could be obtained by an abrupt reduction of APD, corresponding to electrical remodeling. The influence of APD on the average duration of AF was computed.
Conclusion: The maintenance of multiple wavelets appears to be a consistent feature of AF. The simulations studies suggest that the restitution dynamics (describing the dependence of the action potential duration on the previous diastolic interval) and the APD may play a crucial role in determining initiation and duration of AF. This new computer model therefore allows us to confirm existing hypothesis and develop new concepts in AF.

P383 Time interval from the initiation of the P wave to the start of left atrial appendage ejection flow predicts atrial fibrillation recurrence

O. Kinay[1], C. Nazli[2], O. Ergene[1], A. Dogan[1], O. Gedikli[1], Y. Hoscan[1], G. Acar[1], A. Altinbas[1]. *[1]Suleyman Demirel University, Cardiology Dept., Isparta, Turkey; [2]Izmir, Turkey*

Purpose: The rate of paroxysmal and persistent atrial fibrillation (AF) recurrence is high and unpredictable. This study investigates the ability of a novel method based on the measurement of the time interval from initiation of the electrocardiographic P wave to the start of left atrial appendage (LAA) ejection flow (P-LAA time) in predicting the risk of AF recurrence. P-LAA time was thought to reflect the interatrial conduction time which may be considered as a predictor of AF recurrence.
Methods: Fourty-five consecutive patients (age:61±11, 20 male) with newly diagnosed AF (AF duration: 132±725 hours) who converted to sinus rhythm spontaneously or with cardioversion were studied prospectively.
Real-time, simultaneous tracings of electrocardiogram and transesophageal Doppler recordings of the left atrial appendage flow was obtained in each patient. The time interval from the initiation of the electrocardiographic P wave to the start point of Doppler echocardiographic left atrial appendage ejection wave was measured (P-LAA time). This time interval was thought to reflect the interatrial conduction time; since the beginning of P wave is recorded when the depolarization first begins in the right atrium close to sinus node, and ejection of left atrial appendage which is quite away from sinus node, can only occur after the propagation of impulses up to left atrial appendage. Various clinical and echocardiographic parameters (age, sex, left and right atrial dimensions and areas, left and right atrial volumes, spontaneous echo contrast grade in LAA, flow velocity profiles and fractional area shortening of LAA)were analyzed with multiple regression analysis to identify the major predictors of AF recurrence.
Results: The patients were followed for a period of 163±72 days for the recurrence of AF. AF recurred in 17 (38%) patients after a mean time of 81±67 days. P-LAA time was significantly higher in patients with AF recurrence (123±36 vs. 92±24 msec, p=0.0047) and multiple regression analysis revealed that P-LAA time was the only significant independent predictor of AF recurrence (p=0.046). Left and right atrial dimensions, markers of LA and LAA mechanical function and other clinical factors were not identified as independent predictors of AF recurrence.
Conclusion: The results of the current study indicates that P-LAA time, which is thought to reflect interatrial conduction, may be considered as a reliable, independent predictor of AF recurrence.

P384 The increase of the atrial pacing ratio determines the antiarrhythmic effect of atrial overdrive pacing – experiences from the PROVE study

R.C. Funck[1], L. Slegers[2], K. Pomsel[1], H. Naegele[3], A. Capucci[4], R. Nitzsché[5] on behalf of the PROVE Study Group. *[1]Philipps University Marburg, Department of Cadiology, Marburg, Germany; [2]Sint Joseph Ziekenhuis, Dept. of Cardiology, Velhoven, Netherlands; [3]University Hospital Hamburg-Eppendorf, Hamburg, Germany; [4]Ospedale Civile, Piacenza, Italy; [5]le Plessis Robinson, ELA Medical, Paris, France*

The PROVE study intended to assess the benefit of fixed overdrive pacing in the prevention of atrial arrhythmias (AA). This sub-analysis is focused on the influence of the increase of the atrial pacing (Ap) ratio in patients implanted with dual-chamber pacemakers (ELA Talent DR 213).
Methods: AA burden was assessed by using appropriate Fallback Mode Switch episode (FMS) and atrial bursts documented by the pacemaker. After 1 month of monitoring, patients with >2 FMS were submitted to the following randomized therapies (T), each with a duration of 3 months. T1: basic rate (BR) = mean atrial rate + 10 bpm, rest rate (rR) = 60 bpm; T2: BR = rR = 60 bpm. The population was divided into 2 groups (G) according to the increase in Ap between the two therapies, compared to the median: GI: <15%, GII: >15%.
Results: Among 33 patients (15 males, 71±7 years), 4 presented with an AV-Block (AVB), 10 with a Sinus Node Dysfunction (SND), 9 a Brady-Tachy Syndrome (BTS), 9 AVB±SND±BTS and 1 AV node ablation.

Increase of the atrial pacing ratio

		threapy 1	therapy 2	p*
Group I (n=16)	mean Ap ratio	91 ± 10	88 ± 12	ns
	mean number of FMS	65 ± 97	62 ± 93	ns
	mean number of A bursts	318 ± 680	386 ± 693	ns
Group II (n=17)	mean Ap ratio	80 ± 10	49 ± 18	0001
	mean number of FMS	12 ± 21	50 ± 92	01
	mean number of A-bursts	109 ± 154	243 ± 361	03

Conclusion: Our results suggest that overdrive pacing is efficient in preventing AA only if it can significantly increase the atrial pacing ratio.

P385 Heart rate turbulence in patients with acute myocardial infarction: Impact of ischaemia and reperfusion

H. Bonnemeier, U.K. Wiegand, J. Friedlbinder, H.A. Katus, G. Richardt.
Medizinische Universität zu Lübeck, Medizinische Klinik II, Lübeck, Germany

Introduction: It has been shown that decreased heart rate turbulence (HRT), a surrogate marker for reflectoric parasympathetic activity, is associated with an increased risk of subsequent mortality in patients in the chronic phase after acute myocardial infarction (AMI). However, the impact of successful reperfusion therapy on HRT and the course of HRT from the acute to the chronic phase in AMI has so far not been investigated.
Methods: Therefore we prospectively enrolled 187 patients undergoing successful direct PCI (TIMI 2 and 3) for a first AMI. Turbulence onset (TO) and turbulence slope (TS) were determined after single ventricular premature beats in the time interval before reperfusion (I.), within the initial two hours after reperfusion (II.), and within the time period from hour 12 to hour 24 after reperfusion (III.) from 24-hour-Holter-ECG-recordings initiated on hospital admission. On day ten after AMI, TO and TC were again determined from an additional 24-hour-Holter-recording (IV.). A total of 133 patients fulfilled the clinical and technical inclusion criteria.
Results: There was a significant increase of TO and TC after reperfusion, followed by a constant moderate rise of both parameters within the observation period (table).

HRT before and after reperfusion in AMI

HRT variable	I.	II.	III.	IV.
Turbulence onset (%)	-0.25±3.3	-1.56±2.6 **	-1.76±2.8 #	-1.94±2.7 ¶
Turbulence slope (ms/RR)	15.9±14.6	18.9±17.7 **	19.7±16.1	22.6±18.1 ¶

** p<0.001 for I. versus II.# p<0.05 for II. versus III.¶ p<0.05 for III. versus IV.

Conclusions: The rise of HRT after successful reperfusion may be a previously unreported beneficial effect of direct PCI for AMI, reflecting a significant increase of the cardioprotective, reflectoric parasympathetic activity. Furthermore, there is a dynamic change of HRT within the phases of AMI. These findings have to be considered using HRT as a post-infarction risk-stratifier.

P386 Temporal distribution of ventricular fibrillation occurrence during acute myocardial ischaemia

J.R. De Groot[1], R.W. Koster[2], R. Coronel[3]. [1]*Academic Medical Center, Experimental and Molecular Cardiology, Amsterdam, Netherlands;* [2]*Academic Medical Center, Cardiology, Amsterdam, Netherlands;* [3]*Academic Medical Center, Experimental and Molecular Cardiology, Amsterdam, Netherlands*

Background: The temporal distribution of ventricular fibrillation (VF) during myocardial ischemia in man is unknown. The available data are scarce and often obscured by immediate medical interventions. In large animals, ischemia-induced VF develops in two separate phases that have different electrophysiological mechanisms (phase 1A, related to reduced excitability and phase 1B, related to partial cellular uncoupling). We hypothesized that a 1B phase of VF is present in man. Therefore, we retrospectively investigated the time course and mode of onset of VF in a cohort patients with chest pain in the pre-thrombolytic era.
Methods: Between September 16 1980 and July 17 1983, 7026 patients with chest pain were investigated in the Amsterdam region, of whom 2258 had a myocardial infarction. A single lead ECG was recorded during 60 minutes from arrival of the ambulance onward. Forty-two of the infarct patients (1.9%) developed VF. Here, we studied ECGs at 25 or 50 mm/s of 32 patients (10 patients were excluded: 5 developed VF before ECG recording started, 2 had asthma cardiale, of 3 data were absent or incomplete). Eight patients received lidocaine (400 mg, intramuscular). Recording started 92±12 (mean±SEM) minutes after onset of complaints.
Results: VF occurred in 16% of patients within the first hour, in 38% between 1-2, in 25% between 2-3, and in 22% after 3 hours after onset of complaints, i.e. after onset of ischemia. An R-on-T premature beat with a coupling interval of 306±17 ms induced VF in 19 cases (59%), whereas a late premature beat (coupling interval 397±22 ms, p<0.01 vs R-on-T) preceded VF in 8 cases (25%). One patient had a 30-second episode of ventricular tachycardia before onset of VF. ST shift was present in 25 patients (elevation in 11 patients, depression in 14 patients. Note that a non-standard lead was recorded), and the ST segment was unchanged prior to VF in 4 patients. ST segment shift normalized in 4 patients before VF occurred, consistent with cellular electrical uncoupling.
Conclusions: Although information on the very early (phase 1A) occurrence of VF lacks in this study; VF occurrence peaked between 1 and 2 hours after onset of ischemia, indicating the presence of a 1B phase of VF. Normalization of ST segments prior to VF indicates partial intact cellular coupling and further supports the presence of a 1B phase. The possible presence of two phases of VF with different electrophysiological mechanisms merits further investigation and might provide future preventive therapies for this lethal condition.

P387 Wavelet analysis of heart rate variability before ventricular arrhythmias retrieved from implantable cardioverter-defibrillators

P. Chevalier[1], H. Burri[2], M. Arzi[3], J. Fayn[3], P. Rubel[3], G. Kirkorian[1], J-Y. Le Heuzey[4], P. Touboul[1] on behalf of the VALID Investigators. [1]*Hôpital Louis Pradel, Cardiology, Lyon, France;* [2]*University Hospital, Cardiology, Geneva, Switzerland;* [3]*Hôpital Louis Pradel, INSERM, Lyon, France;* [4]*Hôpital Georges Pompidou, Cardiology, Paris, France*

Background: changes in autonomic tone leading to ventricular arrhythmias may be studied by heart rate variability (HRV). Wavelet transform is well adapted for analysis of non-stationary signals, such as heart rate recordings. Instantaneous High-Frequency (HF 0.15~0.4 Hz) components reflect vagal activity, while Low-Frequency (LF 0.04~0.15 Hz) components are under the influence of both sympathetic and parasympathetic tone. Thus, an increased LF/HF ratio may indicate increased sympathetic activity or decreased vagal tone.
Methods: 30 patients (mean age 61 years, 27 males) with ischemic heart disease implanted with a Biotronik Phylax XM® or Mycrophylax Plus® defibrillator with extended memory and having had appropriate electrical therapy for a ventricular arrhythmic event were studied. Two continuous recordings during 80 minutes were obtained from each patient: 1)during a routine visit and 2)preceding the ventricular arrhythmic event. Each recording was split into 10-minute intervals and the ratio of squared LF/HF coefficients calculated for each sample.
Results: See figure below.The values of LF/HF during routine recordings and before arrhythmic events were significantly different (* p<0.001 by ANOVA) except at two timepoints.

Conclusions: wavelet transform of HRV shows evidence of sympathovagal imbalance beginning over an hour before ventricular arrhythmic events, culminating just before arrhythmia onset.

P388 Correction of intraventricular asynchrony is the main mechanism by which cardiac efficiency improves by biventricular pacing in heart failure

M. Penicka[1], J. Bartunek[1], B. De Bruyne[2], E. Barbato[1], M. Goethals[1], P. Goemaere[1], M. De Zutter[1], P. Geelen[1]. [1]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium;* [2]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium*

Biventricular pacing (BP) has been shown to improve mechanical efficiency and to reverse remodeling of the left ventricle (LV) in patients (pts) with refractory heart failure and wide QRS complex. Yet, among the pts with biventricular pacing, approximately 25% do not respond to the therapy despite a wide QRS complex.
Aim: To identify mechanisms responsible for a positive remodeling to BP in pts with severe heart failure and a wide QRS complex.
Methods: Twenty-one consecutive patients with refractory heart failure (NYHA 3.2±0.8) and wide QRS complex (179±28 ms) underwent echocardiography before, 3 days and 3 months after active BP. Intra- and interventricular asynchrony was quantified by tissue Doppler as a difference of activation times between basal segments of the LV (asynLV), and between left and right ventricular walls (asynLV-RV), respectively.
Results: Baseline heart rate, duration of AV interval and QRS complex, LV end-diastolic diameter, LV ejection fraction (LVEF), LV filling time and isovolumic contraction time did not correlate with the change of stroke volume (SV) or LVEF at 3 days or at three months. In contrast, a significant correlation was found between both baseline asynLV and asynLV-RV and the change of SV at 3 days (r=0.6, p<0.05, and r=0.54, ns) and at 3 months (r=0.88, p<0.01, and r=0.66, P<0.05). Also, the change of LVEF at 3 months correlated strongly with both baseline asynLV (r=0.75, p<0.01) and asynLV-RV (r=0.65, p<0.05). In addition, reduction of asynLV by BP inversely correlated with an increase in LVEF during follow-up (r=-0.66, p<0.05).
Conclusions: A reduction of intraventricular asynchrony is the main mechanism underlying an improvement of LV efficiency and reverse remodeling after BP. Conversely, a failure to reduce asynchrony predicts an unfavorable response during follow-up.

P389 Ventricular tachyarrhythmias during permanent pacemaker therapy – first results from the German multicenter EVENTS study

T. Faber[1], J. Brachmann[2], S. Treusch[3], C. Bode[1], M. Zehender[1] on behalf of the EVENTS Investigators. [1]*University Hospital of Freiburg, Cardiology, Freiburg, Germany;* [2]*Cardiology, Hospital of Coburg, Coburg, Germany;* [3]*GUIDANT Corp., Giessen, Germany*

Objectives: Ventricular tachyarrhythmias during permanent cardiac pacing have been reported casuistically in up to 20% of cases. Spontaneous incidence and potential interaction with cardiac pacing have become of increasing importance when newer pacing modalities (e.g. bi-ventricular pacing) are applied to patients with severe heart disease.
Methods: In a prospective multicenter trial (EVENTS) 227 consecutive patients eligible for permanent dual chamber pacing according to the ACC/AHA-Guidelines were included. No pts with overt ischemia, atrial fibrillation, or ICD indication were enrolled. Implanted pulse generators (PG; Pulsar, Discovery; GUIDANT Corp., Minneapolis), able to store 40 s of electrograms (EGMs) were programmed to trigger on ventricular tachyarrhythmias (4 cycles >120 bpm) closely to the MADIT criteria. Stored EGMs, histograms and counters were retrieved after 3, 9 and 15 months and systematically analyzed.
Results: During a mean follow-up (FU) of 12.8±4.9 months a total number of 3162 EGMs were documented and 2455 EGMs were finally further processed. 206 out of 227 pts had at least one FU, 145 pts were followed for 15 months. Of all analyzed EGMs ventricular tachyarrhythmias (at least 8 beats >120 bpm) occurred in 52 pts (25.2%), verified by stored EGM. VPBs and Lown IVa arrhythmia were documented in 4.5%. In 21 pts (10%) potential malignant forms of ventricular tachyarrhythmias occurred in more than one FU.
Conclusion: First data analysis revealed complex forms of ventricular tachyarrhythmias occurring in more than 25% of pts during permanent pacing within the first 15 months after implantation. The results may be of particular importance when complex pacing modalities are applied to pts with severe heart disease (e.g. bi-ventricular pacing). However, further data evaluation and studies using extended PG storage and capacity are needed to identify interaction and onset mechanisms of ventricular tachyarrhythmias and their prognostic significance during permanent pacing.

P390 Correlation of heart rate turbulence with other autonomic markers

P. Barthel, R. Schneider, A. Bauer, G. Schmidt. *University of Technology, Munich, Deutsches Herzzentrum & 1. Med. Klinik, München, Germany*

Background: The (cardiac) autonomic nervous system plays a decisive role in control and modulation functions at the origin of malignant arrhythmias. In the last years makers, which characterizes the autonomic state, became more and more important as risk stratifiers for post infarct mortality. A new marker of the autonomic nervous function is the Heart Rate Turbulence Slope (TS). Goal of this investigation was to examine the correlation of TS with other makers of the autonomous nervous system.
Method: 949 consecutive patients with acute myocardial infarction (AMI) take part in the study. Inclusion criterion was sinus rhythm and at least 1 VPC/24h. 90% of these patients were treated by PTCA and/or stenting during the acute phase of AMI. 91% received beta - blocker, 88% ACE Hemmer, 80% statins and 99% aspirin as adjuvant pharmacotherapy. In the second week after the AMI the following parameter were assessed: heart rate variability (HRV), TS, arrhythmia count, mean heart rate (mHR) and the left ventricular ejection fraction (LVEF).
Results: There were weak but significant correlations between the tested parameters (see table).

Correlation coefficients

	SDNN	mean HR	VPC/h	LVEF
TS	0.33; p<0.0001	-0.36; p<0.0001	-0.15; p<0.0001	0.26; p<0.0001
SDNN		-0.56; p<0.0001	-0.03; n. s.	0.28; p<0.0001
mean HR			0.08; p<0.01	-0.39; p<0.0001
VPC/h				-0.11; p<0.0001

Summary: The results shows significant correlations between TS and other markers of the autonomic control mechanisms.

ATRIAL FIBRILLATION: PACING AND TECHNICAL ASPECTS

P391 Prevalence and clinical characteristics of immediate reinitiation of atrial fibrillation after electrical cardioversion

T. Van Noord[1], C. Kingma[1], H.J.G.M. Crijns[2], D.J. Van Veldhuisen[1], I.C. Van Gelder[1]. [1]*University Hospital Groningen, Cardiology, Groningen, Netherlands;* [2]*University Hospital Maastricht, Cardiology, Maastricht, Netherlands*

Objective: In patients with persistent atrial fibrillation (AF) sinus rhythm can be restored by electrical cardioversion(ECV). However, in about 10-20% of patients ECV has an unsuccessful outcome. An unsuccessful ECV outcome can be divided into two scenarios. First, ECV fails to restore sinus rhythm (total shock failure). Secondly, although sinus rhythm is restored, immediate reinitiation of AF (IRAF, recurrence within 2 minutes) occurs. Prevalence of shock failure and IRAF are unknown. However, this is of important since it has been established that patients with IRAF may eventually maintain sinus rhythm while patients with shock failure have a poor arrhythmia outcome.
Methods and Results: We evaluated ECV outcome in 482 consecutive patients and investigated which variables predicted the occurrence of either shock failure or IRAF. Shock failure occurred in 39 (8%) while IRAF occurred in 67 patients (14%). 131 patients had a first episode of persistent AF and were not treated with a class I or III anti-arrhythmic drug. Of these 131 patients 12 patients(9%) had an unsuccessful ECV due to shock failure, while 21 patients (16%) had IRAF. A longer duration of AF (8 versus 4 months, p=0.03) and the use of diuretics (58% versus 29%, p=0.05) predicted the occurrence of total shock failure while the use of ACE inhibitors (57% versus 33%, p<0.05) and a longer duration of AF (7 versus 4 months, p<0.01) were predictors of IRAF. There was a trend for a larger left atrium (49 versus 45 mm, p=0.1), a larger left ventricular end diastolic diameter (53 versus 50 mm, p=0.09) in patients with IRAF. Pretreatment with calcium channel blockers, digoxin and beta-blockers was not related to IRAF. Multivariate analysis revealed that a longer duration of AF was the only parameter predicting the occurrence of IRAF.
Conclusion: Unsuccessful ECV outcome is predominantly caused by IRAF. Both IRAF and shock failure occur more frequently if AF duration is longer.

P392 Does pace termination of atrial arrhythmias influence time of recurrence? Results of the European AT500 verification study

B. Hügl[1], A. Große[2], C. Unterberg-Buchwald[3], C. Israel[4], T. Lawo[5], I. Kennis[6], A. Germer[6], B. Lauer[2] on behalf of AT500 Verfication-Study. [1]*Machern, Germany;* [2]*Zentralklinik Bad Berka, Cardiology, Bad Berka, Germany;* [3]*University of Göttingen, Cardiology, Göttingen, Germany;* [4]*University of Frankfurt, Cardiology, Frankfurt, Germany;* [5]*University of Bochum, Cardiology, Bochum, Germany;* [6]*Medtronic, Bakken Resaerch Center, Maastricht, Netherlands*

Introduction: Prompt re-initiation of atrial fibrillation (AF) commonly occurs following electrical or chemical cardioversion. However, AF re-initiation following atrial anti-tachy pacing (ATP) is unknown. The purpose of this study was to compare the time to AF recurrence between episodes successfully terminated by ATP therapy (success), episodes spontaneously terminating after unsuccessful ATP (fail) and episodes spontaneously terminating without therapy (NoRx).
Methods: Data were obtained from 205 consecutive patients (3.2 ± 1.8 months of FU) implanted with the Medtronic AT500 (95% with AF history). We analyzed 2081 episodes from 109 patients meeting the following inclusion criteria: 1) stored EGM, 2) appropriately detected and terminated, 3) > 1 month post implant and, 4) available date and time of the next AF episode. To correct for multiple episodes, each patient's median time to AF re-initiation after success, fail and NoRx episodes was used for paired comparisons and data reports.
Results: Many of the patients (51/109) experienced a median time to AF re-initiation shorter than 5 min in all success, fail and NoRx episodes. There were no statistical differences in the median time to re-initiation among success, fail and NoRx episodes across patients.

	No Therapies(Rx)	success	fail
Number of episodes/pt, median (range)	0 (0-41)	2 (0-56)	5 (0-35)
Median time (minutes) to AF re-initiation/pt, median (range)	3.6 (0.3-7313)	1.6 (0.2-43494)	1.0 (0.2-26983)

Conclusion: AF re-initiation within a few minutes following successful ATP is common. These short re-initiation times do not depend on whether the AF episode was terminated by therapy or terminated spontaneously.

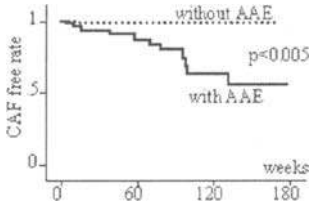
P393 Abnormal right atrial electrograms predict the development of chronic atrial fibrillation in paced patients with sick sinus syndrome

K. Miyamoto, K. Nakao, S. Seto, K. Matsuo, N. Komiya, S. Isomoto, K. Yano.
Nagasaki University School of Medicine, Third Department of Internal Medicine, Nagasaki, Japan

Although pacing therapy for sick sinus syndrome (SSS) is established, subsequent development of chronic atrial fibrillation (CAF) makes pacing therapy not feasible in some patients. The aim of this study was to evaluate whether electrophysiologic characteristics of atrial muscle can predict the development of CAF after pacemaker implantation in patients with SSS.

Methods: Eighty-nine patients with SSS underwent electrophysiologic study (EPS) before pacing therapy. In EPS, catheter mapping of 12 sites (four aspects of the high, middle, and low right atrium) was performed during sinus rhythm. An abnormal atrial electrogram (AAE) was defined as having a duration of 100 ms or longer or eight or more fragmented deflections or both. Right atrial extrastimulation was also performed for atrial vulnerability.

Results: During follow-up for 85 ± 50 months, development of CAF was observed in 12 patients (group A). The remaining 77 patients remained in sinus rhythm (group B). The number of AAE was significantly grater in the group A than in the group B (2.7 ± 2.3 vs 0.8 ± 1.2; $p<0.001$). The distribution of AAE was also greater in the group A; patients in the group A had a greater number of AAE than patients in the group B in both high and middle right atrium ($p<0.005$ and $p<0.01$, respectively). Figure shows the CAF free curve according to Kaplan-Meier analysis. Almost 50% of the paced patients with AAE (n=42) in high and/or middle right atrium developed CAF after 15 year, whereas only 2% of the paced patients without AAE (n=47) developed CAF ($p<0.005$). Indices of atrial vulnerability did not influence the transition to CAF.



CAF free rate.

Conclusion: Our data suggest that the existence of AAE in high and/or middle right atrium is predictive of the development of CAF in paced patients with SSS.

P394 High-rate overdrive pacing for prevention of immediate reinitiation of atrial tachyarrhythmias: results from a prospective randomized trial

C.W. Israel, G. Grönefeld, J.R. Ehrlich, Y.G. Li, S.H. Hohnloser. *J. W. Goethe University Hospital, Cardiology, Frankfurt, Germany*

In patients (pts) with atrial tachyarrhythmias (ATs), immediate reinitiation of AT (IRAT) can be responsible for the progression of atrial electrical disease. Atrial overdrive pacing at a high rate after restoration of sinus rhythm may be able to suppress IRAT. This hypothesis was examined in a prospective, randomized, single-blind cross-over trial.

Methods: In pts with pacing indication and AT, a DDDRP system (AT500, Medtronic Inc.) was implanted. Atrial preventive and antitachycardia pacing (ATP) was deactivated during the first month after implantation. Thereafter, devices were interrogated and pts with stored AT episodes and reliable AT detection were randomized to receive either post mode switching overdrive pacing (PMOP) at 120 bpm for 2 min or no PMOP after spontaneous or paced termination of the AT. Atrial ATP and 2 other preventive pacing algorithms (atrial rate stabilization, atrial pacing preference) were activated. After another 3 months, pacemaker memory functions (stored AT episodes with atrial electrograms, AT burden) were interrogated, and quality of life and AT related symptoms were assessed using questionnaires (SF-36, symptom checklist). Pts were then crossed over for a second 3 month period. Stored AT episodes were manually reassessed for reliability of AT detection. Primary study endpoint was the time that the pts were in AT (AT burden in %) with vs without PMOP active (intention to treat analysis). A secondary endpoint referred to the number of pts in whom AT burden was reduced with PMOP.

Results: 30 pts with AT episodes and reliable AT detection were enrolled and completed both study periods. Two early cross-overs occurred (1 pt from PMOP 120 bpm to no PMOP, 1 pt the alternative) due to symptoms. Mean AT burden (11 ± 21 vs 11 ± 19%), quality of life and AT related symptoms were not different with or without PMOP. AT burden was reduced with PMOP in 12 pts, unchanged in 6 pts, and increased in 12 pts.

Conclusions: In this study, overdrive pacing at 120 bpm for 2 min after spontaneous or ATP induced termination of AT did not change the AT burden. Further studies are necessary to identify a subset of pts who may benefit from this therapy.

P395 Impact of left ventricular function on atrial antitachycardia pacing efficacy: AT500 Italian registry

G. Boriani[1], S. Favale[2], M. Disertori[3], A. Capucci[4], A. Spampinato[5], F. Giraldi[6], R. Ricci[7], M. Vimercati[8] on behalf of the AT500 Italian Registry Investigators. *[1]S.Orsola H, Bologna, Italy; [2]Policlinico, Bari, Italy; [3]S.Chiara H, Tranto, Italy; [4]Civile H, Piacenza, Italy; [5]Villa Tiberia H, Rome, Italy; [6]Cardiologico H, Milan, Italy; [7]S.Filippo Neri H, Rome, Italy; [8]Medtronic Italy, Milan, Italy*

Introduction: The AT500 Italian Registry enrolled at present time 330 patients (pts) with frequent episodes of paroxysmal atrial fibrillation (AF) implanted with a Medtronic AT500™ pacemaker (mean age 71 ± 9 years; mean follow-up 6.3 ± 4.9 months).

Aim of the study: To assess how left ventricular ejection fraction (LVEF) may influence the efficacy of atrial antitachypacing therapies (ATP) delivered to treat atrial tachyarrhythmias.

Results: ATP efficacy in treating AF and atrial tachycardia (AT) episodes (as classified by the device) is reported in the following Table.

We considered 1238 episodes recorded in 37 pts with known left ventricular ejection fraction (LVEF)(19 M, 18 F - mean age 70 years).

ATP efficacy in the two groups of pts

	LVEF<55%	LVEF≥55%	
	10 pts	27 pts	
Total	124/350	93/878	p<0.005
	35.4%	44.8%	
AF	50/163	74/289	p = ns
	30.7%	25.6%	
AT	74/187	319/589	p<0.0001
	39.6%	54.2%	

Conclusion: Our data show that a preserved left ventricular ejection fraction is associated with an higher efficacy of atrial antitachycardia pacing, especially when treating slower and/or more organized atrial tachyarrhythmia episodes. These data are of clinical relevance with regard to device and hybrid treatment of atrial fibrillation associated with left ventricular dysfunction or congestive heart failure.

P396 Patients with atrial tachyarrhythmias have multiple onset patterns: implications for pacing for prevention of atrial tachyarrhythmias

C.W. Israel, G. Grönefeld, J.R. Ehrlich, Y.G. Li, S.H. Hohnloser. *J. W. Goethe University Hospital, Cardiology, Frankfurt, Germany*

Atrial pacing is being studied for its potential to prevent atrial tachyarrhythmias (ATs). To tailor optimal AT prevention pacing algorithms to an individual patient (pt), knowledge about AT onset patterns may be helpful.

Methods: Pts with a pacing indication and ATs received a DDDRP system (AT500, Medtronic Inc) with dedicated memory functions for storage of AT episodes including an atrial electrogram and marker annotation for 48 events before AT onset. Memory functions were activated after implantation and devices were interrogated before hospital discharge and 1 month after implantation. During this time period, all preventive pacing algorithms and antitachycardia pacing were deactivated. AT episodes were printed out, the reliability of atrial sensing was manually assessed and all AT episodes with atrial under- or oversensing were excluded. For the following prospectively defined onset patterns, the incidence was calculated: 1. immediate (< 1min) reinitiation of AT, 2. supraventricular (SV) run before AT, 3. SV bigeminus, 4. SV trigeminus, 5. > 3 isolated atrial premature beats (APBs), 6. continuous atrial rate increase, 7. continuous atrial rate decrease, 8. > 3 ventricular premature beats, 9. alternating atrial pacing and sensing, 10. regular intrinsic atrial activity, 11. regular atrial pacing, 12. no pattern. Primary endpoint of this study was the number of pts with > 1 onset pattern, secondary endpoint was the relative incidence of each onset pattern in all episodes.

Results: In 65 of 90 pts enrolled into the study, 1430 AT episodes were stored. 844 AT episodes were excluded due to atrial sensing errors; of the remaining 586 AT episodes, immediate AT reinitiation was found in 217 (37%), regular atrial pacing in 165 (28%), SV runs in 118 (20%), SV bigeminus in 114 (19%), regular atrial sensing in 53 (9%), SV trigeminus in 27 (5%). APB related onset patterns were found in 276 (47%) episodes, short-long sequences in 192 episodes (33%). Eight pts had only 1 AT onset patterns, the remaining 32 pts had 2-8 (mean 3.5 ± 1.8) onset patterns.

Conclusions: The majority of pts with ATs have multiple onset patterns. While immediate AT reinitiation and APB related onset patterns are frequent, also a high percentage of AT episodes start from regular atrial pacing or sensing.

P397 Does left atrial size modify response to pacing algorithms dedicated to prevent atrial fibrillation?

J. Mansourati[1], F. Hidden-Lucet[2], F. Zolezzi[3], Y. Poezevara[4], J.J. Blanc[1] on behalf of the PIPAF study investigators. [1]*University Hospital of Brest, Cardiology Dept., Brest, France;* [2]*Hopital Jean Rostand, Cardiology, Ivry-Sur-seine, France;* [3]*Ospedale Civile, Divisione Cardiologia, Vigevano, Italy;* [4]*ELA Recherche, Montrouge, France*

Background: Although standard atrial pacing seems to prevent atrial fibrillation (AF) recurrences in some pts with documented paroxysmal (P) AF, further beneficial effects of additional pacing algorithms (alg) remain controversial. We sought to determine left atrial (LA) size influence on pts response to these pacing alg.

Methods: Pts with PAF (at least 3 episodes during the last year) were included in a multicentre, randomized, cross-over study (6 months each). They were implanted with a DDD pacemaker (chorum 7334, ELA, Montrouge, France) and after one month, randomly assigned to DDD pacing at 70 bpm with (DDD+alg) or without alg (DDD). Three different alg were used: Sinus Rhythm Overdrive (permanent atrial pacing just above the sinus rate), Post-Extrasystolic Pause Suppression (controls cycle length variation after premature atrial contraction, PAC) and Acceleration on PAC's (increases temporarily pacing rate upon frequent PAC's). Study end points were recurrences (number and duration) of PAF detected by pacemaker during both pacing modes. LA diameter was measured at inclusion by M-mode echocardiography.

Results: The study group included 59 pts (mean age 68 ± 10 years; 36 M). Median LA diameter (40 mm) was used as a cut-off value to separate pts into 2 subgroups LA < 40 mm (27 pts; LA diameter 34.7 ± 3.6 mm) or > or = 40 mm(32 pts; LA diameter 44.5 ± 4.1 mm, p<0.0001). Results are summarized in the table.

	LA < 40 mm		LA > or = 40 mm	
Pacing mode	DDD	DDD + alg	DDD	DDD + alg
AF duration (days)	12.7 ± 37.3	12 ± 29.4 (NS)	16.6 ± 32.6	13.3 ± 30.8 *
Number of AF episodes	111.6 ± 271.5	105 ± 227.9 (NS)	113.4 ± 173.9	86.1 ± 148.3 *

* p<0.05

Conclusion: Additional algorithms to standard DDD pacing seem to be more effective to reduce PAF recurrences (length and number of episodes) in pts with dilated LA. This result could be explained by a higher vulnerability to PAC of this group of pts leading to a higher protection of the studied algorithms.

P398 Advanced pacemaker diagnostic features in the identification of "substrate fibrillators": relevance for AF preventive pacing algorithms

A. Yang, T. Lewalter, M. Hochhäusler, J. Schrickel, H. Bielik, J.O. Schwab, N. Shlevkov, B. Lüderitz on behalf of VIP Study Group. *University of Bonn, Department of Cardiology, Bonn, Germany*

Pacing algorithms to prevent paroxysmal atrial fibrillation (AF) are mainly based on the suppression of premature atrial contractions (PAC's) which are supposed to play a major role in the initiation of AF. For the specific use of the various offered algorithms a detailed characterisation of the AF episodes was performed by analysis of the pacemaker (PM) arrhythmia diagnostic features according to the PAC activity before AF onset.

Methods: 49 patients (67 ± 11 years) with dual chamber pacing (Vitatron, "Selection" Series) and a history of paroxysmal AF were included. After a mean follow-up of 94 ± 25 d the following PM diagnostic parameters were studied: (1) number of PAC's/hr during sinus rhythm, (2) total AF burden (% of storage period), (3) AF episode duration, (4) number of AF episodes/d, (5) frequency of PAC's/min during the last 5 min before AF onset, (6) percentage of atrial pacing. According to the frequency of PAC's/min during the last 5 min before AF onset the patients were divided into Group A with "few PAC's before AF onset" (>70% of the episodes preceded by <2 PAC's/min, n=23) and Group B with "frequent PAC's before AF onset" (<70% of the episodes preceded by <2 PAC's/min, n=26).

Results: Group A patients presented significant smaller numbers of PAC's/hr overall (10.9 ± 12.8 vs. 93.7 ± 172.7, p<0.05), significant higher total AF burden (14.3 ± 17.8% vs. 7.6 ± 13.5%, p<0.05) and significant higher numbers of "long" AF episodes >1 hr (29.9 ± 27.6% vs. 12.8 ± 17.8%, p<0.01). The number of AF episodes/d did not differ significantly between both groups (2.8 ± 4.7 vs. 1.9 ± 2.7, p=0.22) as not the frequency of atrial pacing (52.4 ± 34.9% vs. 61,5 ± 30.5%, p=0.41).

Conclusions: 1. Patients with few PAC's during the last 5 minutes before AF onset demonstrated to have a higher AF burden compared to patients with a high PAC activity. 2. The elevated AF burden in these patients is due to longer AF episodes. 3. This coincidence of few or missing PAC activity before AF onset ("sudden onset"), increased AF burden and longer episode duration may be the consequence of a higher atrial "substrate factor". 4. Depending on the AF onset characteristics a differential programming of AF preventive pacing algorithms may be necessary for effective electrical AF prevention.

P399 Chronic single-site interatrial septal pacing prevents paroxysms of atrial fibrillation and reduces atrial wall stretch

D.I. Perchatkin[1], P.G. Platonov[2], I.V. Efimov[3], T.N. Novikova[4], S.V. Retnev[1], V.G. Solovjeva[1], A.B. Vygovsky[3]. [1]*Pokrovskaya Hospital, St.Petersburg, Russian Federation;* [2]*CPR Institute, St.Petersburg, Russian Federation;* [3]*Research Institute of Cardiology, Arrhythmia Research Laboratory, St. Petersburg, Russian Federation;* [4]*Medical Academy Postgraduate Studies, St.Petersburg, Russian Federation*

Objective: to evaluate effects of chronic single-site interatrial septal pacing on intraatrial conduction, haemodynamics and assess its potential to prevent paroxysms of atrial fibrillation in patients with sick sinus syndrome (SSS).

Methods: Thirty five consecutive patients with SSS underwent electrophysiological study and received single-chamber pacemaker for chronic AAI pacing. In 22 patients (68±8 years) with history of SSS and weekly symptomatic paroxysms of atrial fibrillation (PAF group), the active-fixation atrial lead was positioned at the posterior interatrial septum (IAS). The other 13 patients (67±9 years) had SSS only (SSS group) and the atrial lead was placed in the right atrial appendage (RAA). All patients underwent transthoracic echocardiography. All patients have been followed up for up to 36 months for assessment of PAF recurrence.

Results: 1) P-wave duration during sinus rhythm at baseline was not different between the PAF and SSS groups. IAS pacing shortened P-wave duration (105±16 ms vs. 92±18 ms, p<0.05), while RAA pacing increased P-wave duration (100±19 ms vs. 116±18 ms, p<0.01). 2) Baseline cardiac haemodynamics assessed by EchoCG was not different between the groups. Left atrial volume index (LAVI) was decreased during IAS pacing in PAF patients (45±12 vs. 32±11 ml/m^2, p<0.05, for measurements at baseline and during pacing respectively), while RAA pacing did not affect that. 3) During the follow-up period (17±11 months), 17 of 22 PAF patients were free from recurrence of arrhythmia paroxysms. None of SSS patients had PAF during the follow-up period.

Conclusion: 1) Our findings suggest that IAS pacing facilitates atrial conduction as it shortens P-waves while RAA pacing tends to prolong them. 2) Prevention of PAF by chronic IAS pacing in patients with SSS shown in our study may be explained not only by enhanced atrial synchronism but also by modification of other proarrhythmic factor such as atrial wall stretch as demonstrated by reduction of LAVI during the pacing.

P400 Autocapture enhancements: (1) unipolar and bipolar lead compatibility and (2) bipolar pacing capability on bipolar leads

L. Binner[1], J. Messenger[2], J. Sperzel[3], H. Bondke[4], Y. Vandekerckhove[5], J. Scheiner[6], G. Bornzin[7], J.W. Poore[7]. [1]*University of Ulm, Internal Medicine II - Cardiology, Ulm, Germany;* [2]*Long Beach Memorial Hospital, Cardiology, Long Beach, United States of America;* [3]*Kerckhoff Klinik, Cardiology, Bad Nauheim, Germany;* [4]*University Hospital Charité, Cardiology, Berlin, Germany;* [5]*A Z St. Jan, Cardiology, Brugge, Belgium;* [6]*St. Jude Medical, Nürnberg, Germany;* [7]*St. Jude Medical, Sylmar, United States of America*

Beat-by-beat AutoCapture (AC) maximizes device longevity by minimizing stimulus amplitude while assuring patient safety. Currently, AC permits use of only bipolar leads. We have now devised a detection method that operates on unipolar and bipolar leads and covers all pacing and sensing combinations (but bipolar pace and sense at the same time). A new detection method for unipolar sensing uses the integral of the negative portion of the unipolar evoked response (UVERI) as a robust capture detection feature. When using bipolar leads, the new method provides the flexibility of bipolar or unipolar pacing. Unipolar ventricular IEGM signals were collected from 71 patients age 73.7 ±9.9 years; 9 with high polarization (POL) leads, 62 with low POL leads. High POL leads have polished platinum or activated carbon electrodes. Low POL leads had TiN, platinized platinum, or IrOx electrodes. The IEGMs were recorded 544 ±796 days after implant. Affinity pacemakers (St. Jude Medical, Sylmar, USA) performed an automatic capture threshold test while the IEGM signals were recorded in a 3500 or 3510 programmer (St. Jude Medical, Sylmar, USA). These digitized signals were saved for off-line analysis. We calculated the UVERI at up to six (depending on capture threshold) pacing voltages and the POL integral at 4.5 volts and at loss of capture. An automatic calibration algorithm determined whether signal to noise was adequate for AC operation. AC is possible with 60/62 of the low polarization leads. While AC operation was possible with 6/9 of the high polarization leads. The average values from the data collected are: average UVERI is -4.1 ±2.1 mV; average peak negative voltage is -10. ±3.7 mV; average POL is 0.3 ±0.34 mV; and average signal to noise (UVERI/POL) is 38 ±71. In all cases the algorithm correctly determined feasibility of using AC with the lead electrodes tested and, if so, what UVERI threshold should be used.

P401 Testing a new single lead for left atrial and left ventricular-based DDD pacing in an animal experiment

T. Zerm[1], T. Rauwolf[1], S. Hansen[2], H. Kregel[2], A. Herrero-Yraola[2], R H. Strasser[1]. [1]*Medical Clinic II, Technical University, Dresden, Germany;* [2]*Biotronik GmbH, Berlin, Germany*

Background: Biventricular and left ventricular pacing was reported to improve hemodynamics, physical capacity, and quality of life in patients with congestive heart failure. A recently developed left-sided, single-pass pacing lead has the advantage of reducing the number of implanted electrodes to only one lead with the capability of left atrial- and left ventricular-based VDD/ DDD pacing (LSDL – Left-Sided Single-Pass DDD Lead).
Methods: To test the feasibility and pacing characteristics the LSDL was implanted in four pigs (two acute, two acute/chronic; weight 60 ± 11 kg). The pigs were chosen because of their anatomic similarities to human hearts. After inserting the introducer set (SCOUT, Biotronik) under fluoroscopy via the jugular vein and into the coronary sinus, an angiogram was recorded to select one of three LSDL types (atrio-ventricular pole distance: 6.5, 9.0, or 11.5 cm). After introducing the LSDL and taking the intra-operative (acute) measurement, a dual-chamber pacemaker was implanted.
Results: The time for lead insertion was 40 ± 33 min with 2.3 ± 2.9 repositions. Recorded amplitudes were for P-waves 2.1 ± 0.1 mV and for R-waves 8.5 ± 2.1 mV, left atrial and left ventricular pacing thresholds were 2.6 ± 0.3 V and 1.2 ± 0.6 V at 0.5 msec, respectively and the atrial and ventricular impedances were 244 ± 27 Ohm and 691 + 232 Ohm, respectively. Chronic measurements were performed every other day over a two-week period; pacing and sensing values were constant. No far-field R-wave sensing in the left atrium and no safety window pacing (indicating ventricular cross talk sensing) was observed.
Conclusion: These data show, that the LSDL has good implantation handling and acceptable pacing and sensing characteristics. As a result, patients with congestive heart failure could profit from the LSDL, suggesting that the hemodynamic benefit of this one lead configuration is similar to conventional biventricular pacing, using a three lead system. The LSDL is currently being tested in humans in an ongoing feasibility study (Corox SL Pilot Trial).

P402 Does the availability of multiple left heart lead and delivery systems matter for cardiac resynchronization therapy?

J. Gurley[1], S. Lamba[1], K. Moulton[2], B. Miller[2], J. Mullin[2], D. Hine[3] on behalf of MIRACLE and InSync III investigators. [1]*University of Kentucky, Lexington, United States of America;* [2]*Prairie Heart Institute, Springfield, United States of America;* [3]*Medtronic Inc, Cardiac Rhythm Management, Minneapolis, United States of America*

Background: Cardiac resynchronization therapy has been shown to improve quality of life and functional capacity in a subset of heart failure patients. Improvements in implant time and success rate are being pursued. We evaluated the impact of having multiple left-heart (LH) lead and delivery system (DS) options on implant time and success rate with the belief that multiple designs are needed to access the Coronary Sinus (CS) and fixate the lead in the various patient anatomies.
Methods: In the MIRACLE trial, investigators chose from using a 6 Fr unipolar lead (2187) or a 6 Fr bipolar lead (2188). During this study, a DS (6216) was used to cannulate the CS providing a pathway to the cardiac veins. The DS included a Modified MB1 or MB2 curved guide catheter to achieve CS cannulation. In the InSync III trial, investigators chose from using the same leads (2187/2188) or a new 4 Fr over-the-wire design (4193). This lead can be placed in the cardiac veins using a standard pacing stylet or an interventional guide wire (.014"-.018"). A new DS (6218) was also provided as a second option in the InSync III trial. The new DS included a longer soft-tipped catheter with a straight distal end for deeper CS engagement. This DS is inserted into the CS using a steerable or fixed shape EP catheter.
Results: Implant success rates and median procedure times with interquartile (IQ) ranges (25%-75%) are compared below in table 1.

Table 1: Success Rate and Implant Times

	Implant Success Rate		Time to Engage CS (min)		Time to Place LV Lead (min)		Total Operative Time (min)	
	N	Rate	Median	IQ Range	Median	IQ Range	Median	IQ Range
MIRACLE	528/571	92.5%	11	5-22	29	17-59	162	123-216
InSync III	253/264	95.8%	7	3-14	10	5-20	131	98-180
p-value	p=0.078		p<0.0001		p<0.0001		p<0.0001	

P-values calculated using t-test (implant times) and chi square (success rate) analysis.

Conclusions: These data support our belief that the availability of multiple LH lead designs and DS options are associated with a trend toward a higher success rate and significantly reduced median implant times. Current technology has shown a 95.8% implant success rate with a mean operative time of 131 minutes.

P403 High versus normal impedance leads: impact on pacemaker generator longevity

T. Berger[1], G. Fischer[2], S. Gozolits[1], F.X. Roithinger[1], O. Pachinger[1], F. Hintringer[1]. [1]*University Hospital Innsbruck, Dep. of Cardiology, Innsbruck, Austria;* [2]*University of Technology, Institute of Biomedical Engineering, Graz, Austria*

Background: Pacemaker generator longevity correlates negatively to current consumption and positively to the resistance of the pacing lead. Therefore, the use of a high impedance pacing lead theoretically results in an extension of generator longevity due to the high pacing impedance and the consecutive reduction of the charge transfer from the battery through the electrode-tissue interface. In this prospective, randomized trial the effect of high versus normal impedance ventricular leads on generator longevity was studied.
Methods: Twenty-six pts were included in this study (11 male, 15 female, age 73±13 years). A normal impedance lead (SJM model 1452t, bipolar) was implanted in 13 pts, the remaining pts received a high impedance lead (Medtronic model CapSure Z 5034 bipolar) in a randomized fashion. In order to create almost identical pacing conditions, all pts received a Medtronic Kappa KDR pacemaker and the same atrial lead model (Medtronic model 5068).
Results: After a mean follow up of 36.6±4.3 (Medtronic 5034) and 33.5±4.9 months (SJM 1452) no significant differences were observed in pacing and sensing thresholds in both groups. There were no significant differences in atrial lead performance as well as in lead related complications in both groups. The mean impedance of the high impedance pacing leads (5034) was 875.7±299.2 Ohms as compared to 631.5±152.5 Ohms for the standard pacing leads ($p < 0.001$). The longevity of the generator was calculated automatically by a programmed pacemaker algorithm. The 5034 leads provided a significant increase in generator longevity of 104.6 ±8.9 months vs. 98.0±7.7 months as compared to 1452 leads (p=0.028). This means an increase in longevity of 6.6 months in the high impedance lead group.

longevity (months)	maximum	minimum	mean
5032 lead	115.2±10.1	94.6±8.1	104.6±8.9
1452 lead	108.0±8.5	88.8±6.8	98.0±7.7
difference (months)	7.2±1.6	5.9±1.3	6.6±1.2
p-value (t-test)	0.023	0.042	0.028

Conclusion: Implantation of a high impedance lead for ventricular pacing results in a clinically relevant extension of generator longevity.

P404 Results of a randomized study comparing two atrial lead implantation sites: right atrial appendix versus lateral wall

K. Seidl[1], H. Schwacke[1], M. Rameken[1], A. Brandt[1], M. Vater[1], C. Wolpert[2], S. Spehl[2], J. Senges[1]. [1]*Klinikum Ludwigshafen, Cardiology Dept., Ludwigshafen, Germany;* [2]*Klinikum Mannheim, Cardiology, Mannheim, Germany*

Aim of this prospective randomized study was to evaluate the impact of the atrial lead implantation site on the subsequent development of atrial fibrillation. Patients (pts) with an indication for a dual chamber pacemaker without a history of atrial fibrillation were included. Pts were randomized either for atrial lead implantation at the right atrial lateral wall (RALW) vs implantation in right atrial appendix (RAA). Primary endpoint was the new development of atrial fibrillation during follow up.
Results: Dual chamber pacemakers were implanted in 99 pts. The indication was AV-block in 48 pts, sick-sinus syndrome in 51 pts. No pt had a history of atrial fibrillation before implantation. At the time of implantation 49 pts (67 ± 12 years) were randomized to the RAA, 50 pts (66 ± 12 years) were randomized to RALW. There was no significant differences either in demographic datas, clinical parameters and the indication of dual chamber pacemaker. Mean follow-up duration was 484 ± 358 days. In 28/99 pts (28%) atrial fibrillation was documented. In the Kaplan-Meier analysis the probability for the occurrence of atrial fibrillation during the initial 3 years was 29% in pts after lead implantation in the RALW and 54% in pts after implantation in the RAA ($p = 0.08$).

Atrial lead implantation site	Atrial fibrillation	No atrial fibrillation
RAA (49 pts)	17 pts (35%)	32 pts (65%)
RALW (50 pts)	11 pts (22%)*	39 pts (78%)

* $p = 0.16$

Conclusion: New onset of atrial fibrillation was observed in 1/3 of pts after lead implantation in the RAA vs 1/5 of pts after atrial lead implantation at the RALW ($p = 0.16$). In the Kaplan-Meier analysis a tendency was observed that pts after lead implantation in the RAA had earlier and more often episodes of atrial fibrillation during follow-up compared to pts with implantation at the RALW.

INFLAMMATORY INJURY OF THE VESSEL WALL

P405 Soluble VEGF and its soluble receptor, sFLT-1, and their correlation to endothelial-dependent vasodilation

C A S. Schmidt-Lucke[1], F. Belgore[2], D. Reinhold[3], G.Y.H. Lip[2], J.A. Schmidt-Lucke[1]. *[1]University Magdeburg, Cardiology, Angiology and Pneumology, Magdeburg, Germany; [2]City Hospital, University Department of Medicine, Birmingham, United Kingdom; [3]Immunology, Magdeburg, Germany*

Elevated concentrations of sVEGF are found in certain diseases with endothelial dysfunction. Similar VEGF concentrations were measured in healthy smokers (S) and controls (C). sFLT-1 has a high affinity for VEGF and may function as antagonist to VEGF. We were interested in the correlation between VEGF, sFlt-1 and endothelial function in healthy S and C.
In 20 healthy smokers and 20 matched control subjects without further cardiovascular risk factors, VEGF and free FLT-1 were measured from citrate plasma with an ELISA. Flow- (FMD) and acetylcholine-mediated (AMD) vasodilation (endothelial-dependent) (EDV) and nitroglycerine-mediated (NMD) vasodilation were measured on lower extremities with plethysmography (ml/100 ml tissue/min).
AMD was lower in S compared to C (11 vs. 15 ml/100 ml tissue/min ($p < 0,05$)). FMD (11 vs. 14) and NMD (3,5 vs. 4,4) showed only a trend. S and C showed similar VEGF-concentrations (12,9 ± 5,9 and 14,9 ± 11,8 pg/ml). sFLT-1 was lower in S than in C (33,9 ± 5,9 vs. 47,1 ± 34,0 ng/ml, $p < 0,01$), without a correlation between pack-years and FLT-1. There was no correlation between VEGF and sFlt-1 levels. An inverse correlation was found in both groups between VEGF and AMD (S: r= - 0,6, $p < 0,01$, C: r= -0,71, $p < 0,005$) and FMD (S: r= -0,56, $p < 0,05$, C: r= -0,58, $p < 0,005$), but not NMD. S and C with higher AMD (>12 ml/100 ml tissue/min) showed lower plasma VEGF ($p < 0,001$).
Healthy smokers showed impaired EDV. The soluble VEGF receptor, sFlt-1 is lower in smokers without showing a correlation to EDV. No correlation between FLT-1 and VEGF was found in these subjects. The amount of plasma sFlt-1 greatly exceeds VEGF. Longstanding smoking did not show an effect on VEGF concentrations. Circulating VEGF correlates inversely with EDV in smokers and controls, sFLT-1 seems not to play a dominant regulatory role in this context.

P406 Intraplaque C-Reactive protein is associated with plaque vulnerability

M. Meuwissen[1], A.C. van der Wal[2], R.J. de Winter[1], K.T. Koch[1], H.W.M. Niessen[3], C.M. van der Loos[2], A.E. Becker[2], J.J. Piek[1]. *[1]Academic Medical Center, Cardiology Dept., Amsterdam, Netherlands; [2]Academic Medical Center, Cardiovascular Pathology, Amsterdam, Netherlands; [3]Vrije Universiteit Medical Center, Cardiovascular Pathology, Amsterdam, Netherlands*

Background: The acute phase protein C-reactive protein (CRP) is an important risk factor for coronary artery disease. Preliminary data showed that CRP also accumulates in coronary plaques and promotes foam cell formation and/or complement activation that may lead to unstable coronary plaques.
Aim of the study:
To investigate the relation between CRP off culprit coronary atherectomy specimen and the expression of coronary syndromes.
Methods: A total of 54 patients with stable (SA, n=21) and unstable (UA, n=15) angina and acute myocardial infarction (MI, n=18) underwent directional coronary atherectomy (DCA) for culprit lesions. Cryostat sections of atherosclerotic plaques were immunohistochemically stained with the monoclonal antibodies CD-68 (macrophages; MAC), 5G4 (CRP), aE11 (complement, C5b-9) and 12E7 (Ox-LDL). Qualitative examination was performed by determination of the immunopositive areas in relation to fibrous cap, atheroma and colocalization. Quantitative analysis was performed by using image cytometry (QPRODIT 5.2) with systematic random sampling (expressed as percentage immunopositive tissue area of the total tissue area).
Results: Colocalization of CRP and complement was observed in the fibrous cap and atheroma and was more frequently present in plaque specimen of patients with MI (100%) compared to patients with SA (75%, p=0.079). Moreover, colocalization of CRP with Ox-LDL was significantly more frequently present in MI (100%) compared to SA (47%, p=0.0016). The table below shows the quantitative relation between CRP and MAC in relation to SA, UA and MI.

	SA (n=21)	UA (n=15)	MI (n=18)
MAC**	20±10	30+/13*	44±12*#
CRP**	12±9	25±16*	24±14*

**percentage immunopositive tissue area/total tissue area*p< 0.01 compared to SA and #p<0.01 compared to UA (ANOVA).

Conclusions: Amounts of CRP in culprit coronary lesions increase with the severity of acute coronary syndromes. Colocalization of CRP, complement, ox-LDL and macrophages suggests a pathogenic role for CRP in plaque destabilization.

P407 Increased levels of the furin, membrane type-1 metalloproteinase and metalloproteinase 2 activation cascade after balloon dilation

J.P.G Sluijter, M.B. Smeets, R.E. Verloop, E. Velema, G. Pasterkamp, D.P.V de Kleijn. *University Medical Centre Utrecht, Experimental Cardiology Laboratory, Utrecht, Netherlands*

Background: Matrix Metalloproteinase (MMP) activation is an important event in cardiovascular diseases such as de novo atherosclerosis, restenosis after balloon angioplasty and during sustained flow changes. Inhibition of MMPs, which are the only enzymes capable of degrading collagen, results in diminished arterial remodeling. Understanding the activation cascades of the MMPs might result in the development of more specific inhibitors. MMP-2, one member of this family, is activated by membrane type-1 MMP (MT1-MMP) that is activated by Furin, a proprotein convertase. Recently, we described the existence of the Furin, MT1-MMP and MMP-2 activation cascade in the arterial wall after sustained flow changes (physiological). Now we studied this activation cascade after pathological arterial injury (balloon dilation).
Methods: Unilateral balloon dilation was performed in femoral and iliac arteries in 25 New Zealand White rabbits. Arteries were harvested after 2, 7, 14 and 28 days. Diameter changes and intimal hyperplasia were determined compared to post-dilatation as a percentage of the total vessel area. Furin and MT1-MMP mRNA expression were determined by quantitative-PCR, MT1-MMP protein levels by western blotting and MMP-2 activation by zymography. Contralateral arteries were used as controls.
Results: see table

Expression levels

Days of survival	2	7	14	28
Diameter change (%)	3.8 ± 2.4	-8.3 ± 11.0	-9.0 ± 4.6	-9.7 ± 7.8
Intimal hyperplasia (%)	0	1.5 ± 0.6	5.0 ± 1.3	16.7 ± 2.7
Furin mRNA	9.5 ± 4.7 *	5.9 ± 3.2 *	3.1 ± 1.0	5.6 ± 2.7
MT1-MMP mRNA	6.8 ± 3.9	3.3 ± 0.7 *	7.9 ± 2.3 *	5.2 ± 1.7 *
MT1-MMP protein	1.6 ± 0.3	3.1 ± 0.7 *	16.9 ± 8.0 *	25.1 ± 11.0
active MMP-2 protein	17.2 ± 5.9 *	65.2 ± 23.7 *	124.9 ± 38.2 *	40.0 ± 20.2 *

Ratio operated/control for expression levels; mean ± sem, * =p<0.05

Conclusions: Increase in arterial Furin and MT1-MMP expression preceded or coincided with increased MMP-2 activation after balloon dilation. This study confirmed the presence of a proprotein convertase- metalloproteinase axis in the artery and opens the use of Furin inhibitors to prevent arterial remodeling and neointima formation after injury at the root of activation.

P408 Synthesis of the interleukin-6 receptor in human PMN is regulated post-transcriptionally via the mTOR signaling pathway

S. Lindemann[1], N D. Tolley[2], N H. Riedel[2], A S. Weyrich[2], G A. Zimmerman[2]. [1]*Johannes Gutenberg-University Mainz, Department of Medicine II, Mainz, Germany;* [2]*Eccles Institute of Human Genetics, Program in Human Molecular Biology, Salt Lake City, United States of America*

Polymorphonuclear leukocytes (PMN) adhesion and migration are involved in host defense and serve a beneficial role in a well-contained inflammatory response. However, in dysregulated inflammation, PMN may contribute to myocardial tissue damage (i.e. myocardial infarction). The cytokine Interleukin-6 and its receptor (IL-6R) are considerably involved in this inflammatory scenario. Although these mechanisms are complex, it is generally believed that the majority of tissue damage results from the release of preformed mediators. To date, it is not known, if PMN have regulated protein synthesis at the transcriptional level. We isolated PMN from healthy donors and activated them with platelet activating factor (PAF) [1nM-1μM] for 1-60 min.. Gene array analysis revealed that PMN contain multiple mRNAs, but PMN-activation with PAF does not induce a broad transcriptional response. Therefore, we concluded that PMN bypass well-known transcriptional regulatory pathways in favor of direct translation of preexisting mRNAs into protein. The mTOR (mammalian target of rapamycin) translational pathway is activated in PMN that were stimulated by PAF. By western blot analysis, we were able to show, that p70S6 kinase, a downstream kinase of mTOR, and 4E-BP1 are phosphorylated within one minute. The phosphorylation of p70S6 kinase and 4E-BP-1 were completely inhibited by rapamycin [10nM] indicating that mTOR is a crucial upstream signaling component of this translational pathway in PMN. By PCR, sequencing and western blot analysis we confirmed that mTOR1 is the predominant homologue present in PMN. Using S35-methionine incorporation and 2-dimensional gel electrophoresis, we also found that PMN synthesize multiple proteins upon activation with PAF [10nM]. The synthesis of some proteins was suppressed by rapamycin, while actinomycin D had minimal effect. We identified one of these proteins as the IL-6R. Further studies demonstrated that IL-6R transcripts are constitutively present in resting PMNs and the 5'-untranslated region of this mRNA has complex secondary structure and multiple polypyrimidine tracts making it an excellent candidate for mTOR-dependent translation. By western blot analysis we demonstrated, that the IL-6R is rapidly (within 30 min) synthesized in PMN. Rapamycin completely abrogated this response while actinomycin D had no influence, indicating again that the production of the IL-6R in PMN is translationally regulated. Taken together, these data demonstrate that PMN synthesize biologically relevant proteins - among these the IL-6R - through translationally driven mechanisms.

P409 Effects of vitamins C and E on serum levels of leukocytes adhesion molecules and lipid hydroperoxides, in chronic smokers

C. Antoniades, D. Tousoulis, M. Toutouza, C. Vassiliadou, C. Toutouzas, G. Goumas, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, Cardiology Unit, Athens University, Athens, Greece*

Background: Serum levels of soluble vascular cell adhesion molecule (sVCAM-1) and soluble intercellular adhesion molecule (sICAM-1), as well as lipid hydroperoxides (LPO) (marker of lipid peroxidation), are implicated in the pathogenesis of atherosclerosis. Purpose of this study was to investigate the effect of combined administration of antioxidant vitamins C and E on endothelial function, and serum levels of sICAM-1, sVCAM-1 and LPO, in chronic smokers.

Methods: 36 healthy young smokers (20 males 16 females aged 36±2 years) were enrolled in this double blind placebo controlled study. Subjects were divided into 4 groups receiving vitamin C 2g/day (n=10) (group A), vitamin C 2g/day and vitamin E 400IU/day (n=11) (group B), vitamin C 2g/day and vitamin E 800IU/day (n=9) (group C) or placebo (n=6) (group D), for 4 weeks. Forearm blood flow was measured using venous occlusion strain gauge plethysmography. Endothelium dependent flow mediated vasodilation (FMD) was expressed as the % change from baseline to post reactive hyperemia blood flow. Endothelium independent % change flow (NTR%) was assessed after sublingual nitroglycerin administration. Plasma levels of sVCAM1, and sICAM1 were determined by enzyme linked immunosorbent assay, while LPO was determined using a spectrophotometric assay.

Results: Blood pressure, heart rate, body weight, basal forearm blood flow and NTR% were similar before and after treatment. FMD was significantly increased in groups B (46.6±5.5 to 74.1±9.3%, $p<0.05$) and C (43.6±3.9 to 74.9±4.2%, $p<0.01$), while remained unaffected in groups A and D. Serum levels of sVCAM-1 and sICAM-1 significantly reduced in group C (from 339±14 and 318±21 to 298±11 and 250±19 ng/ml respectively, $p<0.05$ for both), while remained unaffected in groups A, B and D. LPO was significantly reduced in groups B and C (from 14.5±1.2 and 15.4±2.9 to 8.8±1.6 and 8.3±1.7 iM respectively, $p<0.05$ for both).

Conclusions: Chronic administration of vitamin C (2g/day) combined with vitamin E (800IU/day), reduces blood levels of sVCAM-1 and sICAM-1, improves endothelial function and reduces lipid peroxidation in healthy young smokers. These findings may have therapeutic implications in chronic smokers.

P410 Signal pathways of integrin-rac-p38MAPK mediate p53-dependent SMC apopotsis

F. Wernig, M. Mayr, Y. Hu, Q. Xu. *St George's Hospital Medical School, Cardiological Sciences, London, United Kingdom*

Apoptosis of smooth muscle cells (SMCs) caused by biomechanical force represents one of the first events in the pathogenesis of ateriosclerosis (Xu Q, Trands Cardiovasc. Med. 2000;10:35-41). To investigate signal transduction pathways leading to apoptosis, SMCs growing on flexible membranes precoated with collagen I, laminin, elastin, and pronectin® were subjected to cyclic strain stress. Increased SMC apoptosis was 5.7 fold higher on collagen I matrix-coated plates compared to other matrices. Such increased apoptosis was blocked by pretreatment with either cytochalasin B, a toxin inhiniting integrin signaling, or with an anti-beta1 integrin monoclonal antibody. Only SMCs grown on collagen I showed a significant increase in p53 protein production. Gel mobility shift assays revealed that mechanical stress rapidly led to p53 activation, which was largely attenuated by SB202190 (p38MAPK inhibitor) pretreatment, or dominant negative Rac transfection. Kinase assays demonstrated that p38MAPK directly phosphorylates p53. SMCs derived from p53-/- mice lacking p53-binding activity lost its ability to express Bax and showed no apoptosis by strain stress. Likewise, mechanical stress resulted in upregulation of anti-apoptotic Bcl-2 and Bcl-xL, and a marked loss of mitochondrial membrane potential occurred. Furthermore, when integrin receptors were block p38MAPK activation and p53 phosphorylation were significantly inhibited in stressed SMCs. Taken together, our data provide the first evidence that p53 activation and Bcl-2 family protein expression play a crucial role in SMC apoptosis induced by mechanical stress, during which mitochondria are key regulators, while integrin-rac-p38MAPK pathways contribute to p53 activation.

P411 Role of caveolin in mechanic stretch induced proliferation of vascular smooth muscle cells

D. Sedding[1], J. Hermsen[2], U. Seay[2], M. Heil[3], H. Tillmanns[2], R.C. Braun-Dullaeus[2]. [1]*Medizinische Klinik I, Abteilung für Molekulare Kardiologie, Giessen, Germany;* [2]*Giessen University, Internal Medicine/Cardiology Dept., Giessen, Germany;* [3]*Max-Planck-Institut Bad Nauheim, Dept. of experimental Cardiology, Bad Nauheim, Germany*

Backrgound: Increased mechanic forces as ocuring in severe hypertension or venous bypass grafts cause increased proliferation of vascular smooth muscle cells (VSMC) which represents a major component in vascular lesion formation. The Phosphoinositide 3-kinase (PI3K)/proteinkinase B (Akt) pathway represents a central signalling system in the regulation of these processes. We hypothesiced that caveolin 1 is involved in the sensing of mechanic stimuly and subsequent activation of the PI3K/Akt pathway. Methods and results: Quiescent, mitogen-free rat VSMC were subjected to cyclic-stretch for up to 24 h (0,5 Hz at 120% resting length).Lysates were used for immunoblot of activated (phospho-) Akt. Akt was phosphorylated and activated after 10 min of stretch and after 24h we observed an increase in cellular proliferation as measured by propidium iodid staining and FACS analysis (16±2,1 vs. 24±2,6% of cells in S/G2 phase n=6, $p<0,05$). Transfection of cells using caveolin 1 antisense (cav1-AS) but not control AS prevented phosphorylation of Akt. cav1-AS as well as inhibitors of the PI3K (Wortmannin and LY294002) inhibited stretch-induced proliferation of VSMC (cav1-AS:18±3,1% vs. 24±2,6% cells in S/G2 phase, n=6, $p<0.05$). Transfection of cav1-AS also resulted in an increase of apoptotic cells after 24h of stretch (26±5% vs. 8±2% in control cells) as measured by dUTP-biotin nick end labeling (TUNEL).

Conclusion: Caveolin1 is essential for the stretch-induced activation of the PI3K/Akt pathway, thereby controling proliferation and apoptosis of VSMC. Caveolin 1 is an important regulator in mechanical stress induced remodeling of the vascular wall.

LIPIDS AND ATHEROSCLEROSIS

P412 Changes in serum lipids, lipoproteins and apolipoproteins in patients with acute infection

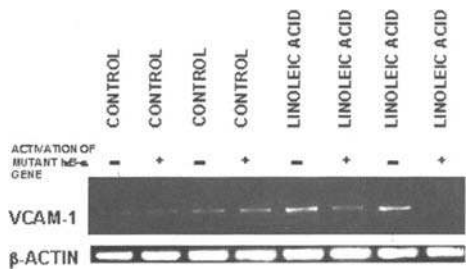
E. Liberopoulos[1], G. Pappas[1], G. Alexandridis[1], S. Tsiara[1], H. Milionis[1], E. Bairaktari[2], E. Tsianos[1], M. Elisaf[1]. [1]*University Hospital Of Ioannina, Internal Medicine Dept., Ioannina, Greece;* [2]*University Hospital Of Ioannina, Biochemistry Laboratory, Ioannina, Greece*

Background: Transitory changes in the serum levels of lipids, and particularly hypocholesterolemia, have been observed in the course of acute infections. However, there are limited data on the effect of acute inflammatory response on the serum levels of apolipoproteins (Apo) AI, B, E and lipoprotein (a) [Lp(a)].
Aim: To examine the incidence of hypocholesterolemia and the changes of serum lipid parameters during acute infection in patients hospitalized in an internal medicine clinic.
Patients and methods: Serum lipid parameters were measured in 3.000 patients who were admitted to our clinic during a period of one year. Hypocholesterolemia was defined as serum total cholesterol <120 mg/dl. Hypocholesterolemic patients with acute infection were compared with 116 age and sex matched healthy individuals. Serum lipid parameters of 20 hypocholesterolemic patients with acute infection were followed up after their discharge. All values are expressed in mg/dl.
Results: Hypocholesterolemia was found in 120 patients (4%). 58 patients (48.3%) had acute infection [45 patients (77.5%) had bacterial infections, 8 patients (13.8%) viral infections and 5 patients (8.7%) kala-azar]. Compared with control patients, hypocholesterolemic patients with acute infection had significantly lower levels of total cholesterol (98±19 vs 204±42, $p<0.001$), HDL cholesterol (20±8 vs 42±8, $p<0.01$), LDL cholesterol (59±19 vs 120±36, $p<0.001$), ApoAI (64±22 vs 146±24, $p<0.01$) and ApoB (66±20 vs 102±26, $p<0.01$), whereas serum triglycerides were unaffected (127±61 vs 120±98, p=NS). Interestingly, ApoE levels were significantly higher (47±23 vs 39±11, $p<0.05$) and Lp(a) levels were significantly lower [median 3.85 (range 0.8-33.2) vs 7.9 (0.8-56), $p<0.01$] compared with the control population. During the follow-up the levels of total cholesterol, HDL cholesterol, LDL cholesterol and ApoAI were increased by 48.7% ($p<0.001$), 45.5% ($p<0.05$), 79.4% (p=0.002) and 88.3% ($p<0.001$), respectively. Furthermore, ApoE levels were significantly reduced by 36% ($p<0.05$), while Lp(a) levels were significantly increased (from a median value of 2.5 to a median value of 9.6, $p<0.05$).
Conclusion: Infection-induced hypocholesterolemia is a frequent metabolic disorder in hospitalized patients. Our data point out that Lp(a) may be a negative acute phase reactant. Furthermore, we show for the first time that serum ApoE levels are elevated during the acute inflammatory response.

P413 Linolic acid induced vascular cell adhesion molecule-1 expression depends on nuclear factor kappa-B activation

W. Dichtl[1], M.P. Ares[2], O. Pachinger[1], J. Nilsson[2]. [1]*Universitätsklinik Innsbruck, Innere Medizin - Kardiologie, Innsbruck, Austria;* [2]*Wallenberg Lab, MAS, Department of Medicine, Malmö, Sweden*

Endothelial activation is an important step in atherogenesis. In addition to established cardiovascular risk factors such as hypercholesterolemia, hypertension, diabetes mellitus and homocysteinemia, high plasma levels of triglyceride-rich lipoproteins may be an important cause of endothelial activation as well. Free fatty acids hydrolysed from core triglycerides of these particles can exert both pro- and antiinflammatory effects on the vascular wall. Omega-3 fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), have been shown to inhibit cytokine-induced endothelial activation. In contrast, we and others have previously shown that the omega-6 fatty acid linoleate activates transcription factor nuclear factor kappa B (NF-kappa B) in endothelial cells.
In this study we show that linoleic acid stimulates vascular adhesion molecule-1 (VCAM-1) protein and mRNA expression in cultured human endothelial cells, as assessed by immunoflourescence and northern blotting. By use of cultured rat aortic endothelial cells transfected with an IkappaB super-repressor (delta N2 cells), we provide evidence that NF-kappa B signalling is required in the linoleic acid-induced VCAM-1 expression in endothelial cells, whereas other transcription factors appear to be involved in the increased endothelial plasminogen activator inhibitor-1 (PAI-1) production in response to linoleic acid.
In conclusion, these findings support the notion that linoleic acid influences the expression of inflammatory genes in endothelial cells by interference with the redox-sensitive transcription factor NF-kappa B.



P414 AT1 receptor antagonism improves hypercholesterolemia-associated endothelial dysfunction

S. Wassmann, S. Hilgers, U. Laufs, M. Boehm, G. Nickenig.
Universitaetskliniken des Saarlandes, Medizinische Klinik-Innere Medizin III, Homburg/Saar, Germany

Hypercholesterolemia-induced AT1 receptor overexpression is thought to be a key event in the development of endothelial dysfunction. To verify this pathophysiological concept, the effect of a 6 week-treatment with the AT1 receptor antagonist candesartan (16 mg/d) on endothelium-dependent vasodilatation and serum inflammation markers was compared to the treatment with placebo or the calcium channel antagonist felodipine (5 mg/d) in 47 hypercholesterolemic patients (LDL cholesterol>160 mg/dl).
Methods and Results: Endothelial function was assessed by measurement of forearm blood flow (FBF) by venous occlusion plethysmography. FBF during reactive hyperemia was significantly improved by candesartan, whereas felodipine and placebo exerted no effect. Nitroglycerin-induced vasorelaxation and basal FBF were not altered. Blood pressure as well as cholesterol levels were not affected significantly by any drug. Serum concentrations of 8-isoprostanes, monocyte chemoattractant protein-1 (MCP-1), and soluble intercellular adhesion molecule-1 (sICAM-1) were significantly reduced by AT1 receptor antagonist treatment but not by placebo or felodipine. Levels of high-sensitivity C-reactive protein (hs-CRP) and tumor necrosis factor-alpha (TNF-alpha) were not altered significantly by any treatment.
Conclusions: AT1 receptor antagonism improves vascular function during hypercholesterolemia applying to endothelium-dependent vasodilatation, oxidative stress, and events involved in monocyte attraction and adhesion. Thus, AT1 receptor blockade may potentially represent a novel approach for the prevention of vascular dysfunction associated with hypercholesterolemia independent of lipid and blood pressure-lowering interventions.

P415 Effects of atorvastatin on in-stent-stenosis in normo- and hypercholesterolemic rabbits

C. Herdeg[1], M. Oberhoff[2], A. Baumbach[2], S. Schroeder[1], I. Spyridopoulos[1], K. Karsch[2]. [1]*Medizinische Uniklinik III, Cardiology, Tuebingen, Germany;* [2]*Bristol Heart Institute, Cardiology, Bristol, United Kingdom*

Background: Statins can inhibit proliferation irrespective of total plasma cholesterol levels. In-stent-stenosis goes along with an elevated and prolonged proliferation, but also inflammatory reactions with macrophages, foam cells and lymphocytes around the stent struts. Potentially, the antiproliferative and lipid-lowering effects of statins can synergistically limit neointima formation after stenting. This hypothesis was tested in normo- and hypercholesterolemic rabbits. Methods: Stents were placed in the iliac arteries of 40 rabbits according to the Schwartz-injury-model. Twenty animals were fed an 0.5% hypercholesterolemic diet, the other half was normocholesterolemic. Both groups received either atorvastatin (3 mg/kg b.w. per day) or placebo (4 groups, n=10 each). After 28 days, the animals were killed and stented segments were excised. Immunohistochemistry (bromodeoxyuridine, alpha-actin, RAM11-macrophages and von Willebrand factor) was performed, morphometric analysis was done in cuts with the stent left in place. Data were related to injury- and inflammation scores and the total drug uptake. Results: Proliferation was significantly increased in both hypercholesterolemic groups. No significant difference in proliferation was found in atorvastatin-treated animals, both normo- or hypercholesterolemic, versus controls. Apparently significant differences in morphometric results between the 4 groups disappeared when carefully relating the results to the extent of injury and the total drug uptake. Conclusion: In this animal model, atorvastatin was not able to limit in-stent-stenosis, neither via its lipid-lowering properties nor via an independent antiproliferative effect.

P416 Prevalence, distribution and correlates of thoracic aortic atherosclerosis in patients with heterozygous familial hypercholesterolemia

S.G. Lambrou, C. Aggeli, D. Panagiotakos, I. Skoumas, A. Frogoudaki, C. Pitsavos, C. Stefanadis, P. Toutouzas. *Athens University, Dept. of Cardiology, Athens, Greece*

Atherosclerosis of the thoracic aorta (ATA) correlates with atherosclerotic affliction of other vascular sites and prognosticates cardiovascular morbidity. In this study, multiplane transesophageal echocardiography (TEE) was employed to asssess the characteristics of ATA among an unselected population of patients (pts) with heterozygous familial hypercholesterolemia (hFH) attending the outpatient dyslipidemia unit of our department.

Methods: Between Jan 1999-Jan 2002 TEE was performed in 82 pts with hFH (aged 41±11 years, 41 men). The studies of the thoracic aorta were stored on tape and were reviewed off-line in a blinded fashion. ATA was graded by a modified Ribakove score as: grade 1: normal intima; 2: increased intimal echodensity without thickening or irregularity; 3: single atheroma of ≤3 mm maximum width; 4: >1 atheromas ≤3 mm; 5: ≥1 atheromas >3 mm; 6: mobile/ulcerated plaques. ATA was scored separately in each aortic segment (ascending, arch, descending) and each pt was assigned a single score based on the largest identified lesion overall. Grades >3 were regarded as representing significant ATA.

Results: Twenty-one pts had never received hypolipidemic treatment prior to the examination; 14 pts had a history of clinically manifest coronary artery disease. Mean serum LDL-cholesterol was 265±91 mg/dl. ATA grade was 1 in 1 pt, 2 in 31, 3 in 20, 4 in 17, 5 in 12 and 6 in one pt. The descending thoracic aorta was the commonest single location of the major grade-defining ATA lesions (n=25, 30.5%), followed by the aortic arch (n=13) and the ascending thoracic aorta (n=4); among the remaining cases, lesions of equal severity were hosted by 2 aortic segments in 21 and by all 3 segments in 19 pts. Ordinal regression analysis performed on demographic, clinical and biochemical variables identified age (p=0.02), postmenopausal status (p=0.008), lack of previous therapy (p=0.04), and serum LDL-C level (p=0.04) as independent positive correlates of ATA severity; Intriguingly enough, a history of cholecystectomy due to gallstone disease (p=0.02) was a significant negative correlate of ATA severity.

Conclusions: ATA is highly prevalent in unselected pts with hFH. The duration of the disease and the success of lipid-lowering treatment influence ATA severity in this patient population. In view of potential therapeutic implications entailed by significant ATA, the traits indicating a high likelihood of its presence might be exploited in order to select hFH patients for evaluation of the thoracic aorta by TEE.

P417 Role of oxysterol stereospecificity in patients with coronary artery disease

I. Spyridopoulos[1], K. Shatat[2], S. Al Makdessi[2], H. Sweiden[2], A. Rimner[2], W. Schöbel[2], P. Mayer[2], D. Hilbert[2]. [1]*Universitätsklinikum Frankfurt, Department of Cardiology, Frankfurt, Germany;* [2]*Medizinische Klinik III, Cardiology, Tuebingen, Germany*

Circulating oxidized LDL is a known marker for identifying patients (pts) with coronary artery disease (CAD). While unmodified cholesterol does not exert toxicity, oxysterols as one compound in oxLDL are believed to be mainly responsible for endothelial toxicity. We developed a method to quantify circulating oxysterols in human plasma by gas chromatography. Validation for the identity of chromatography peaks was achieved by mass spectometry.

In this preliminary study we included pts who underwent coronary angiography to either exclude (Control) or secure the diagnosis of CAD. Pts with coexisting diseases other than diabetes or hypertension were excluded from this study. Total LDL cholesterol was higher in the Control group (130.4 vs. 129.5 mg/dl). The table shows, that the only significant difference between the 2 groups is represented by the 5-beta-epoxide plasma levels ($p<0.05$) and a trend in 7-beta-OH-cholesterol (p=0.11). Both were elevated in pts with CAD. In parallel we performed in-vitro studies using human arterial endothelial cells (HAECs). We found induction of apoptosis through caspase-3 like enzymes by oxysterols. This effect was highly dependent on the stereospecificity of oxysterols: beta-isomers of epoxide or 7-OH-cholesterol induced up to 3-fold higher amounts of apoptosis and mitochondrial cytochrome C release in HAECs compared to their alpha-isomers.

Free Plasma-Oxysterols [ng/ml]

mean (± SEM)	Control (n=4)	CAD (n=9)
7-alpha-OH-cholesterol	66.8 (9.9)	64.7 (21.3) NS
7-beta-OH-cholesterol	5.9 (5.7)	19.5 (17.0) NS
5-alpha-epoxide	67.6 (12.1)	74.2 (27.0) NS
5-beta-epoxide	4.6 (2.5)	58.3 (21.8) *
25-OH-Cholesterol	2.5 (1.5)	3.4 (1.1) NS

NS not significant, *$p<0.05$

Conclusion: Beta-isomers of oxysterols were significantly elevated in plasma from pts with CAD. In-vitro studies demonstrated the importance of oxysterol stereospecificity concerning their potential to harm endothelial cells. While analysis of oxysterol levels in a large cohort of CAD pts has to further solidify their role in atherosclerosis, stereospecific effects might be of superior importance in the mechanism of atherogenesis.

P418 Effects of atorvastatin treatment on vascular endothelium, inflammatory process and heart function, in patients with heart failure

M. Koutsiopoulou[1], D. Tousoulis[2], C. Antoniades[2], E. Bosinakou[1], C. Tentolouris[2], C. Pitsavos[2], C. Stefanadis[2], P. Toutouzas[2]. [1]*Hippokration Hospital, Athens, Greece;* [2]*Hippokration Hospital, Cardiology Unit, Athens University, Athens, Greece*

Background: Heart failure is characterized by endothelial dysfunction and increased serum levels of inflammatory markers such as interleukin-6 (IL-6), tumor necrosis factor (TNF-a) and soluble vascular cell adhesion molecule (sVCAM-1). Statin treatment, seems to restore endothelial function in hypercholesterolemic patients while its anti-inflammatory effects are unknow. Purpose of this study was to investigate the effect of atorvastatin treatment on endothelial function and inflammatory processin patients with heart failure.

Methods: In this double blind placebo controlled study, 38 patients with heart failure (30 males 8 females, aged 65±2 years old) were enrolled. 20 patients received atorvastatin 10mg/day (group A) while 18 patients received placebo (group B) for 4 weeks. All patients were NYHA II to IV. Forearm blood flow was measured using venous occlusion strain-gauge plethysmography. Endothelium dependent flow mediated vasodilation (FMD) was expressed as the % change from baseline to maximal flow during reactive hyperemia. Endothelium independent flow (NTG%) was expressed as the % change from baseline to post sublingual nitroglycerin administration flow. Serum levels of IL-6, TNF-a and sVCAM-1 were determined with ELISA. All values are expressed as mean±SEM

Results: FMD was significantly improved in group A (from 44.1±5.4 to 96.1±13.1% $p<0.01$) while remained unaffected in group B (from 51.9±5.6 to 47.9±6.35%). Serum levels of IL-6, TNF-a and sVCAM-1 were decreased in group A (from 7.05±0.7, 3.4±0.3 and 585.5±50.1 to 5.9±0.51 pg/ml $p<0.05$, 2.7±0.2 pg/ml $p<0.05$ and 490.4±51.0 ng/ml p=NS) while remained unaffected in group B (from 7.52±0.81, 4.35±0.76 and 698.46±69.1 to 6.5±0.88 pg/ml, 4.45±0.71pg/ml and 585.08±75.3ng/ml p=NS for all, respectively).

Conclusions: Treatment with atorvastatin improves endothelia function in patients with heart failure. Atorvastatin treatment also decreases serum levels of IL-6 and TNF-a in those patients. These findings indicate that statins might be useful in patients with heart failure by affecting endothelial function and inflammatory process.

ANGIOGENESIS

P419 Human tissue kallikrein: a new bullet for therapeutic angiogenesis

M.B. Salis[1], C. Emanueli[1], A. Pinna[1], G.L. Condorelli[2], A.F. Milia[1], P. Madeddu[1]. [1]*Cardiovascular Medicine Unit, INBB National Laboratory, Osilo, Italy;* [2]*Internal Medicine, La Sapienza University, Rome, Italy*

Therapeutic angiogenesis represents a new promising strategy for the treatment of ischemic disease. Following successful application in animal models, the strategy has been transferred from the bench to the bedside. However, clinical results did not result in the level of efficacy for which researchers had hoped. Mechanistic approaches based on molecules capable of completing the angiogenic program may help overcoming the present impasse. We evaluated the pharmacological profile and the vascular and molecular targets of human tissue kallikrein (hTK), a protease that cleaves the vasodilator peptides kinins from kininogen. Local adenovirus-mediated hTK gene (Ad.CMV-hTK) transfer increased capillary density in mouse normoperfused limb muscle. A infecting dose of 10^5 pfu increased muscular capillary density by 23%, while 10^4 pfu was not effective. The angiogenic response to hTK reached a plateau (53% increase in capillarity) in a range between 10^7 and 10^9 pfu. Similar effects were observed by delivering hTK in a plasmid vector (980±41 vs 580±20 cap/mm^2 in contralateral non-injected muscle, $P<0.01$). Ad.CMV-hTK also increased arteriole density from a value of 8±2 art/mm^2 in controls to 20±3 and 21±4 art/mm^2 at 2 and 8 weeks post-injection ($P<0.01$), while no significant change was detected in muscles injected with reporter gene Ad.CMV-Luc. Morphometric analysis documented that the increase encompasses arterioles up to 164 μm of internal diameter. Expression of angiogenesis-related genes was evaluated by microarray analysis in muscles injected with Ad.CMV-hTK or Ad.CMV-Luc. We found that transfection with hTK gene results in induction of VEGF, angiopoietin 2, plasminogen activator receptor 2, plasminogen activator inhibitor, and thrombospondin genes. In separate experiments, dominant negative Akt gene was coadministered with Ad.CMV-hTK to see if Akt is implicated in the angiogenic action of hTK. Dominant negative Akt blunted the microvascular effects of hTK (767±59 vs 962±16 cap/mm^2, $P<0.02$) while wild-type Akt gene did not produce significant effects (858±57 cap/mm^2). These results indicate that neovascularization promoted by hTK derives from capillary sprouting and collateral artery growth, which is consistent with induction of both angiogenesis and arteriogenesis. The abilty of hTK to interfere with various angiogenesis modulators may account for the formation of a persistent, well-tempered neovascularization. The pleiotropic kallikrein-kinin system may represent a new target for therapeutic angiogenesis.

P420 Sonic hedgehog induces angiogenesis, upregulates VEGF and angioproteins, and is postnatally activated in response to skeletal muscle ischaemia

R. Pola[1], L. Ling[2], E. Gaetani[3], A. Flex[3], T. Aprahamian[4], M. Bosch-Marcè[4], D.W. Losordo[4]. [1]*A. Gemelli University Hospital, Lab. of Vascular Biology and Genetics, Rome, Italy;* [2]*Biogen Inc., Cambridge, MA, United States of America;* [3]*A. Gemelli University Hospital, Internal Medicine, Rome, Italy;* [4]*Cardiovascular Research, Medicine, Boston, MA, United States of America*

Sonic hedgehog (Shh) is a morphogen that regulates epithelial-mesenchymal interactions in many tissues during embryonic development. We found that systemic administration of Shh induced upregulation of the Shh receptor Ptc1 in heart and peripheral vasculature, indicating that the Shh pathway can be activated in vivo in adult animals. In vitro studies, showed no effect of Shh on endothelial cell migration or proliferation. In vivo, however, Shh was found to induce robust neovascularization in the murine corneal model of angiogenesis. Similarly, Shh was also able to induce angiogenesis, augmented blood flow recovery and limb salvage in operatively induced hindlimb ischemia in aged mice. The angiogenic response to Shh appears to occur indirectly through the activation of Ptc1 on neighboring fibroblasts. Shh stimulation of human fibroblasts in vitro increases mRNA synthesis of VEGF121, VEGF165, VEGF189, Ang-1 and Ang-2. Production of VEGF165 protein from human fibroblasts is also increased by Shh. Then, we studied whether the endogenous Shh pathway, so important during embryogenesis, plays a physiologic role in muscle regeneration following ischemia in adults. We demonstrated that, while no Shh is expressed under baseline, quiescent conditions, muscle regeneration induced in response to ischemic injury is associated with activation of the Shh signaling pathway. Shh was strongly activated in skeletal muscle after ischemia and its receptor Ptc1 was upregulated in interstitial mesenchymal cells within the ischemic area, indicating that these cells respond to Shh and that the Shh pathway is functional. The Shh responding cells produced VEGF under ischemic conditions and treatment with a Shh blocking antibody inhibited the angiogenic response and the upregulation of VEGF.

Conclusions: Our study shows for the first time that the Shh signaling may be functional in adult and fully differentiated muscular tissues and has a regulatory role on angiogenesis during muscle regeneration following ischemia. In addition, the discovery of angiogenic activity for Shh, combined with its known morphogenic functions in development, suggests that Shh may coordinate epithelial/stromal interactions with the ingrowth of vasculature during development. The ability of Shh to promote limb salvage in aged mice, through the enhancement of blood flow and capillary density, suggests that Shh may merit further investigation as proangiogenic therapy for ischemic disorders.

P421 Adventitial delivery of the gene for an amphipathic peptide using optimized gene transfer conditions

S. Nikol[1], J. Pelisek[1], M.G. Engelmann[2], A. Golda[2], A. Fuchs[3], M. Shimizu[2], C. Mekkaoui[4], P.H. Rolland[4]. [1]*University Hopsital, of Cardiology and Angiology, Muenster, Germany;* [2]*Klinikum Grosshadern, Med. Clinic I, Munich, Germany;* [3]*Klinikum Grosshadern, Clinic of Pediatrics, Munich, Germany;* [4]*Universite Mediterranee, Laboratoire Cardiovasculaire, Marseille, France*

Amphipathic peptides are animal peptide antibiotics that inhibit mitochondrial functions and thus tumor growth in animal models. Therefore they could be of use in preventing cell proliferation and restenosis. The aim of this study was to investigate the potential therapeutic effects of locally delivering the gene for an amphipathic peptide into a porcine injury model. Extensive investigations were performed to achieve maximum gene transfer efficiencies for non-viral vectors in vivo. Alos, further improvements of the needle injection catheter for local drug delivery was achieved by increasing the length, flexibility and modification for the use with guide wire.

Numerous DNA/liposome ratios for 17 different liposomes and adjuvant agents were tested in quiescent smooth muscle cells for maximum transfer efficiencies. The gene was inserted into an expression vector plasmid and mixed with DOCSPER liposomes in a ratio of DNA to liposome of 1:10 according to optimal results achieved. Domestic pigs (n=24) were fed a normal chow diet. Porcine iliac artery segments were balloon-injured on both sides in vivo in a standard manner. The needle injection catheter was used to deliver the gene locally into the adventitial of injured artery on one side in each pig; the other side served as a control and was only balloon-injured. Arterial segments were excised at 7 days, 3 weeks or 4 months. Tissues were examined at histology, with computer-assisted morphometry and PCR/RT-PCR. Similar experiments with the β-galactosidase reporter gene served to confirm expression of transfected gene. A reduction in neointimal hyperplasia in arteries treated with the gene of the amphipathic peptide could be shown. At 21 days, neointimal area in balloon-injured segments was 0.32±0.13mm^2 SEM compared with a reduced neointimal area in treated segments: 0.05±0.02mm^2 SEM ($p < 0.05$). Gene transfer efficiency was up to 15% in the adventitia using optimized transfer conditions for non-viral gene transfer.

In conclusion, the gene for an amphipathic peptide was successfully and safely delivered using the needle injection catheter resulting in reduction of neointimal formation. Gene transfer effciciencies were comparable to those achieved by viral gene transfer. Such peptides may therefore have therapeutic potential in the prevention of restenosis.

P422 Alpha 5 beta1 is a new interesting target for the treatment of SMC migration and invasion dependent vascular pathologies

R. Blindt[1], F. Vogt[1], J. vom Dahl[1], N. Krott[2], K. Filzmaier[1], P. Hanrath[1], A.K. Bosserhoff[3]. [1]*University Hospital RWTH Aachen, Medical Clinic 1, Aachen, Germany;* [2]*"Biomat", Interd. Center of Clinical Research, Aachen, Germany;* [3]*Institute for Pathology, University Hospital Aachen, Aachen, Germany*

Migration and invasion of human arterial smooth muscle cells (haSMC) are essential steps during the development of atherosclerosis, restenosis after vascular intervention, and transplant vasculopathy. Due to their contact to the surrounding extracellular matrix integrins have been previously shown to regulate cell phenotype and cell function. There is evidence that differential expression of integrins has a major impact on the invasive phenotype of myocytes. For this reason, a quiescent and a migrating, invading haSMC phenotype was induced by cell culture conditions. Using a Boyden Chamber model migrating and invading haSMCs in contrast to quiescent haSMCs were capable to migrate towards chemoattractive stimuli and even capable of invading through a basement membrane equivalent. FACS analysis of integrin expression between both phenotypes showed a strong upregulation of alpha 5 beta 1 (13.1x) as well as alpha v beta 3 (3.4x) in proliferating haSMCs in comparison to quiescent haSMCs. Other integrins analysed (alpha 2, alpha 3, alpha 4, alpha IIb) did not show significant differential regulation. In further functional assays, inhibition of alpha 5 beta 1 led to inhibition of migration in cell sedimentation manifold assay (CSM, -29±8%), Boyden chamber assay (-49±16) and collagen contraction (-125%). In contrast, inhibition of alpha v beta 3 had no effect on inhibition of haSMC migration in CSM assays but reduced invasion in the Boyden chamber (-45±8%). Interestingly alpha v beta 3 caused even a significant stimulation of collagen contraction in comparison to control (+52%). We conclude that alpha 5 beta 1 is a new interesting target for the treatment of SMC migration and invasion dependent vascular pathologies.

P423 Angiogenesis in human atherosclerotic carotid plaques is associated with expression of macrophage migration inhibitory factor 1-alpha

A. Schmeisser[1], C. Graffy[2], T. Illmer[3], C. Schwencke[1], H. Loesel-Sadee[4], G. Ehninger[3], C. Garlichs[2], R.H. Strasser[1]. [1]*Medical Clinic II, TU Dresden, Dresden, Germany;* [2]*University Erlangen-Nürnberg, Medical Clinic II, Erlangen, Germany;* [3]*TU Dresden, Medical Clinic III, Dresden, Germany;* [4]*Hospital, Dept. of Vascular Surgery, Nuernberg, Germany*

Background: Neovascularization within atherosclerotic plaques may play a role in the pathogenesis of plaque progression and vulnerability.The purpose of this study was to determine if the existence of intraplaque vessels may be associated with the expression of macrophage migration inhibitory factor 1-alpha(MIF), a protein known participate in inflammatory and immune responses. It also plays a key role in tumor angiogenesis.
Methods: Carotid endartherectomy and vessel samples were collected from 21 patients and 4 young accident victims controls (co) and were assessed for histological classification by Stary (SI-VI). Immunohistochemistry was performed by using a specific monoclonal antibody (mAb) to MIF and to visualize 1.intraplaque vessels, endothelial cell (EC) specific mAb to CD34 and vWf, 2.Monocytes/macrophages (Mo), mAb to CD68 and 3.vascular smooth muscle cells (VSMC), mAb to alpha-actin were used. The extent of neovascularization was graded on scales of d0 to d3 in terms of specific staining intensity und distributions in the wall.
Results: All specimens from patients contained advanced plaques (S IV - VI) with neovessels of degree d3 in the shoulder and/or cap regions of 13 plaques (52%), d2 in 6 plaques (24%), d1 in 2 plaques (8%) and no vessels in intima or media from the 4 samples of the co (16%).Strong MIF staining was localized only in areas of marked neovascularization and inflammation (d3,d2) and was expressed exclusively by CD68-positive Mo and CD34/vWf-intraplaque EC. There was no detection of MIF expression in alpha-actin-positive VSMC. In plaques with small or no expression of neovessels (d1,d0) only a weak or no MIF staining respectively was observed.
Conclusion: The results demonstrate a marked upregulation of migration inhibitory factor 1-alpha in close correlation to Mo infiltration and neovesssels in plaques suggesting a pivotal role of MIF in neoangiogenesis and plaque inflammation.

P424 Platelet-activating factor is detectable in human carotid atherosclerotic plaques and correlates with intra-plaque neoangiogenesis

A. Pucci[1], E. Lupia[2], P. Peasso[2], P. Baron[2], C. Zanini[1], G. Emanuelli[2], G. Camussi[2], G. Montrucchio[2]. [1]*Regina Margherita Hospital, Pathologic Anatomy Dept., Torino, Italy;* [2]*Università degli Studi di Torino, Fisiopatologia Clinica, Torino, Italy*

Plaque instability is considered the major factor in the development of thromboembolic sequelae in atherosclerotic lesions. Several factors have been implicated in plaque instability, including the infiltration of inflammatory cells and the process of neoangiogenesis. Platelet-activating factor (PAF), a phospholipid mediator of inflammation, has been recently shown to mediate endothelial cell recruitment triggered by TNF-a and VEGF and to contribute to neoangiogenesis. In the present study we evaluated the presence of PAF and its potential role in neovascularization within atherosclerotic plaques. Endarterectomy specimens of carotid plaques were obtained from 18 patients with previous signs or symptoms of cerebrovascualr disease; 6 specimens of carotid artery and 12 of aorta from kidney donors were used as controls. Adjacent cross-sections were processed for PAF extraction and histological analysis.
Advanced atherosclerotic lesions were always present in endarterectomy specimens. The amount of PAF extracted from the carotid plaques (266.65 + 40.07 pg/100 mg dry tissue; mean + SE) was significantly higher than that extracted from controls (4.72 ± 2.31 pg/100 mg dry tissue; mean ± SE). The mass spectrometric analysis of PAF-bioactive lipid extracts from carotid atheromas, but not from normal arteries, showed the presence of several molecular species of PAF, including alkyl-PAF C16 and alkyl-PAF C18, which are angiogenic in vivo. The levels of PAF significantly correlated with the infiltration of CD68-positive macrophages and with the extent of neovascularization, detected as Factor VIII-related antigen immunoreactive cells, analysed by morphometry. The amount of PAF also correlated with the area positive for avb3integrin (considered an endothelial cell proliferation marker) and with the extension of TNF-a immunoreactivity. The lipid extracts of atherosclerotic plaques containing high levels of PAF-bioactivity, but not those of control arteries, were angiogenic in a murine Matrigel model. WEB 2170, a PAF receptor antagonist, significantly prevented angiogenesis induced in mice by the lipid extracts of atherosclerotic plaques. In conclusion, the present results demonstrate that PAF is detectable in carotid plaques, that PAF amount correlates with intraplaque angiogenesis and inflammation and that PAF extracted from atherosclerotic plaques induces angiogenesis in mice, suggesting that an enhanced concentration of PAF may contribute to intra-plaque neoangiogenesis.

P425 Protease activated receptor-2 (PAR-2) mediates angiogenesis and ameliorates post-ischaemic recovery of mouse hindlimbs

A. Milia[1], M.B. Salis[1], T. Stacca[1], A. Pinna[1], P. Geppetti[2], P. Madeddu[1], C. Emanueli[1]. [1]*I.N.B.B., National Laboratory, Osilo, Italy;* [2]*Ferrara University, Experimental and Clinical Medicine, Ferrara, Italy*

Background: Protease Activated Receptors (PARs) form a novel class of G-protein-coupled receptors that are activated by proteolytic cleavage able to unmask an N-terminal sequence acting as a tethered ligand. Synthetic peptides may activate PARs in the absence of proteolysis. PAR-2 is highly expressed by the cardiovascular system and mediates endothelial cell proliferation, vasodilation, and plasma extravasation, three mechanisms able to favour neoangiogenesis. **Aim:** To investigate the angiogenic potential of PAR-2 in hindlimb skeletal muscles.
Methods: Unilateral limb ischemia was induced in anaesthetized CD-1 mice by removing the left femoral artery. Modulation of PAR-2 gene expression by ischemia was evaluated by RT-PCR. Then, the PAR-2 activating peptide (AP, n=8) SLIGRL-NH2 or control reverse peptide (RP, n=7) was daily injected (300 nmol/20 μL) into the left adductor for 21 days from surgery. Additional groups of mice received trypsin (1.5 nmol, n=9), a protease able to preferentially activate PAR-2, or vehicle (n=7). Tail-cuff SBP and HR were measured in conscious mice basally and weekly after surgery. Hindlimb blood flow (BF) of anaesthetized mice was evaluated by colour laser doppler (Lisca, Sweden) every 7 days from ischemia induction. Anaesthetized mice were perfusion-fixed at 21 days and both adductors harvested for histologic analysis of capillary density.
Results: One day of ischemia doubled mRNA level. Up-regulation was maintained for 7 days. Systemic hemodynamic was not affected by ischemia or pharmacological treatments. AP ameliorated limb BF recovery (63±12 vs. 32±15% in RP, $P<0.05$) and trypsin had a similar effect (62±11% vs. 33±10% in saline, $P<0.05$). Both AP and trypsin increased capillary density in the ischemic injected muscle (AP: 1213±97 vs. 868±82 cap/mm^2 in RP, $P<0.05$; trypsin: 1107±62 vs. 715±79 cap/mm^2 in saline, $P<0.01$), without affecting capillarity of contra-laterals (data not shown).
Conclusions: Our study is the first one to demonstrate the angiogenic potential of PAR-2. In perspective, potentiation of PAR-2 signaling might be exploited for the treatment of ischemic disease.

TISSUE DOPPLER IMAGING

P426 Longitudinal ventricular function: normal values of annular and myocardial velocities measured with colour tissue Doppler imaging

N.P. Nikitin, K.K.A. Witte, S.D.R. Thackray, A.L. Clark, J.G.F. Cleland. *Univ. of Hull/Castle Hill Hosp., Academic Dept. of Cardiology, Hull, United Kingdom*

Impaired longitudinal function may be a marker of early myocardial disease. Colour tissue Doppler imaging (TDI) is a new method of assessing left ventricular (LV) and right ventricular (RV) long axis function. Age- and sex-related reference values for atrioventricular annular and regional myocardial velocities are essential for the clinical use of the method.
Methods: 123 healthy subjects (age 57±19 years, range 22 to 89 years, 59 women) underwent echocardiography including colour TDI using GE Vingmed System Five and Vivid Five scanners with post-processing analysis (Echopac 6.3). For the assessment of LV longitudinal function, regional myocardial velocities were measured in basal and mid-wall segments of lateral, septal, anterior, inferior, posterior and antero-septal LV walls. Mitral annular velocities were measured from six positions at corresponding sites of the mitral annulus. For the assessment of RV longitudinal function, myocardial velocities were measured in basal and mid-wall segments of free RV wall, and tricuspid annular velocities were calculated at the lateral site of the tricuspid annulus. At each position, systolic (Sm), early diastolic (Em) and late diastolic (Am) velocities were measured, and the Em/Am ratio was calculated.
Results: Subjects were classified into 4 groups aged 20-39, 40-59, 60-79, and 80-89 years. Mitral annular and regional LV myocardial Sm and Em velocities progressively decreased with age ($p<0.001$), and Am velocities, while very low in the youngest age group, significantly rose in patients over 40 years of age ($p<0.001$). The Em/Am ratio declined with ageing ($p<0.001$). Mitral annular Em velocity and the Em/Am ratio strongly correlated with age ($r=-0.79$ and $r=-0.77$, $p<0.001$). There were no differences between age groups in Sm velocities measured at the tricuspid annulus and free RV wall (p=NS) but the pattern of age-related changes of diastolic velocities and Em/Am ratios was the same as in the left ventricle. Women in the two middle age groups had lower TDI velocities than men ($p<0.05$).
Conclusions: This study establishes age- and sex-related reference values of atrioventricular annular and myocardial velocities measured with colour TDI. Systolic longitudinal LV function declines with age, whereas RV function remains unaffected. A reversal in the pattern of diastolic atrioventricular annular and myocardial velocities suggests that LV and RV diastolic function deteriorates with age.

P427 Opposite effects of coronary artery disease and hypertrophic cardiomyopathy on left ventricular long axis physiology during dobutamine stress

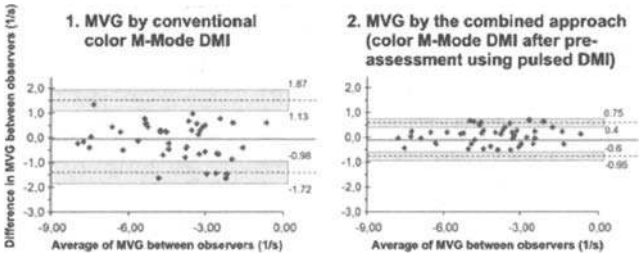
W. Arshad, D.P. Francis, A.M. Duncan, C.O. Sullivan, A.J.S. Coats, U. Sigwart, D.G. Gibson, M.Y. Henein. *Royal Brompton Hospital, Cardiology Department, London, United Kingdom*

Background Early diastolic long axis lengthening velocities are depressed in hypertrophic cardiomyopathy (HCM). From a clinical standpoint, these have been proposed as a means of selecting phenotypically normal relatives of HCM patients for counselling. Pathophysiologically, the reason for this abnormality in HCM is not known, although proposed mechanisms include subendocardial ischaemia, myocardial fibrosis or disarray.
Methods We digitised M-Mode measurements of the septal long axis in 23 patients with HCM, 17 normal subjects and 22 patients with coronary artery disease (CAD) of the left anterior descending artery at rest and at peak stress.
Results The lengthening velocity was reduced not only in HCM (3.5 ± 1.9 cm/s) but also in CAD (4.1 ± 2.5 cm/s, $p<0.001$ and $p<0.01$ respectively). Long axis amplitude was also depressed in both groups. With dobutamine stress, the lengthening velocity increased by 3.5 ± 1.8 cm/s ($p<0.001$) in normals, by 2.8 ± 2.5 cm/s ($p<0.001$) of rest in HCM but not in patients with CAD (0.5 ± 2.1, p=NS). Increment in long axis total amplitude was subnormal in CAD and HCM. However, the increment in lengthening velocity was higher with stress for a corresponding change in amplitude in HCM (60% lying above the 95% confidence interval of CAD). Post-ejection shortening developed or worsened in all CAD patients but not in any with HCM.
Conclusion Depression of peak early lengthening velocity is not specific for HCM but occurs equally in CAD. This is not due to subendocardial ischaemia in HCM, because unlike CAD, its velocity increases with stress and there is no aggravation of post-ejection shortening with stress. The HCM heart shows evidence of greater elastic recoil per unit deformation than heart of patients with CAD, compatible with increased muscle stiffness due to fibrosis or disarray.

P428 Additional estimation using pulsed Doppler myocardial imaging improves the reproducibility of measurement of myocardial velocity gradients

T. Poerner, B. Goebel, C. Wolpert, T. Sueselbeck, S. Pfleger, M. Borggrefe, K.K. Haase. *University Hospital of Mannheim, 1st Dept. of Medicine, Mannheim, Germany*

Background: Peak negative myocardial velocity gradient (MVG) across the left ventricular wall is an important indicator of regional diastolic performance. The reproducibility of MVG assessment by color M-Mode Doppler myocardial imaging (DMI) is still unsatisfactory, restraining its use in clinical practice.
Aim of this study was to improve the interobserver variability of MVG measurements.
Methods: Two-dimensional color-coded DMI cineloops were acquired in 50 consecutive patients in parasternal long axis view (Sonotron GE, Echopac 6.3.2). The maximal early diastolic MVG of the posterior basal wall was determined successively by 2 independent investigators in 2 ways: using directly standard anatomic color M-Mode DMI (mean off-line analysis time of 2 minutes) and by the same technique, but guided by a preliminary MVG estimation with pulsed DMI using 4 measurement sets within ventricular wall (mean analysis time of 4.5 minutes).
Results: Additional use of pulsed DMI provided a higher linear correlation between pairs of measurements (r = 0.98, SEE = 0.34 1/s) compared to MVG determination by conventional color M-Mode DMI (r = 0.92, SEE = 0.69 1/s). Accordingly, as displayed in the picture, the agreement limits by the method of Bland and Altman of the combined method [-0.78 1/s (95% CI of -0.95 1/s to -0.6 1/s) to 0.57 1/s (95% CI of 0.4 1/s to 0.75 1/s)] were clearly superior to those shown by color M-Mode DMI without B-Mode pre-assessment [-1.35 1/s (95% CI of -1.72 1/s to -0.98 1/s) to 1.5 1/s (95% CI of 1.13 1/s to 1.87 1/s)].



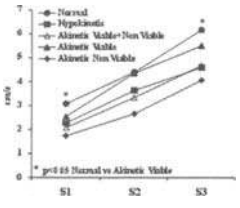
Interobserver agreement for MVG.

Conclusions: These study results recommend the utility of an initial estimation by pulsed DMI to achieve a clinically acceptable reproducibility of MVG measurements.

P429 Influence of myocardial SPET viability on evaluation of regional systolic performance with color tissue Doppler imaging

S. Dellegrottaglie[1], P. Perrone-Filardi[1], M. Galderisi[1], L. Pace[2], M.P. Ponticelli[1], W. Acampa[2], O. deDivitiis[1], M. Chiariello[1]. [1]*Federico II University, Cardiology, Naples, Italy;* [2]*Federico II University, Nuclear Medicine Dept., Naples, Italy*

Aim of the study was to evaluate the influence of SPET myocardial viability on Color Tissue Doppler Imaging (C-TDI) measurements of regional systolic function in patientes with severe left ventricular dysfunction.
Methods: Twelve patients (mean age 65±5 years; 9 men) with post-ischemic dysfunction (mean ejection fraction 28±4%) underwent, in the same week, 99mTc tetrofosmin SPET (rest-NTG) and dobutamine C-TDI. Regional wall motion was graded [1=normokinetic (N), 2=hypokinetic (H), 3=akinetic (A)] using a 18 segments/patient model, and peak systolic velocities (S) was measured off-line with C-TDI at rest (S1), low dose (S2) and high dose (S3) of dobutamine infusion. Regional myocardial viability was defined by the presence of >70% of 99mTc tetrofosmin uptake at rest or by >10% improvement after NTG.
Results: In the 216 segments analysed feasibility of C-TDI was 97% at rest and during dobutamine infusion. In every step of dobutamine infusion the values of S were significantly higher ($p<0.05$) in N than in H and A segments (Figure 1), while no difference were observed between H and total A segments (p=n.s.). In A segments with evidence of viability higher value of S1 (2.56±1.32 vs. 1.75±1.26, p=0.015), S2 (4.36±2.09 vs. 2.65±1.75, p=0.002) and S3 (5.52±2.80 vs. 4.06±2.45, p=0.048) were observed with respect to non viable A. There were no differences in S2 between N and A viable segments (p=n.s.).

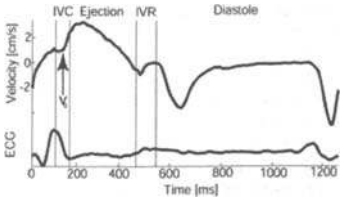


Conclusions: Dobutamine C-TDI is a feasible modality to study regional inotropic reserve in patients with severe ventricular dysfunction. Myocardial SPET viability influences S values in severely dysfunctional segments, but not in H regions.

P430 Relation between surface electrocardiogram and site of earliest/latest motion in DCM and ICM patients with LBBB – a Doppler myocardial imaging study

L. Herbots, O.A. Breithardt, P. Claus, M. Kowalski, W. Droogne, M.C. Herregods, B. Bijnens, G.S. Sutherland. *University Hospital Gasthuisberg, Cardiology Dept., Leuven, Belgium*

Doppler Myocardial Imaging(DMI) has been proposed to guide cardiac resynchronisation therapy(CRT). It might provide new insights in the relation between electrical and mechanical left ventricular (LV) activation and help to identify the optimal pacing site.
Aim: To identify the onset of systolic motion throughout the myocardial walls with DMI in ischemic (ICM)/idiopathic dilated cardiomyopathies(DCM) with LBBB and normals (nls) and compare this with QRS width/axis.
Methods: Colour DMI data(>150 frames/s)from 10 pts with DCM/LBBB(age 52±14y,EF 22±8%),10 pts with ICM/LBBB(age 64±11y,EF 30±8)and 10 nls(age 51±15y,EF 69±11%) was post processed to determine the time from onset of QRS to the onset of regional systolic velocity(Vo). Analysis was performed on custom made software enabling exact and reproducible timing of global cardiac events. Mechanical activation of sept, lat, inf, ant, post walls of the LV was compared with QRS width and presence of left axis deviation.
Results: No significant correlation was found between QRS width/axis and site of earliest/latest Vo. QRS width was 79±12ms (nls),169±29ms (DCM),155±26ms (ICM)with 0%,60% and 80% pts with left axis deviation respectively.Both regions of earliest/latest Vo were variable. Dominant region for earliest Vo was apical-mid sept(in 60% of nls(94±13ms), in 50% of DCM(147±41ms)and in 60% of ICM(126±18ms))while 100% of nls (148±25ms), 80% of DCM (226±48ms) and 70% of ICM (171±43ms) had latest Vo in the basal post wall.



ICM: Basal segment inf wall velocity.

Conclusions: Region of latest Vo in nls was always posterior wall. However latest Vo in DCM and ICM with LBBB and earliest Vo in all groups was heterogenously spread. Since there was no correlation with QRS with/axis, selecting pts for CRT solely on QRS with/axis might have its limitations.

P431 Myocardial strain after cumulative Ischaemia: tissue Doppler evidence of preconditioning?

R I. Williams[1], N. Payne[2], J. D'Hooge[3], T. Phillips[1], N D. Masani[4], A G. Fraser[1]. [1]*University Hospital of Wales, Wales Heart Research Institute, Cardiff, United Kingdom;* [2]*Providence Health System, Portland, Oregon, United States of America;* [3]*University Hospital Gasthuisberg, Department of Cardiology, Leuven, Belgium;* [4]*University Hospital of Wales, Cardiology Dept., Cardiff, United Kingdom*

Experimentally, ischaemic myocardium has altered systolic and diastolic function, though walk-through angina or preconditioning is well recognised, and difficult to identify by echocardiography (echo). The timing of repeated ischaemic episodes is also unclear. We investigated which tissue Doppler parameters could identify this phenomenon.

Methods: 14 patients (I)(13 men) age 57±9 yrs with IHD (>75% area stenosis in >2 major vessels, and no history of MI), and 12 controls(C) (10 men) age 56±8 yrs with normal angiography, underwent 2 maximal symptom-limited exercise (ex) tests(Ex1 and 2) 1 hour apart (Bruce protocol). All had transthoracic echo (Vingmed System V) at baseline, immediately post ex, and at intervals up to 1 hour after each test. Digital loops were analysed off-line for tissue Doppler velocity and strain-rate parameters.

Results: Chest pain and ischaemia limited both tests for I. Ex2 was longer for I (447±115 v 385±122s; $p<0.01$). C ex time and workload was similar in both tests, but C Ex1 longer than I Ex1 (475±143 v 385±122s; $p<0.05$) and had higher workload (30.2±2.0 v 28.5±4.2 x10^3 mmHg/min; $p<0.01$). For Ex2, I had similar ischaemia and workload (ns) but exercised for longer (447±114 v 385±121s; $p<0.01$). The absolute changes in peak (pk) systolic velocity (V) from baseline to pk ex were different between groups for Ex1 (C>I) (3.2±2.0 v 1.0±3.0 cm/s; $p<0.05$) but were unchanged for Ex2 (2.0±2.0 v 1.9±3.0 cm/s; ns). Early and late diastolic strain (S) parameters showed differences between C and I after Ex1 (Table; basal anterior segment) which persisted for 60 mins. Following Ex2, this lasted only 15 mins.

Diastolic Strain after exercise

	Ex1 pk	Ex1 15m	Ex1 30m	Ex1 60m	Ex2 pk	Ex2 15m	Ex2 30m	Ex2 60m
dE S I	-6.0±7.0*	-3.1±5.0*	-3.0±5.0*	-4.1±7.0*	-1.3±5.0	-3.2±5.0*	-2.5±9.0	-2.5±5.0
dE S C	1.0±5.0	2.0±7.0	0.6±4.0	2.7±5.0	1.4±7.0	2.3±5.0	-1.6±6.0	-3.1±6.0
dA S I	-1.8±4.0*	-1.5±2.0*	0.5±4.0	-0.5±3.0*	-2.8±5.0*	-2.0±4.0*	0.3±3.0	-0.3±6.0
dA S C	2.0±5.0	2.3±4.0	1.4±3.0	1.9±5.0	0.8±5.0	2.2±4.0	1.1±5.0	-0.6±6.0

*$p<0.05$; Ischaemia (I) vs Control (C); dE S changes in early diastolic strain; dA S changes in late diastolic strain

Conclusion: This biphasic response in S, E and A associated with increased ex time, cardiac workload and improved regional V after Ex2 may describe tissue Doppler evidence of myocardial preconditioning at a time previously associated with myocardial stunning.

P432 Wall motion abnormalities in ischaemic and scarred myocardium. Do strain and strain rate patterns differ?

J.U. Voigt, B. Exner, C. Huchzermeyer, M. Regenfus, U. Nixdorff, F.A. Flachskampf, W.G. Daniel. *University Erlangen, Medical Clinic II, Erlangen, Germany*

Background: In the clinical setting, the site and size of an acute myocardial infarct (MI) is often determined by visually assessing wall motion abnormalities in the echocardiographic image. However, this may be misleading if regional dysfunction is (in part) due to previous events. I this study we therefore investigated typical myocardial deformation patterns of acute and old MI by Strain Rate Imaging, a new tissue Doppler based method to non-invasively measure regional function.

Methods: Two patient groups were investigated: a) 30 acutely ischaemic infarct patients (iPAT) on admission to the emergency room, b) 37 patients with infarct scars (sPAT) of at least 25 volume% per segment (SEG). In iPAT, ischaemic SEG were determined by a blinded read of the coronary angiogram. In sPAT, scar was defined by late enhancement in magnetic resonance imaging. In all PAT, colour tissue Doppler loops were acquired from an apical four, three and two chamber view and stored digitally. Off-line evaluation included calculation of strain (S) and strain rate (SR) curves for the basal, medial and apical SEG of all six left ventricular walls. S and SR parameters in both systole and diastole as well as the visual impression of the curves were compared between iPAT and sPAT and to data of 20 healthy volunteers.

Results: Distribution of MI site and size was comparable in the two PAT groups. Compared to normals, systolic S was sign. reduced in both iPAT and sPAT (-16.6s-1 vs. -5.6 s-1 and -2.8 s-1, resp., $p<0.01$). Systolic stretching occurred in SEG of both iPAT and sPAT (23% vs. 27%, resp., n.s.). Post systolic shortening occurred in approximately one fourth of SEG in normals but was only 7% of systolic S. In iPAT and sPAT, it reached 40% and 86%, respectively ($p<0.01$). In the visual assessment, systolic and diastolic changes did not differ significantly between diseased SEG in iPAT and sPAT. Normal SEG in PAT showed the same S and SR patterns as SEG in healthy volunteers.

Conclusion: Our data suggest, that SRI sensitively shows significant changes in myocardial deformation patterns during acute ischaemia and after MI. Those changes, however, appear to be uniform and dependent on the amount of myocardial damage rather than being specific for the particular condition.

P433 Differentiating ischaemic and idiopathic dilated cardiomyopathy using left ventricular long axis function during dobutamine stress

A. Duncan, D.G. Gibson, M.Y. Henein. *The Royal Brompton Hospital, Echocardiography Department, London, United Kingdom*

Background: Subendocardial longitudinal fibres are sensitive to ischaemia. Interference with the timing of long axis motion during ischaemia causes incoordinate left ventricular (LV) contraction.

Aim: To study long axis response to dobutamine stress in patients with ischaemic- (Is-DCM) and idiopathic dilated cardiomyopathy (Id-DCM).

Methods: 18 patients with Id-DCM (EDD 6.6±0.7cm, ESD 5.5±0.7cm, aged 63±12 years) were compared with 25 patients with Is-DCM (EDD 7.0±0.8cm, ESD 5.9±0.9cm, aged 63±9 years), and 17 controls (EDD 5.0±0.4cm, ESD 3.3±0.6cm, aged 58±11 years). Transthoracic septal long axis M-mode echograms with an ECG (lead II) were obtained at rest and peak dobutamine stress. The time from the q wave of the ECG to the onset of shortening (q-OS), total long axis amplitude, shortening and lengthening velocities, and post-ejection shortening (PES) were measured.

Results: Rest. In controls, q-OS was 81±11ms, total amplitude 1.4±0.3cm, shortening velocity 6.9±1.6m/s, lengthening velocity 5.7±1.4m/s, and PES was absent. In Id-DCM, q-OS was longer than controls (139±46ms, $p<0.001$), total amplitude and shortening velocity were reduced (0.9±0.3cm and 3.3±1.0m/s, both $p<0.001$), lengthening velocity was not different (4.9±1.9m/s), and PES was increased (0.9±1.2mm, $p<0.01$). In Is-DCM, q-OS was not different from Id-DCM (127±34ms), total amplitude and shortening velocity were lower (0.7±0.3cm, $p<0.05$ and 2.1±1.2m/s, $p<0.01$), lengthening velocity was reduced (1.5±1.8m/s, $p<0.001$), and PES was not different (0.8±0.1mm).

Response to stress

Variable	Controls	Id-DCM	Is-DCM
q-OS (ms)	- 46 ± 13	- 52 ± 33	+ 17 ± 25 ** °°
total amplitude (cm)	+ 0.3 ± 0.2	+ 0.2 ± 0.1	+ 0.1 ± 0.2 *
shortening vel (m/s)	+ 4.4 ± 1.8	+ 3.4 ± 2.2	+ 1.7 ± 1.9 ** °
lengthening vel (m/s)	+ 2.8 ± 1.7	+ 3.2 ± 1.8	+ 0.9 ± 2.0 * °°
PES (mm)	0	- 0.7 ± 1.0 *	+ 0.9 ± 1.2 * °°

*: $p<0.01$; **: $p<0.001$ v controls; °°: $p<0.01$; °°: $p<0.001$ Id-DCM v IS-DCM

Conclusion: Long axis electromechanical delay shortens and PES decreases in idiopathic DCM (similar to controls). Stress-induced ischaemic dysfunction includes increased electromechanical delay, exaggerated post-ejection shortening and impairment of total amplitude and long axis velocities. These differences may be used to confirm the presence of ischaemic aetiology in patients with DCM.

P434 Regional systolic function by Doppler tissue imaging in dilated cardiomyopathy; contribution for prediction of clinical outcome and prognosis

G. Athanassopoulos[1], P. Iakovis[2], C. Hasikides[2], N. Koutsogiannis[2], G. Karatasakis[2], D.V. Cokkinos[2]. [1]*Onassis Cardiac Surgery Center, First Dept. of Cardiology, Athens, Greece;* [2]*Onassis Cardiac Surgery Center, Cardiology Dept., Athens, Greece*

Introduction: In dilated cardiomyopathy (DCM) NYHA class II-III, prognostic accuracy remains limited. The longitudinal component of left (LV) and right ventricular (RV) function seems important and may be studied by Doppler tissue imaging (DTI). The isovolumic and ejection systolic components may be also studied. We interrogated the relationship between regional LV, RV function and prognosis in DCM.
Methods: 42 pts with DCM were studied (age 53±14 years, EF 32±9%). VO2max was estimated within <1 month from echo study (ml/kg/min:18±6). Mean time from DCM diagnosis was 6±4.4 years and time elapsed from index echo 15±8 months. DTI profile was interrogated in 9 sites/pt: in the annulus(site 1), in the middle of the segment (site 3) and in the middle between sites 1 and 3 (site 2) of septal (IVS), lateral wall (LAT) for LV and RV free wall. Systolic phase consisted of two waves, an early-isovolumic (Siso) and a late one-ejection (Sez). Displacement was measured in the posterior mitral annulus (LATann) and tricuspid annulus (Rvann). 18 pts had cardiac events (CE: 3 death, decompensation/hospitalization, 3 transplant list, 12 NYHA III-IV), where 24 remained stable or improved NYHA class (nonCE).
Results: Group CE/nonCE had similar LVDD, EF, LATann, transmitral E, A, dec E. However group CE had lower: VO2max, Rvann, all R S indices, all IVS except 2Siso and 3Sez, all LAT except 2Siso, 3Siso, 3Sez. With receiver operating curve analysis (ROC) applied for prediction of outcome, the best discriminative parameters were as follows:

	cut of point: cm/sec	sens	spec	area under ROC	p
IV1Sez:	4.2	89	68	0.88	0.000
RV3Siso:	5.5	82	74	0.83	0.000
VO2max:	16	73	100	0.85	0.001
LAT1Siso:	2.5	71	80	0.79	0.002
IV3Siso:	3.6	73	60	0.71	0.037

LATann and Rvann had no contribution. The VO2max<14 as predictor of adverse outcome had sens=0.53, spec=0.94, pos.pred.v.=0.89, neg.pred.v.=0.70. When DTI data were considered in the presence of VO2max<14, then its negative predictive value was improved from 0.70 to 0.85, 0.92, 0.82, 0,82 with IV1Sez, RV3Siso, LAT1Siso, IV3Siso cut off points respectively.
Conclusions: Regional LV long axis and RV free wall interrogation by DTI provides a prognostic information which is independent from VO2max. Both isovolumic and ejection phase components by DTI provide incremental negative prognostic yield in the presence of low VO2max values.

P435 L-thyroxine replacement therapy improves left ventricular functions in subclinical hypothyroidism, as assessed by Doppler tissue imaging

H. Muderrisoglu[1], M.Z. Ulucam[1], A. Yildirir[1], M. Korkmaz[2], N. Tanaci[2], E. Tayfun[1], N. Guvener[2]. [1]*Baskent University, Cardiology Dept., Ankara, Turkey;* [2]*Baskent University, Endocrinology, Ankara, Turkey*

Aim: Subclinical hypotyroidism (SH) is usually an asymtomatic state associated with normal serum free thyroid hormones, but slightly elevated serum thyrotropin (TSH) levels. Doppler tissue imaging (DTI) is an objective method to quantify regional and global left ventricular (LV) functions through the assessment of myocardial velocity data. Several invasive or noninvasive diagnostic tools indicated a close correlation between LV functions and thyroid status, but limited data is available related to the effects of changes in thyroid status on DTI. The aim of the study was to evaluate the effects of L-thyroxine replacement therapy on LV functions in patients with SH by means of DTI.
Methods: Twenty patients with SH and 20 healthy subjects were included in the study. The diagnosis of SH was made based on elevated serum TSH >5.2mIU/L, with normal T4 and T3 levels. All subjects underwent standard M-mode, 2-D and Doppler echocardiography, as well as, DTI studies from septum and lateral wall. After echocardiographic assesment patients received L-thyroxine replacement therapy at a dose that could keep the serum TSH levels within normal range. After 6th month the echocardiographic and laboratory investigations were repeated.
Results: Patients with SH (2 male, 18 female; age 40.8±2.1yrs) were similar to controls with respect to age and sex characteristics (2 male, 18 female; age 39.3±2.3yrs) (p>0.05). The mean serum TSH, T4 and T3 levels of the SH patients before inclusion were 9.2±0.5mIU/L, 6.2±0.8ng/ml and 1.4±0.3ng/ml respectively. At baseline DTI studies indicated that SH patients had significantly lower lateral wall S velocity (p=0.001), lateral wall S time velocity integral (TVI) (p=0.001), lateral wall E velocity (p=0.009), lateral wall E TVI (p=0.01), septal S velocity (p=0.0001), septal S TVI (p=0.01), septal E velocity (p=0.008) and septal E TVI (p=0.007) values compared to controls. After a 6-month therapy with L-thyroxine DTI data showed significant increases in lateral wall S velocity (0.122±0.001 cm/sec to 0.145±0.001cm/sec, p=0.025), lateral wall S TVI (0.017±0.001cm to 0.023±0.001cm, p=0.001), septum E velocity (0.179±0.012cm/sec to 0.210±0.014cm/sec, p=0.021) and septum E TVI (0.018±0.001cm to 0.025±0.001cm, p=0.003) values in parallel with the significant improvement in ejection fraction (60.4±2.2% to 66.8±1.4%, p=0.039).
Conclusion: Patients with SH might have some functional cardiovascular abnormalities detected by DTI method despite the absence of clinical signs and symptoms. However, these findings can be reversible with L-thyroxine therapy.

P436 Specific tissue Doppler predictors of preserved systolic and diastolic left ventricular function after an acute anterior myocardial infarction

O. Akdemir[1], B. Dagdeviren[2], M. Yildiz[3], C. Gul[3], H. Surucu[3], G. Ozbay[3]. [1]*Trakya University, Cardiology Dept., Edirne, Turkey;* [2]*Siyami Ersek Center, Cardiology, Istanbul, Turkey;* [3]*Trakya University, Cardiology, Edirne, Turkey*

Background: The degree of left ventricular (LV) dysfunction determines the outcome of patients suffering an acute anterior myocardial infarction (AAMI). Many recent studies have utilized tissue Doppler echocardiography (TDE) parameters in the assessment of LV long axis function.
Aim: We sought to investigate whether some variables easily obtained from pulsed wave TDE profiles of mitral annular corners would predict a relatively preserved LV global function traditionally assessed with ejection fraction (EF) and deceleration time (DT), within the acute phase of AAMI.
Methods: Included were 50 consecutive patients with a first AAMI. Standard echocardiography and TDE of mitral annulus were performed within 36 hours of admission. TDE velocity profiles were obtained by placing four sample volumes at septal, lateral, anterior and inferior corners of mitral annulus. Preserved LV function was defined as an EF > 40% together with a DT between 140 ms and 220 ms.
Results: With respect to the limits of EF and DT mentioned above, 16 (32%) patients had a relatively preserved LV global function. An inferior annular Sm of > 7.5 cm/s predicts preserved global LV function with a sensitivity of 81% and specificity of 71%. An anterior mitral annular Em of > 8cm/s had a sensitivity of 69% and specificity of 85%. Patients who had both an inferior Sm and anterior Em exceeding the limits above, such a combined index yielded a sensitivity of 69%, specificity of 94%, and an overall diagnostic accuracy of 86% – with only 5 false positive and 2 false negative results – for the estimation of a preserved LV global function.
Conclusion: The parameters derived from TDE profiles of inferior and anterior mitral annulus corners provide valuable information to predict a preserved global LV function during the early period of AAMI. When the difficulty and operator dependency of particularly measuring EF in asymmetrically contracting ventricles to consider, these two parameters, which could easily, quickly, and reliably be measured, would be helpful to predict a well-preserved global ventricular function in clinical setting.

P437 Prediction of contractile function recovery by tissue Doppler imaging: a usefulness of myocardial pre-ejection and postsystolic velocities

M. Penicka[1], J. Bartunek[1], W. Wijns[1], I. De Wolf[1], E. Barbato[1], H. De Raedt[1], G.R. Heyndrickx[1], B. De Bruyne[2]. [1]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium;* [2]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium*

So far, a simple and accurate method for assessing viability is missing. In experimental studies, both myocardial pre-ejection velocities (PEV) and postsystolic shortening (PSS) seem to correlate with the extent of the viable myocardium.
Aim: To compare the predictive value of the resting pattern of PEV and PSS to predict recovery of contractile function in patients (pts) with myocardial infarction.
Methods: Fourteen pts with one totally occluded coronary artery (LAD 10, LCx 1, RCA 3) and severe wall motion abnormalities in the region at risk were selected. Longitudinal myocardial velocities were recorded at rest by transthoracic pulsed wave tissue Doppler (TDI) within 24 hours after revascularization. Global and regional left ventricular (LV) function was assessed by LV angiography at baseline and two months after revascularization. Recovery of contractile function was defined as an increase in segment shortening by more than 10% at follow-up angiography.
Results: TDI signals in regions at risk were obtained in all pts regardless the quality of two-dimensional images. A total number of 49 dysfunctional segments were analyzed of which 34 recovered and 15 did not. Table 1 shows accuracy of the presence of +PEV, PSS and their combination to predict recovery at follow-up. The combination of both parameters significantly reduced the number of false positive results and thus increased specificity and positive predictive value as compared to both indices alone.

	Sensitivity	Specificity	PPV	NPV	Accuracy
+PEV	97	67	87	91	88
PSS	74	53	78	47	67
+PEV and PSS	97	80	92	92	92

Conclusions: The resting pattern of PEV and PSS in the infarct-related area may predict the recovery of regional function within hours after reperfusion. The combination of both parameters is superior to either parameter alone.

P438 Post systolic thickening can be a marker of myocardial viability

F. Szaboki[1], I. Balogh[2]. [1]*Hungarian Railways Hospital, Cardiology, Budapest, Hungary;* [2]*Uzsoki Street Hospital, Radiology, Budapest, Hungary*

We wanted to determine the myocardial viability after acute myocardial infarction by tissue pulsed Doppler echocardiography (TDE) measuring the post systolic thickening (PST) of the ischemic myocardial segment. The tissue Doppler echocardiographic data were compared to the myocardial scintigraphic measurements.
We examined 32 patients with acute myocardial infarction and 35 healthy subjects. In the patients group the ischemic wall motion abnormalities were determined by second harmonic 2DE. TDE was applied in all ischemic myocardial segments according to the 16 segments model. The segment was respected as viable if the velocity wave of the post systolic thickening exceeded more than 30% of the amplitude of the systolic velocity wave. Examinations were performed at resting conditions. In the healthy subjects all 16 segments were examined by TDE. Between 24-48 hours later rest-redistribution Tl-201 myocardial scintigraphy was done in each case The reversible myocardial perfusion defect indicated the myocardial viability as hibernating myocardium.
The post systolic thickening can be detected as a velocity wave during the isovolumic relaxation period just before the mitral valve opening. We found it very seldom in the healthy population. We examined 560 healthy myocardial segments and we found PST in 15 segments (2.6%) mostly in the basal region (9 segments 1.6%). In the patient group 161 ischemic segments were observed. Out of them the Tl-201 scintigraphy in 123 cases while the PST in 114 cases indicated myocardial viability. The following statistical data show the accomplishing ability of the PST determing by TDE in the detection of myocardial viability compared to Tl-201 myocardial scintigraphy: sensitivity: 82.1%, specificity: 65.7%, positive predictive value: 88.5%, negative predictive value: 53.2%, accuracy: 78.2%.
Conclusions: The post systolic thickening of the myocardial wall can idicate the myocardial viability. Its positive predictive value highly significantly predicts the viability of the ischemic myocardium. It can be detected easily by TDE and may be very useful even in resting condition.

P439 Clinical significance of postsystolic thickening detected by Doppler myocardial imaging in patients with myocardial infarction

J.K. Song[1], J.M. Song[1], D.H. Kang[1], B. Haluska[2], T.H. Marwick[2]. [1]*Asan Medical Center, Cardiology, Seoul, Korea, Republic of;* [2]*Princess Alexandra Hospital, Cardiology, Brisbane, Australia*

Background: Although it is well known that postsystolic thickening of ischemic segment (PST) can be detected by Doppler myocardial imaging (DMI) in acute ischemic model, the prevalence and clinical significance in patients with myocardial infarction (MI) has not been seriously investigated.
Methods: Among patients who underwent routine dobutamine stress echocardiography (DSE) for detection of peri-infarction viability or ischemia, those with MI at the left anterior descending artery territory were selected. Myocardial velocity data of interventricular septum at apical 4 chamber view and those of inferior wall at 2 chamber view were retrospectively analysed. DMI was routinely recorded in each stage of DSE, and (+) PST was defined as positive velocity > 2 cm/sec after peak systolic velocity at rest or more than 2 times increase of positive velocity at low dose dobutamine infusion compared to the value at rest.
Results: Total 20 patients (16 male, 59.8±12.7 years) were enrolled for this study and DMI data could be analysed in 37 segments (93%). Mean wall motion score index (WMSI) and peak systolic velocity (PSV) in ischemic segments were 2.1±0.6 and 1.4±1.3 cm/sec, respectively. PST was observed in 20 segments (54%) including 3 segments showing PST only in low dose dobutamine stage, and 19 segments (51%) showed peri-infarction viability or ischemia during DSE. There was no significant difference of baseline WMSI (2.1±0.3 vs 2.1±0.5, p=0.76) or PSV (1.1±1.1 vs 1.9±2.0 cm/sec, p=0.05) between segments with PST and those without. Peri-infarction ischemia or viability was more frequently observed in segments with PST compared to those without (85% vs 18%, $p<0.05$). The sensitivity and specificity of PST for prediction of peri-infarction ischemia or viability was 85% and 82%, respectively.
Conclusions: PST is not infrequently detected by DMI in chronic ischemic segments, and is closely related with positive DSE for peri-infarction ischemia or viability. Diagnostic accuracy of DSE for detection of peri-infarction viability or ischemia can be enhanced by objective analysis of velocity data obtained by DMI.

P440 Myocardial pre-ejection velocities assessment by tissue Doppler imaging: a new predictor of recovery of contractile function in humans

M. Penicka[1], J. Bartunek[1], E. Barbato[1], I. De Wolf[1], H. De Raedt[1], G.R. Heyndrickx[1], W. Wijns[1], B. De Bruyne[2]. [1]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium;* [2]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium*

Normal pattern of myocardial pre-ejection velocities (PEV) consists of positive (+) and negative (-) PEV reflecting a brief inward and outward motion of the myocardium during isovolumic contraction (i.e. occurring before the opening of the aortic valve).
Aim: To investigate the relationship between the resting pattern of PEV and the recovery of contractile function upon recanalization of a totally occluded coronary artery in humans.
Methods: Accordingly, 14 patients (pts) with acute coronary syndrome and severe wall motion abnormalities were selected. Pulsed wave tissue Doppler (TDI) using transthoracic approach was performed within 24 hours after revascularization (LAD 10, LCx 1, RCA 3). Longitudinal PEV in dysfunctional myocardial segments were recorded at rest in apical views. Global and regional left ventricular (LV) function was assessed by LV angiography at baseline and two months after revascularization. Recovery of contractile function was defined as an increase in segment shortening by more than 10% at follow-up angiography.
Results: The registration of PEV was possible in all pts despite poor image quality of two-dimensional images in 14% of them. The sampling of all dysfunctional segments lasted on the average 10 min per pts. Of 49 dysfunctional segments analyzed, 34 segments recovered while 15 segments did not. A +PEV was present in 33/34 segments that finally recovered and in 5/15 segments that did not. Any +PEV was absent in 10/15 segments that did not show recovery and in 1/34 segments that did. Accordingly, sensitivity, specificity, and diagnostic accuracy of the presence of +PEV to predict regional recovery were 97%, 67%, and 88%, respectively. In addition, amplitude of +PEV significantly correlated with the change of segment shortening during follow-up ($r=0.55$, $p < 0.05$).
Conclusions: An assessment of PEV by pulsed wave TDI is a promising, simple and fast method not requiring any form of stress to predict recovery of contractile function upon coronary revascularization.

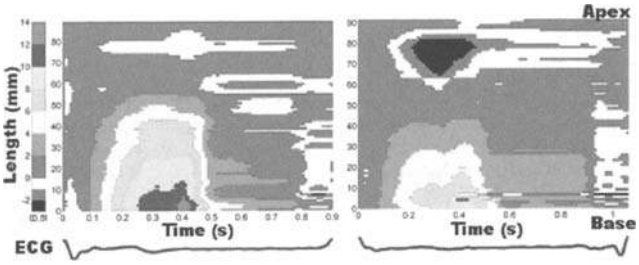
P441 Tissue motion imaging – a new and quicker way to assess left ventricular function by ultrasound

C. Storaa[1], B. Olstad[2], B. Lind[3], L.A. Brodin[3]. [1]*Karolinska Institutet, Division of Medical Engineering, Huddinge, Sweden;* [2]*Norwegian Univ. of Science and Technol, Computer and Information Science, Trondheim, Norway;* [3]*Huddinge University Hospital, Department of Clinical Physiology, Huddinge, Sweden*

Previous ultrasound imaging techniques of the left ventricular function such as tissue velocity imaging and strain rate imaging all have the limitation that they only present one parameter and that they are mainly suitable for the assessment of systolic function.

In the present study we have investigated the visualization of tissue motion which is the result of an integration over time of myocardial velocities extracted on a curved M-mode. By applying a color-map to this information one gets the Tissue Motion Image (TMI).

TMI was applied to two age matched groups of ten individuals who all underwent a standard dobutamine-atropine stress test, the first group consisting of normals, the second of patients with coronary artery disease. The maximum motion in the normals was 13.8±4.4 mm and 14.0±5.4 mm at rest and peak stress, respectively. In the patients maximum motion was 11.2±7.2 mm and 10.8±7.6 mm at rest and peak stress, respectively (values given in mean±1.96SD). The motion of the patients was significantly lower than that of the normals. This is directly reflected by and rapidly interpreted from the images as different colors for the peak values. By TMI one can also typically see reduced diastolic function as a temporally more smeared pattern and dyskinesias as black spots in systole at a glance. In the figure to the right dyskinesia is seen apically.



Healthy (left) and dyskinetic (right).

Knowing that the temporal derivative of this image is the velocity, and that another differentiation gives the acceleration and retardation, both of these are easily interpreted from the TMI. The spatial derivative is the strain, so one can even assess regional strain from TMI, hence one can quickly get a better qualitative impression of regional myocardial function than by previous visualization techniques.

P442 Usefulness of a new automatic segmental motion analysis system in the diagnosis of multivessel disease in anterior acute myocardial infarction

J. Zamorano, R. Moreno, C. Almería, J.L. Rodrigo, W. Taua, V. Serra, A. Aubele, L. Sánchez-Harguindey. *Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain*

It has been previously described that absence of compensatory hyperkinesia in patients with acute myocardial infarction (AMI) suggests the presence of multivessel disease (MVD). However, since the assessment of myocardial contractility is subjective, the diagnostic usefulness of this characteristic is limited. The objective of the study was to evuate the differences in myocardial wall thickness between AMI patients with or without MVD using a new method of cuantifying automatically and in real-time.

The study population is comprised by 14 patients with anterior AMI within 3 days after admission. These patients underwent cardiac catheterization and echocardiographic study using a commercially available equipment (Aloka SSD 870, Tokyo) able to automatically analyse the myocardial segmental thickness in real-time. The myocardial thickness at 80 and 120 msec. from the R wave, and time to maximum thickness were measured in the lateral wall. These parameters were compared between patients with and without MVD.

Results: Mean age was 57±8 years, and 11 (79%) were male. Out of the 14 patients, 8 (57%) had a single-vessel disease (left anterior descending coronary artery), whereas the remaining 6 (43%) had MVD. The comparison between patients with and without MVD is shown in the table:

Single- vs. Multi-vessel disease

	Single-vessel	Multi-vessel	p
80 msec thickenning (%)	8.3±4.3	7.5±3.8	NS
120 msec thickenning (%)	32.1±6.3	16.3±4.1	<0.05
Time to peak (msec)	286±24	278±27	NS

Conclusion: In patients with anterior AMI, those with MVD had an impaired regional wall thickenning at 120 msec. in the contralateral wall, as can be measured by a regional wall thickenning quantification system.

P443 A novel modality to evaluate left ventricular function: tissue tracking

C. Pan[1], R. Hoffmann[2], P. Hanrath[2], X.H. Shu[1]. [1]*Zhongshan Hospital, Fudan University, Department of Cardiology, Shanghai, China;* [2]*Aachen Univ., department of cardiology, Aachen, Germany*

Background: Tissue tracking imaging allows rapid assessment in apical views of the systolic baso-apical displacement for each myocardial segment by a graded color display.

Methods: To assess the ability of Tissue Tracking for assessment of LV function by determination of the systolic mitral annular displacement (MAD), we studied 90 patients (69 male, age 60.4±10.1years) with different LV function, including 25 subjects with normal LV function, 25 patients with homogenous depression of LV function due to cardiomyopathy and 40 patients with prior myocardial infarction (MI) and regional depression of myocardial contractility. The systolic MAD was determined by Tissue Tracking and M-mode echocardiogaphy. The apical four chamber, three chamber and two chamber views were used to determine the MAD of 6 sites. LV ejection fraction (LVEF) was determined by 2-D echocardiography using Simposon's rule in all patients and contrast cineangiography in 27 patients.

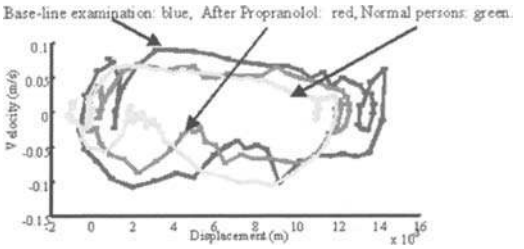
Results: Tissue Tracking was possible in all 90 patients. In 50 patients, including 25 patients with normal LV function and 25 patients with homogenous depression of LV function, mean MAD measured from 6 sites of the mitral annulus correlated closely with MAD determined by M-mode ($r=0.99$, $p<0.001$) and with the LV ejection fraction determined by 2D echocardiography ($r=0.97$, $p<0.001$). Using a cut-off value of 4.8mm for the MAD determined by Tissue Tracking, LV ejection fraction≤30% can be predicted with a sensitivity of 98% and a specificity of 78%. In patients with prior MI correlation between the mean MAD measured by Tissue Tracking and the LV ejection fraction determined by 2D echocardiography was lower($r=0.87$,$P<0.001$).

Conclusions: Systolic MAD determined by Tissue Tracking correlates closely with MAD determined by M-mode and with LV ejection fraction determined by 2D echocardiography. Thus, MAD determined by Tissue Tracking provides a simple, rapid, and noninvasive tool to assess global LV function.

P444 Myocardial velocity-displacement loops constructed from tissue Doppler data in patients with hyperthyroidism

M. Gaballa[1], C. Storaa[2], H. Wahlenberg[3], J. Van der Linden[4], J. Hoffstedt[5], S. Ahnve[1], G. Rasmanis[1], L A. Brodin[6]. [1]*Huddinge University Hospital, Cardiology Dept., Stockholm, Sweden;* [2]*Karolinska institute., Department of Medical Engineering., Stockholm., Sweden;* [3]*Huddinge university hospital, Endocrinology and metabolism, Stockholm, Sweden;* [4]*Huddinge University Hospitals., Thoracic Surgery and Anaesthesia, Stockholm., Sweden;* [5]*Karolinska institute, Endocrinology and metabolism departmen, Stockholm, Sweden;* [6]*Huddinge University Hospital, Clinical Physiology, Stockholm, Sweden*

Objectives: Tissue Velocity Imaging (TVI) is an off-line program with the advantage of extraction myocardial velocity from color-coded Doppler information. Myocardial velocities can be used in calculation of related variables such as displacement (Distance). Plotting myocardial velocity against displacement will construct the myocardial loops that may represent the instantaneous work done by the heart. Thyroid hormones have marked chrono- and inotropic effects on the heart. These effects may be due to enhanced response to catecholamines, and may be partially or totally reversed by beta-blockade. 16 thyrotoxic patients, mean age 38±9 years, with high levels of plasma free tri-iodothyronine (fT3) 30±5 pmol/L, and no previous heart diseases, were examined before and 2 hours after giving Propranolol 40 mg per Os. 36 age-matched healthy individuals served as a control. Velocities were acquired in the basal septum and integrated over time to calculate the displacement. The loops were constructed by plotting the velocity at one time instant with the displacement at the same instant (Diagram 1). The area inside the loop represents the amount of longitudinal work done by the heart to move the basal part of the septum towards the apex with a certain acceleration.



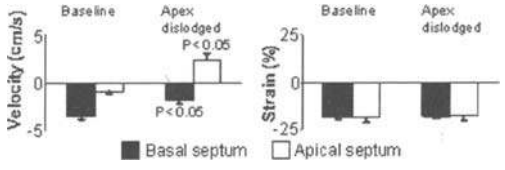
Velocity - displacement loop

Results: The basal longitudinal velocity of the septum were consistently higher in thyrotoxic patients at base-line examination compared to control group ($p<0.001$). Propranolol reduced the longitudinal systolic velocity from 8.5±1.5 to 4.5±1.2 cm/sec ($p<0.001$). Propranolol reduced significantly the area inside loops at base line examination by 40% ($p<0.001$).
Conclusion: Velocity-displacements loops can be used in clinical assessment and demonstration of the inotropic effects of thyroid hormones in thyrotoxic patients.

P445 Importance of the physiologic immobility of the cardiac apex: tissue Doppler assessment during off-pump coronary surgery

H. Skulstad[1], K. Andersen[1], T. Edvardsen[1], R. Lundblad[2], S. Halvorsen[2], P.K. Hol[2], E. Fosse[2], H. Ihlen[1]. [1]*Rikshospitalet, Department of Cardiology, Oslo, Norway;* [2]*Rikshospitalet, Interventional centre, Oslo, Norway*

Background: It is not clearly understood why apex is hardly moving while longitudinal ventricular motion is directed towards apex during systole. This was investigated by tissue Doppler assessment of septal motion before and during exposure of the heart inherent in off-pump coronary bypass surgery.
Methods: Longitudinal systolic velocities of septum were measured by transoesophageal echocardiography in seven patients during the operation, including when apex was dislodged from the pericardial sac. This is part of the regular proce-dure before anastomosing left internal mammary artery to the left anterior descending artery. Invasive haemodynamic measures were monitored throughout the operation.
Results: Basal septal velocity and the normally lower velocity of apical septum were both directed towards apex before thoracotomy (Fig). No definite change occurred after pericardiotomy. However, dislodging apex from the pericardial sac caused a shift of apical septal motion towards the base of the heart, along with reduced basal motion towards the apex (Fig.). Strain Doppler, reflecting myocardial shortening, remained unchanged in both septal segments. Heart rate increased (from 54 ± 6 (mean ± SEM) to 73 ± 6 beats/ min, $p<0.05$) and stroke volume tended to decrease (from 84 ±12 to 71 ± 10 ml, ns), without any other haemodynamic changes.



Conclusions: Dislodging apex from the pericardial sac caused a conspicuous change of longitudinal septal motion as shown by tissue Doppler. Concomitantly, the haemodynamic findings indicated reduced ventricular performance despite normal myocardial shortening. Thus, the normal ventricular motion towards apex, along with apical immobility, seems physiologically important and dependent on apex being situated within the pericardial sac.

P446 Changes in left ventricular morphology of world-class professional bicyclists between 1995 and 1998

E. Abergel[1], G. Chatellier[2], A. Ducardonnet[3], J. Menard[4]. [1]*Cardiologie, Paris, France;* [2] *Informatique médicale, Hôpital Européen Georges Pompidou, Paris, France;* [3]*Institut coeur effort santé, Cardiologie, Paris, France;* [4]*université paris VI, Santé publique, Paris, France*

Illicit use of drugs aiming at improving performance (erythropoietin, growth hormone, androgenic steroids), has disturbed popular cyclist competitions during last years, especially the "Tour de France". We hypothesis that the magnitude of these practices could be investigate by the detection of changes in left ventricular (LV) morphology.
Methods: Two days before the beginning of the "Tour de France", the same investigator obtained in very similar conditions, M-mode LV tracings in 149 bicyclists (1995) and in 139 bicyclists (1998). 37 athletes were included in both studies. All of the readings were taken from anonymous tracings by a single investigator. Final result was obtained as the mean of 3 measurements for diastolic LV diameter (LVIDd), septal thickness (IVST) and posterior wall (PWT).
Results: 1995 and 1998 athletes were similar for age (28 years), size (body surface area: 1.89 m^2), and blood pressure (120/66 mmHg). Participants in the 1998 race had larger LV cavities and thinner walls than those of the 1995 participants(all $p<0.001$):
1995: LVIDd = 59.2±3.7 mm, IVST = 11.6±1.3 mm, PWT = 10.3±1.1 mm
1998: LVIDd = 60.8±4.3 mm, IVST = 10.6±1.2 mm, PWT = 9.8±0.7 mm
A comparable difference was found in the subgroup of 37 who participated in both races(all $p<0.001$):
1995: LVIDd = 58.3±4.8 mm, IVST = 11.8±1.2 mm, PWT = 10.6±1.0 mm
1998: LVIDd = 60.3±4.2 mm, IVST = 10.8±1.2 mm, PWT = 9.9±0.8 mm
In the 1995 population, one cyclist had a LVIDd > 70 mm versus 3 in the 1998 population (one cyclist is common to the two populations).
Conclusion: Our data show that it is possible to quantify cardiac changes in trained athletes over a short period of time. The 2000-2001 law suits have confirmed the large-scale use of EPO and others drugs in cyclists. Since physical training technology is unlikely to change over a few year interval, this suggest that the observed modifications of LV geometry could be, at least in part, due to "pharmacological training" rather than to physical training.

P447 The effect of gestational hypertension on left ventricular geometry

I. Demir, H. Yilmaz, I. Basarici, C. Ermis, E. Altekin, S. Cetin, B. Kalayci.
akdeniz university, cardiology, ANTALYA, Turkey

Objectives: Heart rate, stroke volume, cardiac output and left ventricular mass increases during pregnancy while peripheral vascular resistance decreases. Gestational hypertension (GHT) which is noted in some pregnancies during the third trimester is considered as a temporary condition. Its effects on left ventricular geometry (LVG) is not known. In this study we aimed to assess the effects of this acute pressure overload in GHT on the LVG.
Matherials and Methods: Fortythree pregnant women (mean age 28.7±8.9 years) with gestational hypertension were included in the study (Group A). Blood pressure levels over >140/90 mmHg were considered as GHT in this group. Fiftysix pregnant women (mean age 25.7±5.7 years) with normal blood pressures formed the control group (Group B). Transthoracic echocardiographic evaluation was performed on left lateral decubital position for all women before delivery. Left ventricle (LV) end-systolic (ES) and end-diastolic (ED) diameters, LV septal and posterior wall thickness were measured and LV mass index (MI) and relative wall thickness (RWT) were calculated using Devereux and Ganau formulas. LVG was defined as normal (N), concentric hypertrophic (CH), eccentric hypertrophic (EH) and concentric remodeling (CR).
Results: LVMI and RWT were 138±13.8 g/m^2 and 0.46±0.09 and 117±15 g/m^2 and 0.4±0.03 in Group A and Group B, respectively ($p=0.01$, $p=0.03$). LVG was %38.9 N, %19.4 EH, %14 CH, %27.7 CR in hypertensive pregnants and it was %78.6 N, %7 EH, %5.4 CH, %9 CR in normotensive pregnants ($p<0.001$).
Conclusion: These findings suggest that LVMI and RWT is greater in GHT compared to normotensive pregnants. Most frequently observed abnormal geometric pattern is EH and CR

P448 Effect of acute intravascular volume and arterial pressure changes on left ventricular function during haemodialysis

I. Ikonomidis, L. Soubassi, D. Chaniotis, I. Stathopoulos, A. Laggouranis, N. Zerefos, P. Soubassis, S. Stamatelopoulos. *Alexandra Hospital, Univ. of Athens, Dep. of Clinical Therapeutics, Athens, Greece*

Deterioration of left ventricular (LV) diastolic function has been causally related to hypotensive episodes during hemodialysis (HD).The effect of intravacsular volume and arterial pressure reduction on LV function of patients without hypotensive episodes during HD has not been adequately studied.

Methods: We studied 23 patients on HD for 48±35 months, with mean age 50±12 years, body mass index 24±4kg/m^2 and mean fluid retention between HD sessions 2.2±1.1 kgr using 2D and Doppler echocardiography before and after HD. We measured:a)end-diastolic (LVED) and end-systolic LV diameters,left atrial diameter(LA) and fraction shortening (FS) b)isovolumic relaxation (IVRT) and contraction (ICT) time, deceleration time (DT), E and A waves of the mitral inflow and ejection time (ET) of the LV outflow velocity. The following indices were calculated:E/A ratio, myocardial performance index (MPI) using the formula (IVRT+ICT)/ET, mean arterial pressure (MAP), the % reduction of MAP and the reduction of intravascular volume (ultrafiltration volume-UFV) after HD.

Results: All patients had systolic arterial pressure >90mmHg and normal FS before and after HD, while they demonstrated a restrictive LV diastolic filling before HD (table). MAP, LVED, LA, E wave, E/A, decreased while IVRT increased after HD ($p<0.01$). After HD,low MPI values (normal range<0.44) were related to greater UFV loss ($r=0.53$, $p<0.01$) and greater % reduction of MAP ($r=0.62$, $p<0.01$). Conversely, abnormal MPI values were related to high MAP after HD ($r=0,44$, $p<0.01$). Increased UFV loss was related to greater % increase of IVRT ($r=0.43$, $p<0.01$) and % decrease of E/A ($r=0.40$, $p<0.01$) after HD. Patients with UFV loss >3kg (7/23) had lower MPI (0.47±0.2 vs 0.84±0.3, $p<0.01$) and greater %increase of IVRT and %reduction of E/A ($p<0.01$) than those with <3kgr.

Hemodialysis	MAP (mmHg)	LVED (mm)	LA (mm)	E (m/s)	E/A	IVRT (ms)	ET (ms)
Before	100±15	52±6	43±5	0.86±0.2	1.2±0.2	64±14	298±85
After	86±12	48±6	39±5	0.61±0.2	0.8±0.2	89±19	241±54
p	<0.01	<0.01	<0.01	<0.01	<0.01	<0.01	<0.01

Conclusion: Fluid retention between HD sessions leads to restrictive LV diastolic filling as shown by an E/A>1 and a short IVRT in patients before HD. Reduction of the excess intravascular volume after HD normalises the MAP and thus, improves LV performance

P449 Tissue Doppler data imply that artifacts in conductance measurements in the left ventricle during isovolumic phases are due to tissue movements

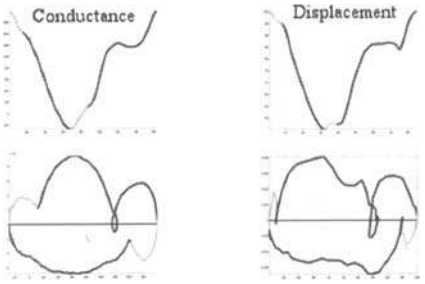
E. Söderqvist[1], L.A. Brodin[2], C. Storaa[1], A.B. Ericsson[3]. [1]*Karolinska Institutet, Div of Medical Engineering, Huddinge, Sweden;* [2]*Huddinge University Hospital, Dept. of Clinical Physiology, Huddinge, Sweden;* [3]*Karolinska Hospital, Dept. of Thoracic Surgery, Stockholm, Sweden*

Objective: Volume measured by the conductance method often decrease during isovolumic contraction (IVCT) and increase during isovolumic relaxation time (IVRT). We evaluated if movements in the muscle of the left ventricle (LV) was correlated to changes in LV conductance during IVCT and IVRT.

Methods: Using ultrasound tissue doppler 18 healthy normal men were studied. Longitudinal velocities were measured in the LV septum and lateral wall. Velocities were integrated to displacement, i.e. movement in LV wall. These displacement curves were compared to the volume curves, measured with the Biometrics conductance catheter on pigs undergoing open-chest surgery with intact pericardium.

Results: The curves from the two types of measurements were similar, with almost identical appearance during IVCT and IVRT.

Conclusion: Movements in the cardiac wall during IVCT and IVRT may influence measured volume by the conductance method.



Conductance to the left, displacement to the right. Top figures are data plotted against time. Below the same data are plotted against their own first derivative (flow and velocity, respectively).

CORONARY CIRCULATION

P450 Phasic coronary blood flow pattern and flow reserve in the atrium: regulation of the left atrial myocardial perfusion

E.I. Skalidis[1], G.E. Kochiadakis[1], N.E. Igoumenidis[1], E.A. Zacharis[1], M.I. Hamilos[1], H.E. Mavrakis[1], K.E. Vardakis[1], P.E. Vardas[2]. [1]*Heraklion University Hospital, Cardiology Dept., Heraklion, Crete, Greece;* [2]*Heraklion University Hospital, Cardiology, Heraklion, Greece*

Background: Due to the limitations of the methods used until now for assessing myocardial perfusion in the small mass of atrial tissue, human atrial myocardial perfusion data is lacking.

Objectives: The purpose of this study was to assess rest and stress atrial coronary blood flow and flow reserve.

Methods: Ten patients with suitable coronary anatomy underwent coronary blood flow velocity (APV) measurements, using a 0.014 inch Doppler guidewire in the proximal left circumflex coronary artery (LCx) and in the left atrial circumflex branch (LACB), at baseline (b) and after adenosine (h) administration. Coronary flow reserve was calculated as h-APV/b-APV. All measurements were done at resting heart rate, at 100 bpm and 120 bpm.

Results: As shown in the table, there was a disproportionate increase in baseline coronary blood flow between LACB and LCx during the two levels of stress (significant interaction $p<0.001$) but no significant differences in coronary flow reserve.

	LCx			LACB		
	Rest	100 bpm	120 bpm	Rest	100 bpm	120 bpm
b-APV cm/sec	16.8 + 5.8	18.9 ± 5.6	20.1 ± 5.7	17.6 ± 5.8	23.6 ±8.1	28.2 ± 7.9
h-APV cm/sec	47.2 ± 17.7	46.7 ± 17.4	44.6 ± 16.2	46.9 ± 14.9	51.9 ± 17.2	52.3 ± 15.9
CFR	2.9 ± 0.7	2.5 ± 0.7	2.3 ± 0.6	2.7 ± 0.6	2.2 ± 0.3	1.9 ± 0.3

Conclusions: Although atrial and ventricular coronary flow reserve show no significant differences at rest and two levels of stress, the disproportionate increase in atrial blood flow during stress indicates a peculiarity of atrial perfusion regulation leading to early exhaustion of vasodilator reserve.

P451 Favorable effect of phentolamine on coronary vasomotion during dobutamine stress testing in patients with coronary artery disease

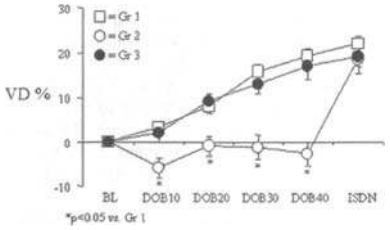
E. Barbato[1], J. Bartunek[1], M. Penicka[1], W. Wijns[1], G.R. Heyndrickx[1], M. Vanderheyden[1], F. Staelens[1], B. De Bruyne[2]. [1]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium;* [2]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium*

Coronary artery disease (CAD) is associated with enhanced alpha-adrenergic vasomotor tone. Dobutamine (DOB), a drug currently used to detect CAD, is an alpha- and beta-adrenergic agonist.

Aim: To explore the contribution of alpha-adrenergic component in the vasomotor response to DOB in patients with CAD.

Methods: Vessel diameter (VD, %) was assessed at baseline (BL), during IV DOB (10, 20, 30, 40 μg/kg^{-1}.min^{-1}) and after IC isosorbide dinitrate (ISDN, 2 mg) in 85 coronary segments of 19 subjects with normal coronaries (Gr 1) and in 36 coronary segments of 12 patients with tight stenoses (Gr 2). A IC bolus of phentolamine (PHENTO, 12 μg/kg), a non-selective alpha-adrenergic antagonist, was followed by the above protocol in 48 coronary segments of 10 patients with tight stenoses (Gr 3).

Results: Angiographic severity of coronary stenoses was similar in Gr 2 and 3. A similar rate pressure product increase during DOB was observed in all three groups. In Gr 1, DOB induced a dose-related increase in VD. In Gr 2, DOB induced no significant vasomotion. Yet, when atherosclerotic vessels were pretreated by PHENTO (Gr 3), a similar vasodilation was observed than in normals during DOB. ISDN resulted in similar vasodilation in all three groups (figure).



Conclusion: In patients with CAD, PHENTO restores DOB-induced vasorelaxation suggesting an overriding of the beta- by the alpha-adrenergic component in CAD.

P452 Parathyroid-hormone related peptide increases coronary flow in a nitric oxide independent way

K. Schlüter, H. Degenhardt, M. Heinemann. *University, Physiology, Giessen, Germany*

Background: Parathyroid hormone-related peptide (PTHrP) is a peptide hormone that is produced and released from the coronary endothelium. It acts as a dilating factor and therefore is able to increase the coronary flow. It is, however, not clear, whether this dilating effect is nitric oxide (NO)- and therefore endothelium-dependent or not. The local concentration of PTHrP is increased at the end of ischemia. Therefore, the early phase of reperfusion is performed in the presence of high endogenously released PTHrP. The answer of the underlying mechanism of the PTHrP effect allows a prognosis about the ability of PTHrP to increase coronary flow in the presence of post-ischemic endothelial dysfunction. Methods: We determined coronary flow in pressure-constant perfused rat hearts (55 mm Hg) which were paced at 3 Hz. Ischemia was performed by a 30 minute no-flow periode. The pre-ischemic apparent coronary flow was 6.2±1.2 ml/g heart weigth which was reduced to a post-ischemic value of 4.7±1.3 ml/g. Experiments were performed in presense of synthetic PTHrP(1-36) (100 nM, EC50: 0.5 nM), the endothelium-dependent vasodilator bradykinin (10 μM), the NO-donor spermine-NONOate (100 nM), and L-nitro-arginin (L-NA, 100 nM), which was used to inhibit NO production by the endothlium. In pre-ischemic experiments, hearts were preconstricted by addition of phenylephrine (10 μM). Results: Under basal conditions, PTHrP increased coronary flow by 19±9%, bradykinin by 37±7%, and spermine-NONOate by 15±8% (each n=4, $p<0.05$ vs. control). In presence of L-NA basal coronary flow was reduced to 3.9±1.2 ml/g, but PTHrP still increased coronary flow by 16±9%. In contrast, bradykinin did not shown an effect in presence of L-NA. Post-ischemically, spermine-NONOate and PTHrP were still able to increase coronary flow by 19±9% and 21±7%, respectively. However, bradykinin did not show any effect on coronary flow during the post-ischemic reperfusion.
Conclusion: PTHrP increased coronary flow in a NO- and endothelium-independent way. Therefore, PTHrP-induced coronary flow is able to compensate for post-ischemic endothelial dysfunction in the heart. PTHrP seems to be a relevant endogenously released factor contributing to post-ischemic recovery.

P453 Endothelin A receptor antagonism promotes decreased vasodilation but has no differential effect on coronary compliance in hypertensive patients

A. Kostopoulou, Z. Kyriakides, I.A. Paraskevaidis, S. Kyrzopoulos, F. Kolokathis, E. Sbarouni, M. Georgiades, D.T.H. Kremastinos. *Onassis Cardiac Surgery Center, B' Cardiology, Athens, Greece*

Endothelin (ET) antagonism causes greater vasodilation in forearm vessels in hypertensive (HT) compared to normotensive (NT) patients. We examined whether there is a differential effect of ETA antagonism on vasodilation and coronary artery compliance in HT compared to NT patients.
Methods: We examined atherosclerotic non-stenotic arteries from 18 non-diabetic, 10 NT and 8 HT patients, before and after intracoronary infusion of BQ-123, an ETA receptor antagonist. The systolic and diastolic artery lumen area (DA) in the proximal segment was measured using an IVUS catheter.

		Baseline	After BQ-123	F	p
DA, mm^2	NT	8.9±2.9	10.8±3.0*	3.98	0.05
	HT	10.6±4.6	10.8±4.0		
beta	NT	1.52±0.63	1.41±0.73	0.86	0.37
	HT	1.80±0.66	1.46±0.58		

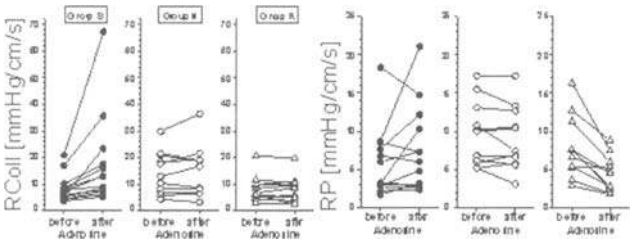
*: $p<0.05$ vs. baseline; â: stiffness index. Systolic blood pressure decreased only in HT patients ($F=5.44$, $p=0.03$).

Conclusion: ETA antagonism causes decreased vasodilation but has no differential effect on coronary artery compliance in HT patients.

P454 Direct assessment of the mechanism of coronary steal in chronic total coronary occlusions

G.S. Werner, H.R. Figulla. *Friedrich-Schiller-University, Klinik Innere Medizin III, Jena, Germany*

Background: Coronary steal can occur in collateral-dependent myocardium during pharmacologically induced vasodilation. This study assessed coronary steal invasively in chonic total coronary occlusions (TCO) to determine the underlying hemodynamic changes of the collateral circulation.
Methods: In 35 consecutive patients with a PTCA of a TCO (>4 weeks duration), a probing catheter was advanced distal to the occlusion to allow the assessment of coronary flow velocity (APV) by a Doppler wire, and distal pressure (PD) by a pressure wire in the collateral-dependent vascular bed. Collateral (RColl) and peripheral (RP) resistance indexes were calculated. These parameters were again obtained during intravenous adenosine (140 ?g/kg/min) and compared with baseline.
Results: APV decreased during adenosine in 13 patients (39%) representing coronary steal (group S), it increased in 11 patients indicating a collateral flow reserve >1 (group R), and no change occurred in 11 patients (group N). There were no clinical and angiographic differences between these groups. With steal RColl significantly increased, and RP remained unchanged, whereas in group R RP decreased and RColl remained unchanged (see Figure). In group N without changes during adenosine, collateral function was less developed with a high RColl.



Resistance changes during adenosin.

Conclusions: Coronary steal is observed in about one third of TCOs, and is associated with specific hemodynamic changes of RColl and RP. These in vivo observations were in accordance with the collateral network model to explain coronary steal. Steal occurred only in a well-developed collateral system, but there were no clinical parameters to predict its incidence.

P455 Limitations of medical therapy in patients with pure coronary spastic angina

S. Sueda, H. Kohno, H. Fukuda. *Saiseikai Saijo Hospital, Cardiology, Saijo City, Japan*

Objectives: To assess the efficacy of medication in pure coronary spastic angina, 71 consecutive patients (55 men, mean age of 63,10 years) with this diagnosis who had undergone coronary arteriography in hospital with a follow-up of at least 2 year were studied.
Methods and Results: All 71 patients without significant organic stenosis were treated with long acting calcium antagonists. The disappearance of chest pain attacks under medical therapy was observed in 27 (38%) patients, whereas the remainig 44 (62%) patients had chest pain attacks. Especially, 30 patients had more than 1 attack/month irrespective of the administration of calcium antagonists or isosorbide dinitrate. Medical treatment showed a good response in female patients (63% vs. 31%, $p<0.05$) and those with ST segment elevation during selective spasm provocation tests (63% vs. 30%, $p<0.05$). In contrast, patients with a longer history of chest pain attacks before admission and those with diffuse spasms (77% vs. 34%, $p<0.01$) had a poor response to medical treatment. In this study, neither sudden death nor acute myocardial infarction was observed during follow-up periods.
Conclusions: Limitations of medical therapy, including long acting calcium antagonists, were observed in 30 (42%) of 71 patients with pure coronary spastic angina. Medical treatment was effective in only 38% of patients with pure coronary spastic angina in Japan.

P456 Induction of coronary artery spasm by two pharmacologic agents: Comparison between intracoronary injection of acetylcholine and ergonovine

S. Sueda, H. Kohno, H. Fukuda. *Saiseikai Saijo Hospital, Cardiology, Saijo City, Japan*

This study examined whether or not intracoronary injection of acetylcholine (ACh) was similar to intracoronary administration of ergonovine (ER) for the induction of coronary artery spasm. We performed selective intracoronary administration of both ER and ACh in the same 171 patients (106 men, 62}10 years) with <50% stenosis. Under no medication, ACh was injected first in incremental doses of 20-100 mg. Ten minutes later, ER was administered in total doses of 40-64 mg. Positive spasm was defined as > 99% luminal narrowing. Coronary spasms were induced by either pharmacologic agents in 134 vessels from 70 patients. In the overall results, no difference was existed in the incidence of provoked spasm between the 2 agents (ACh: 33% vs. ER: 32%, ns). However, ER provoked more focal spasms, whereas ACh provoked more diffuse spasms. Seventy-four (56%) of all 134 vessels had coronary spasms on the same coronary arteries. Coincidence of both provoked spasms and spasm configuration on the same coronary artery was observed in only 16%(22/134). Coincidence of this study was 94% of all vessels, whereas the remaining 6% of vessels were different each other. Non-coincidence rate of RCA was significantly higher than that of LCA (9% vs. 4%, $p<0.01$). In conclusions, there is no difference between ACh and ER as a spasm provocation test. We recommend the supplementary use of these two pharmacologic agents for the induction of CAS in the cardiac laboratory, if available.

P457 Elevated high-sensivity C-reactive protein levels in patients with coronary spasm

X. Tsuka[1], Y. Nagahama[2], H. Kamihata[1], Y. Sutani[1], H. Miyoshi[1], M. Nukui[1], T. Iwasaka[1]. [1]*Kansai Medical University, Cardiovascular Center, Osaka, Japan;* [2]*Toyonaka, Japan*

Background: Elevated high-sensivity C-Reactive Protein(hs-CRP) levels, an exquisitely sensitive objective marker of inflammation, are associated with restenosis, impaired endthelial vasoreactivity, and unfavorable prognosis in patients with coronary artery disease. However, the relation between elevated inflammatory markers and coronary spasm has not been documented. Accordingly, the aim of our study was to assess whether higher levels of hs-CRP could be found in patients with coronary spasm compared with those without coronary spasm.
Methods: The study group consisted of 38 consecutive patients (23 men and 15 women; mean age 60+12 years) undergoing coronary angiography for evaluation of vasospastic angina. Coronary spasm was defined as total or subtotal occlusion of the epicardial coronary arteries after the intracoronary injection of ergonovine. Patients were classified into 2 groups on the basis of coronary; 11 patients with coronary spasm, 27 patients no coronary spasm. All patients had no significant organic stenosis angiographically and free of noncardiac reasons causing increased hs-CRP levels. Blood samples (Total cholesterol, LDL-cholesterol, HDLcholesterol, Triglyceride, HbA1c, hs-CRP) were collected at the time of coronary angiography.
Results: There were no significant differences between 2 groups in age, sex, and incidence of major coronary risk factors. Patients with coronary spasm had significantly higher levels of hs-CRP than those without coronary spasm (1.56+1.26 mg/L vs 0.57+0.44 mg/L, $p < 0.01$).
Conclusion: Elevated hs-CRP levels were verified in patients with coronary spasm, indicating that inflammatory process was associated with coronary spasm.

P458 Nifedipine improves endothelial function and decreases vascular inflammation in coronary circulation: studies on patients with angina pectoris

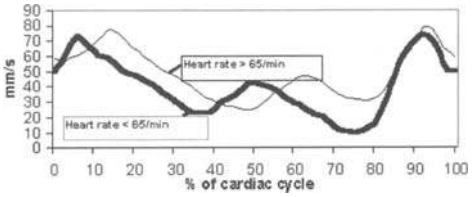
H. Takase[1], T. Toriyama[1], T. Goto[2], T. Sugiura[1], Y. Dohi[2]. [1]*Enshu General Hospital, Department of Internal Medicine, Hamamatsu, Japan;* [2]*Nagoya City University Hospital, 2nd Internal Medicine Dept., Nagaya, Japan*

Objective: Ischemic heart disease is associated with endothelial dysfunction and atherosclerosis of the coronary arteries. The present study was designed to determine whether calcium channel blockers improve endothelium-dependent coronary vasomotion in patients with angina pectoris.
Methods: Fifteen male patients (mean age 65±2 years) with stable angina pectoris who underwent elective percutaneous transluminal coronary angioplasty (PTCA) were enrolled. Following routine PTCA, increasing doses of acetylcholine (3, 10, 30 μg/min for 3min) and then isosorbide dinitrate (ISDN; 2mg/min for 1min) were infused into the study coronary artery. Changes in the coronary blood flow were assessed by an intracoronary Doppler flow wire and blood was sampled from the coronary sinus for the measurement of C-reactive protein (CRP). The patients were then randomly divided into two groups; a nifedipine treatment group (long-acting nifedipine; nifedipine CR® 20mg/day) and a control group. After 120±7 days, coronary angiography was again performed for all the patients to evaluate the patency of the lesions and the procedures performed above were repeated on the same coronary artery.
Results: Baseline characteristics, prescribed medications, coronary risk factors and hemodynamic properties of the patients were the same in both groups. The incidence of coronary restenosis was 33.3% and 16.7% in the control and the nifedipine treatment groups, respectively (n.s.). Treatment with nifedipine markedly enhanced acetylcholine-induced increases in coronary blood flow (normalized by the response to ISDN; 1.67±0.42 to 3.56±0.64; $p<0.05$), while the response to acetylcholine did not change over the follow-up period in control patients. The vasomotor responses to ISDN were similar in the two groups, and no interval changes were noted in either group. Blood sampling revealed a decrease in serum levels of CRP in the nifedipine treatment group (0.35±0.09 to 0.07±0.01mg/dl; $p<0.05$), but not in the control group during the study interval.
Conclusion: These results suggest that treatment with nifedipine improves endothelial function in the coronary circulation and decreases inflammation of the coronary vascular wall. This may contribute to an improvement in myocardial perfusion as well as regression of coronary atherosclerosis.

P459 Velocity of coronary artery motion during the cardiac cycle: measurement by biplane coronary angiography

S. Achenbach, K. Pohle, D. Ropers, H. von Korn, J. Ludwig, W. Moshage, W.G. Daniel. *University of Erlangen, Cardiology & Internal Medicine II Dept, Erlangen, Germany*

To minimize motion artifacts in coronary artery imaging by MRI, electron beam tomography and multislice spiral CT, image acquisition must be performed in the periods of slowest coronary artery motion. However, the exact patterns and velocity of 3-dimensional coronary artery motion are currently unknown.
Methods: In 30 patients with normal ventricular function (mean heart rate 68/min), biplane angiograms were obtained in orthogonal projections. After calibration, the spatial coordinates of predefined bifurcation points in the mid left anterior descending (LAD), left circumflex (LCX), and right coronary artery (RCA) were measured in every angiographic frame, 3-dimensional motion patters were reconstructed, and the motion velocity was calculated throughout the cardiac cycle.
Results: Mean coronary motion velocity was 42.6 mm/s (LAD: 24.7 mm/s, LCX: 38.6 mm/s, RCA: 64.4 mm/s). Highest velocity (mean: 72.4 mm/s). was observed at 92% of the cardiac cycle (atrial contraction). Two periods of slow motion were identified: during isovolumetric relaxation and in mid-diastole. For heart rates below 65/min (15 patients), slowest velocity was observed at 75% of the cardiac cycle, while for heart rates above 65/min (15 patients), slowest velocity was observed at 49% of the cardiac cycle (see graph).



Speed of coronary motion.

Conclusion: Coronary artery motion velocity displays substantial variation between the coronary vessels and during the cardiac cycle. To reduce motion artifacts, coronary imaging should be performed in mid-diastole for slow heart rates and in the period of isovolumetric relaxation for higher heart rates.

P460 Intravenous amiodarone administration increases markedly the coronary blood flow in intact swine heart

A. Ntalianis, C. Charitos, P. Dolou, S. Drakos, C. Pierakos, G. Tanos, J. Nanas. *Dpt of Clinical Therapeutics, University of Athens, Athens, Greece*

Background: Amiodarone is a widely used antiarrhythmic agent with salutary effects on the clinical setting of heart failure and antianginal properties. The aim of our study was to evaluate the hemodynamics and coronary flow after intravenous infusion of amiodarone.
Methods: In eight opened chest pigs (weighting 65±6kgrs),two catheters (7F) were inserted in the aorta and the left ventricle and a third one (6F)was advanced in the right atrium. Transit time ultrasound flowmeter probes were placed around the left anterior descending coronary artery and the pneumonic artery trunk.
Intravenous amiodarone (5mg/kg body weight) was then administered over a period of five minutes. During the infusion of the drug, left ventricular peak systolic (LVSP) and end diastolic (LVEDP) pressures, mean (MAP) aortic pressure, right atrial pressure (RAP), heart rate (HR), pneumonic artery flow (PF) and coronary blood flow (CF) were recorded. Myocardial energy requirements [Tension Time Index (TTI)]were also evaluated.
Results: Amiodarone resulted in a decrease in TTI, HR, LVSP and MAP and an increase in CF, LVEDP and RAP (table)

	Baseline	1 min	5 min
CF (ml/mln)	70±21	128±53*	134±57*
PF (lt/min)	3.7±0.8	3.7±1.3	3.8±1.2
LVSP (mmHg)	121±26	109±23*	119±24
LVEDP (mmHg)	7±2	9±2**	10±3**
MAP (mmHg)	103±18	89±17*	87±24**
RAP (mmHg)	9±3	10±3*	11±4*
HR (bpm)	137±16	125±11*	125±17*
TTI (mmHg.s/min)	2778±571	2376±439**	2623±530*
		*p=0.01 vs Baseline	**p=0.05 vs Baseline

Conclusion: This experimental study demonstrates that intravenous amiodarone decreases heart rate and afterload and increases coronary blood flow, most likely by direct vasodilatation of the coronary arteries.

P461 Characterisation of fluid-dynamic properties of coronary artery stenoses by simultaneous intracoronary pressure and flow-velocity measurements

W. Bojara[1], M. Lindstaedt[1], C. Perrey[2], H. Ermert[2], B. Lemke[1].
[1]*Universitätsklinik Bergmannsheil, Abt. für Kardiologie und Angiologie, Bochum, Germany;* [2]*Ruhr-Universität, Lehrstuhl für Hochfrequenztechnik, Bochum, Germany*

Purpose: Examination of the fluid-dynamic properties of coronary artery stenoses in vivo by describing the changes in transstenotic pressure gradient - flow velocity relationships at rest and during maximal hyperemia.
Method: In 10 patients with different severity of coronary artery stenoses by QCA analysis intracoronary pressure and flow velocity measurements were performed simultaneously. Online parameter registration included the ECG recording, proximal coronary artery pressure (Pa), distal coronary artery pressure (Pd) and instantaneous peak velocity of coronary blood flow (V). Pd and V were registered with 0,014"-guide wires with integrated pressure and doppler transformers. Continous data acquisition was performed with a sampling rate of 200 Hz at rest and during maximal hyperemia induced with i.v. adenosin (140μg/kg/min). Prior to all measurements 0.5 mg of nitroglycerin were administered i.c. in order to keep the effects of epicardial artery vasodilation on stenosis geometry at a minimum. Data processing was done with MATLAB version 6.1.
Results: All recordings of the measurements in 10 subjects were performed successfully. The data was evaluated after the elemination of the accelerative phase of early diastole and the decelerative phase of systole. Using these data the passive diastolic pressure gradient - flow velocity characteristics were described by quadratic curvilinears. The slopes of these separate curves changed in correlation to apparent differences in angiographic stenosis severity.
Conclusions: At present the analysis of the passive diastolic relationship between pressure gradient and flow velocity at rest and during maximal hyperemia probably yields the most comprehensive description of the fluid-dynamic properties of a coronary artery stenosis. We show that in vivo measurements in humans can be performed reliably. With respect to our preliminary data the pressure gradient - velocity curves may allow a classification into categories of mild, moderate, and severe stenoses based on fluid-dynamic characteristics of a stenosis. Weather this method will give superior information to the use of intracoronary pressure or flow velocity measurements with determination of the myocardial fractional flow reserve (FFRmyo) or the coronary flow velocity reserve (CFVR) alone is still unclear. Further investigations are required to determine the potential value in interventional clinical cardiology.

P462 Evaluation of coronary flow reserve before and after left anterior descending artery stent implantation: a transoesophageal echocardiography study

J. Tsutsui, P.A. Lemos, E.T. Tajagi, H.W. Shida, S.B. Leal, J.L. Andrade, W. Mathias. *Heart Institute, São Paulo, Brazil*

Coronary angioplasty and stent implantation is widely used procedure for the treatment of coronary artery disease. Coronary flow reserve (CFR) is considered a precise indicator of the functional significance of coronary stenosis. Transesophageal echocardiography (TEE) is becoming a useful tool for evaluation of CFR in the proximal left anterior descending artery (LAD), and can be used as a non-invasive index of restenosis.
Objectives: To evaluate CFR by TEE before and 48 hours (h) after LAD stenting; to determine the predictors of post-procedural CFR impairment; and to evaluate the diagnostic accuracy of transesophageal Doppler CFR measurements for prediction of restenosis.
Methods: To determine normal flow velocities, we studied a control group of 20 healthy volunteers, mean age 49,1±10,7 years, 7 males. The stenosis group comprised 51 patients (pts) (mean age 59,5±10,4 years, 29 males) with LAD stenosis (> 50%). Successful LAD stenting were performed in all stenosis group pts. Quantitative coronary angiography was done before and after the procedure. CFR was measured by TEE, with spectral Doppler recordings of flow in baseline conditions and during a 4 min infusion of adenosine (140 μg/Kg/min). After 6 months, CFR by TEE and selective angiography was repeated for detection of restenosis.
Results: Feasibility of CFR measurements was 91%, and intraobserver variability was 2,8±1,4%. CFR was significantly lower in stenosis group (1,89±0,66) than in control group (3,82±1,15); $p < 0,001$. Stenosis group presented a statistically significant increase of CFR 48 h after stenting, from 1,89±0,66 to 2,58±0,76 ($p < 0,001$). However, 55% of pts remained with impaired CFR (< 2,5). Multivariate logistic regression analysis showed that multiarterial lesions, age and lesion extension were the determinants of flow impairment after successful stenting. 41 pts of stenosis group completed 6 months follow-up, and angiographic restenosis were detected in 39% of them. CFR for pts with restenosis (1,91±0,54) was lower than that for pts with no restenosis (2,37±0,71), $p < 0,05$. A reduced CFR had good sensibility (94%), but poor specificity (48%) for the diagnosis of restenosis.
Conclusions: TEE is a feasible and safe method for evaluation of CFR, and allows non-invasive identification of pts with lesion > 50% in LAD. It can be used for serial assessment of CFR before and after stent implantation. However, TEE presents limitations for the diagnosis of restenosis, probably due to multifactorial process that alters CFR in pts with established coronary artery disease.

P463 Improved myocardial blush grade post primary angioplasty is associated with reduced peak troponin I elevation

A.M. Prasan, C. Friend, M. Pitney, R. Allan, W. Walsh, R. Giles, N. Jepson. *Eastern Heart Clinic, Prince of Wales Hospital, Sydney, Australia*

Background: Improved myocardial blush post thrombolytic therapy for acute myocardial infarction (AMI) is associated with improved clinical outcomes however the mechanism for this has not been fully established. We sought to address whether reduced myocardial injury as manifested by reduced peak post procedural troponin I was the mechanism of this improvement in a cohort of AMI patients treated with primary angioplasty.
Methods: The coronary angiogram and primary PTCA films of 93 consecutive patients (68 males, age 60.8 ± 14.1 years), presenting with acute myocardial infarction within 6 hours after symptom onset and treated with primary angioplasty, were analysed. TIMI flow and myocardial blush grade (MBG) were evaluated in the culprit artery and subserving myocardial territory respectively, both at baseline and following PTCA and stenting. MBG was graded 0: no blush; 1: minimal blush; 2: moderate blush; 3: normal blush. Peak post procedural troponin I, mortality and target lesion vessel revascularisation rates were recorded in each case.
Results: Peak post procedural troponin I elevation was increased in patients who had poor myocardial perfusion (MBG 0 or 1, n=41) following angioplasty and stenting compared to those with good myocardial perfusion (MBG 2 or 3, n=52) (44.3 ± 8.3 v 17.6 ± 3.2 μg/L, mean ± SEM $p < 0.01$). There was no difference between the two groups in baseline characteristics including age, sex and culprit lesion. A trend to increased mortality in patients with poor post procedural myocardial perfusion was present (7 v 3, p NS). Target lesion revascularisation rates were lower in those with poor myocardial perfusion (4 v 6, p NS).
Conclusion: Improved myocardial blush grade following primary angioplasty is associated with reduced myocardial injury as assessed by troponin I elevation and better clinical outcome. The mechanism is likely to be enhanced microvascular perfusion. Routine assessment of myocardial blush grade following angioplasty and stent deployment is a useful tool for predicting outcomes in AMI patients treated with primary angioplasty.

P464 Influence of side branch on Coronary Flow Reserve (CFR). Measurement by guide wire based thermodilution in the experimental models

Y. Neishi, T. Akasaka, Y. Koyama, M. Akiyama, S. Kaji, Y. Saito, K. Yoshida. *Kawasaki medical school, Cardiology, Kurashiki, Japan*

Background: Fractional flow reserve (FFR) and coronary flow reserve (CFR) are physiological indices of coronary artery stenosis severity. FFR and CFR could only be obtained by 2 separate guidewires previously. Recently, a combined 0.014 pressure/temperature sensor-mounted guide wire has been developed to measure FFR and CFR by thermodilution (CFR-thermo) simultaneously. We aimed to assess the accuracy of CFR-thermo compared with CFR obtained by flow rate (CFR-flow) in the experimental models. Methods: Using experimental models made by the straight-rigid tube (4mm diameter) without stenosis and side branch filled with 36°C water, CFR-thermo and CFR-flow were measured under the different conditions of the sensor position and the injected water temperature (0°C to 40°C). Side branch (2mm diameter) was placed on 4, 6, 8 and 10cm from the injected site just proximal to the stenosis. The degree of stenosis ranged from 0 to 75% (0, 25, 50, 75%). CFR-thermo and CFR-flow were calculated by the inverse ratio of the mean transit time and the flow ratio during high flow to low flow rate, respectively. Results: Under the condition without side branch, there was good correlation between CFR-thermo and CFR-flow when a temperature of injected water was under 32°C and the termo-semsor was not placed within 4 cm from the injection site. In cases with side branch and the stenosis, CFR-thermo were underestimated compared with CFR-flow although there was good correlation between CFR-thermo and CFR-flow. The more proximally placed the side branch to injected site, the more CFR-thermo was underestimated compared with CFR-flow. Conclusions: Temperature of injected water, and the position of sensor, a side branch and stenotic lesion may influence on CFR-thermo. These should be taken into account when CFR would be measured by thermodilution method.

P465 Subendocardial and subepicardial blood flow in normals and patients with coronary artery disease

M A. Khan[1], O E. Rimoldi[1], R J H. Hall[2], P G. Camici[1]. [1]Imperial College, MRC Clinical Sciences Centre, London, United Kingdom; [2]Imperial College, National Heart & Lung Institute, London, United Kingdom

Introduction: Clinical studies in humans and experimental work in animals suggest that in coronary artery disease (CAD) the subendocardium (ENDO) is more susceptible to ischaemia than the subepicardium (EPI). So far, technical limitations have prevented the confirmation of this finding in humans. We measured absolute ENDO and EPI blood flow (MBF) in normal subjects and in patients with CAD using a high sensitivity PET scanner (EXACT3D).
Methods: We studied seven normal volunteers (age 48±2) and ten patients (61±8, $p<0.05$) with stenoses of >70% in two or more coronary arteries. All subjects underwent PET scanning, using oxygen-15 water, at rest and at a maximal tolerated dose of dobutamine. At analysis the LV wall was divided into septal, anterior, lateral, and inferior walls. Each wall was further subdivided into apical and basal segments and then equal ENDO and EPI halves. The segments perfused by each stenosed coronary artery were identified using conventional recommendations. The oxygen-15 water kinetic was fitted to a model corrected for spillover from both ventricular cavities and for partial volume. MBF is presented as ml/min/g of myocardium.
Results: Resting ENDO and EPI MBF (mean±SEM) were 0.92±0.05 and 0.74±0.05 ml/min/g in normals and 0.98±0.06 and 0.77±0.05 ml/min/g in patients (ENDO vs EPI $p<0.0001$ for each group). The rate pressure product in normals increased by 262±39% at a maximum dobutamine dose of 36±5 μg/kg/min and by 210±48% (p=0.03 vs normals) at 32±4 μg/kg/min (p=ns) of dobutamine in patients. In normals, dobutamine MBF increased in 98% of ENDO segments (flow fell in one segment by 0.01 ml/min/g) to 2.40±0.12 ml/min/g and in all EPI segments to 2.30±0.13 ml/min/g. In patients, ENDO dobutamine MBF was 1.3±0.10 ml/min/g and EPI 1.3±0.12 ml/min/g. All patients experienced chest pain and developed ischaemic ECG changes at peak stress and, at this time, MBF fell compared to baseline in 36% of ischaemic ENDO segments and in 25% of EPI segments. ENDO coronary vasodilator reserve (CVR=stress MBF/rest MBF) was 3.0±0.2 in controls and 1.4±0.1 in patients (normals vs CAD $p<0.0001$) and EPI CVR was 3.5±0.2 and 1.8±0.2 ($p<0.0001$) respectively.
Conclusion: Despite an increase in workload, stress MBF falls in a significant proportion of both ENDO and EPI segments perfused by a stenosed coronary artery. The mismatch between demand and supply is greater in ENDO than EPI segments and this may contribute to the greater susceptibility of this layer to myocardial ischaemia.

P466 Myocardial fractional flow reserve and coronary flow ratio in children with Kawasaki disease

S. Ogawa, R. Fukazawa, M. Kamisago, T. Ohkubo, Y. Uchikoba, D. Fukumi, E. Ikegami, Y. Katsube. *Nippon Med. Sch. Hospital, Pediatrics, Tokyo, Japan*

We investigated the detection of silent myocardial ischemia and the effectiveness after PTCA and CABG using myocardial fractional flow reserve (FFRmyo) and coronary flow ratio(CFR) in children with Kawasaki disease (KD). 136 patients (1y-15y) with isolated lesion in one major epicardial coronary artery, normal left ventricular function were divided into three groups; myocardial ischemia (IS) group (n=34), non-ischemia with coronary aneurysm and stenosis (n-IS) group (n=38), and coronary dilation without coronary stenosis (N) group (n= 64) by rest and exercised myocardial scintigraphy and CAG. Pressures were measured at orifice of coronary artery and graft arteries, distal portion of coronary arterial stenotic lesions, anastomosis of arteries, dilated portions by PTCA, and right atrium at the same time. FFRmyo is defined as the ratio of maximal achievable flow in myocardium subtended by a stenosed coronary artery to the maximal achievable myocardial flow induced by papaverine (0.2mg/kg in LCA, 0.15mg/kg in RCA), and FFRmyo can be calculated as next formula; FFRmyo =(Pc-Pv)/Pao-Pv), Pc: mean coronary pressure at distal of stenotic lesions, Pao: mean aortic pressure, Pv: mean right atrial pressure. Average peak velocities were measured at distal portion of stenotic lesions in both rest and papaverine stress(same dose in FFRmyo). CFR was calculated as a ratio of APV before and after papaverine stress at the same positions of FFRmyo. Results: Criteria for detection of myocardial ischemia were defined the mean ± 2SDs for FFRmyo and CFR in N group (Criteria for detection of myocardial ischemia: FFRmyo < 0.75, CFR< 2.0). FFRmyo and CFR were significantly low in IS group (0.64±0.3, 1.1±0.2) as compared to those in n-IS group (0.91±0.6, 2.9±0.5) and N group (0.90±0.7, 3.1±0.5). Sensitivity and specificity for detection of myocardial ischemia were very high by FFRmyo (100%,100%) and CFR (93.7%, 96.8%). Moreover, FFRmyo and CFR pre-PTCA (n=7: 0.62±0.5, 1.1±0.4) and pre-CABG (n=8: 0.60±0.6, 1.2±0.3) were abnormal. But, after PTCA and CABG these values turned to normal same as findings of CAG and clinical.
Conclusions: Criteria of FFRmyo and CFR for detection of myocardial ischemia are the same values in adult. FFRmyo and CFR can be helpful to estimate myocardial ischemia and to evaluate the effectiveness of PTCA and CABG in children with KD.

P467 Change in TIMI frame count correlates with the change in coronary flow parameters

C. Barcin, A.E. Denktas, K.N. Garratt, S.T. Higano, D.R. Holmes, A. Lerman. *Mayo Clinic, Division of Cardiology, Rochester, United States of America*

Background: TIMI frame count (TFC) was introduced as a quantitative and continuous method for defining the coronary blood flow. The data regarding the TFC as compared to Doppler flow wire parameters are limited. We sought to determine the correlation of percent change in TFC with the change in coronary flow parameters in response to acetylcholine (Ach)and nitroglycerin.
Methods: Fifty seven consecutive patients (18 males) without obstructive coronary artery disease underwent coronary physiologic study in the Mayo Clinic were included in the study. Coronary flow parameters were assessed using a Doppler guidewire at baseline, after 0.182, 1.82 and 18.2 microgram/mL concentrations of Ach infusion and after 200 microgram nitroglycerin in left anterior descending arteries. Coronary artery diameters were assessed by quantitative coronary angiography. In each patient a distal landmark was defined in left anterior descending artery and TFCs (number of frames required for the contrast to travel from the ostium to distal landmark) were calculated at baseline and after each Ach infusion and nitroglycerin injection. The percent change in TFC from baseline was compared to the percent changes in averaged peak velocity (APV), coronary artery diameter (CAD), and coronary blood flow (CBF) after each Ach and nitroglycerin administration. Also, a new TFC index (TFCI) was defined as the vessel area divided by TFC and percent change in the TFCI from baseline was then calculated and compared with the change in coronary blood flow.
Results: The correlations of the variables stated above at the end of 208 measurements in 57 patients are shown in the table:

	Spearman R	p
d TFC vs. d APV	- 0.66	< 0.001
d TFC vs. d CAD	0.30	< 0.001
d TFC vs. d CBF	-0.40	< 0.001
d TFCI vs. d CBF	0.77	< 0.001

d: percent change; vs.:versus

Conclusion: Percent change in TFC correlated significantly with the percent change in APV. There is a good correlation between the change in TFCI and change in coronary blood flow. TFCI can reflect the changes in coronary blood flow and can be used as a simple and reliable method of assessment of coronary blood flow.

P468 Coronary flow velocity reserve does not correlate with TIMI frame count in patients undergoing non-emergent percutaneous coronary intervention

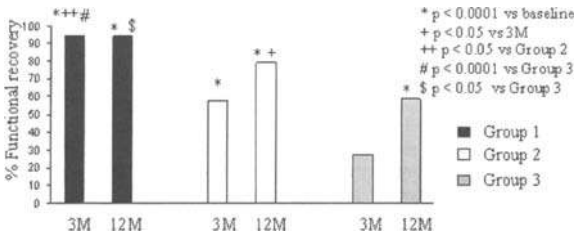
S.K. Chugh[1], L. Shewchuk[2], R. Bonan[3], J.C. Tardiff[3], S. Worthley[4], I. Meredith[4], C. DiMario[5], T.J. Anderson[6]. [1]FHH, Uof C, Interventional Cardiology, CALGARY, Canada; [2]Division of Cardiology, U of C, Interventional Cardiology Research, Calgary, AB, Canada; [3]Montreal Heart Institute, Interventional cardiology, Montreal, Canada; [4]Monash Medical Center, Interventional cardiology, Melbourne, Australia; [5]Milan Hospital, Interventional Cardiology, Milan, Italy; [6]U of C, Division of Cardiology, Calgary, Canada

Corrected TIMI frame count (CTFC), a quantitative yet simple angiographic measure of blood flow, is a predictive marker of outcome in the setting of reperfused myocardial infarction. However, much less is known about the physiological relevance of CTFC in patients undergoing non-emergent percutaneous coronary intervention (PCI). In elective procedures, doppler derived measurements of coronary flow velocity reserve (CFVR) have proven useful in predicting outcomes of PCI, but expense limits general use. Since both CFVR and CTFC are a measure of coronary blood flow, we hypothesized that the two measures would be related. The objective of this study was to compare the CTFC with CFVR in patients undergoing non-emergent PCI. We studied 62 patients with TIMI 3 flow who underwent successful non-emergent PCI as part of a randomized multi-centre study of coronary stenting and optimal balloon angioplasty (Doppler Endpoint Stenting International Investigation). All patients had doppler evaluation of CVR, CTFC and QCA pre and post intervention.
PCI increased minimal lumen diameter (MLD) from 0.94 ± 0.32 to 2.78 ± 0.54 mm (% stenosis: 69 ± 10 to15 ±11%). The CTFC decreased from 27 ± 13 to 18 ± 8 and CVR increased from 1.5 ±0.4 to 2.6 ± 0.7 (both $p<0.0001$). Although the pre PCI CTFC and the CFVR were closely related to MLD ($p<0.0001$) there was no relationship between CTFC and CFVR pre intervention (p=0.12). Following PCI, there was no correlation between CTFC and CFVR or other doppler parameters. The post intervention CTFC was closely related to pre CTFC (p=0.003). Interestingly, post-PCI, the CTFC/MLD ratio correlated with CFVR ($p<0.05$).
Conclusion: There was no correlation between CTFC and doppler derived parameters in patients undergoing non-emergent coronary intervention but there was a relationship between CVR and the CTFC/MLD ratio. The utility of CTFC in predicting outcomes in this setting requires further evaluation.

P469 Relation between postprocedural TIMI frame count and functional recovery after revascularization of viable myocardium

G. De Luca, F. Piscione, P. Perrone-Filardi, M. Prastaro, G. Galasso, G. Marrazzo, O. Viola, M. Chiariello. *"Federico II" University, Division of Cardiology, Naples, Italy*

Introduction: It has been reported that postprocedural angiographic flow, evaluated by the TIMI frame count (cTFC) method, may affect regional functional recovery of patients undergoing primary PTCA. No extensive data have been so far published about the relationship between postprocedural cTFC and long-term functional recovery of viable myocardium in patients with chronic coronary artery disease undergoing coronary angioplasty (PTCA).
Methods and Materials: From a consecutive series of patients undergoing evaluation of myocardial viabiltiy at our Institute, we selected patients that underwent singlevessel revascularization by PTCA. Thus 21 patients (59±12 ys, 3 females) represented the population of the current study. They underwent rest-redistribution 201Tl SPECT and echocardiogram at rest before revascularization, at three months (3M) and 1 year (12M) after revascularization. Patients were devided in three groups according to postprocedural cTFC: Group 1 (< 13 frames; 6 pts), Group 2 (13-23 frames; 10 pts) and Group 3 (> 23 frames; 5 pts).
Results: See Figure.

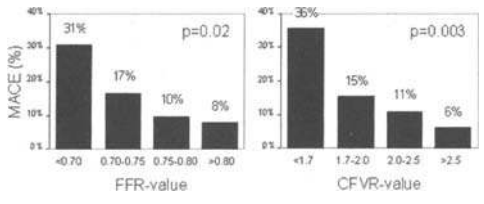


Conclusions: Our study demonstrated that the timing of functional recovery after revascularization of viable myocardium is significantly affected by post-procedural angiographic coronary flow. Thus for a correct assessment of viability, echocardiographic follow-up should be prolonged at least till one year after revascularization.

P470 Risk stratification using different cut-off values of fractional and coronary flow reserve after deferral of PTCA of intermediate lesions

M. Meuwissen[1], S.A.J. Chamuleau[1], M. Siebes[1], K.T. Koch[1], R.J. de Winter[1], J.G.P. Tijssen[1], J.A.E. Spaan[2], J.J. Piek[1]. *[1]Academic Medical Center, Cardiology Dept., Amsterdam, Netherlands; [2]Academic Medical Center, Medical Physics, Amsterdam, Netherlands*

Purpose: To evaluate deferral of PTCA in intermediate lesions (40-70% diameter stenosis using different thresholds for fractional flow reserve (FFR) and coronary flow velocity reserve (CFVR).
Methods: PTCA was deferred in 130 patients, including 141 coronary lesions (mean diameter stenosis of 55%)based upon normal myocardial perfusion stress testing and/or discordant results between CFVR and FFR. Both intracoronary pressure and flow velocity were obtained during baseline and maximum hyperemia (by 15-20 mcg adenosine IC). FFR was defined as the ratio of mean distal pressure to mean aortic pressure during maximum hyperemia and CFVR was defined as the ratio of hyperemic to baseline flow velocity. Patients were followed for one year to document major adverse cardiac events (MACE: death, myocardial infarction (MI), CABG, PTCA) related to the intermediate lesion. Patients were divided into quartiles determined by the distribution of MACE and the established cut-off values used for FFR (0.75) and CFVR (2.0).
Results: A total of 16 (11%, 5x MI, 2x CABG, 9x PTCA) events occurred during follow up. There was a significant positive trend between the occurrence of MACE and the used cut-off values of FFR (p=0.017, Cochrane Armatege test) and CFVR (p=0.0025), see figure below.



Conclusion: Differentiation of threshold values of FFR and CFVR allows risk stratification in patients following deferral of PTCA of intermediate coronary lesions.

P471 Feasibility of assessment of coronary fractional flow reserve during ambulatory coronary angiography

M.F. Seronde, P. Sewoke, N. Meneveau, L.I.U. PinMing, F. Schiele, J.P. Bassand. *Department of Cardiology, Besancon, France*

Purpose: To assess the feasibility of coronary fractional flow reserve (FFR) assessment in outpatients through diagnostic 4 or 5 French catheters.
Methods: Over 1 year, FFR was determined using pressure flow wire (Endosonics) in consecutive patients in case of intermediate angiographic stenosis (40 to 60% diameter stenosis (DS) by quantitative coronary analysis) and lack of demonstrated ischemia. FFR was measured using a 4 or 5F diagnostic catheter or through a 7F guiding catheter, after injection of 0.2mg adenosine intracoronary. All patients received 2500IU heparin before FFR assessment. When no additional procedure was needed, heparin was neutralised with 2.5 ml protamine and the sheath removed immediately. When diagnostic catheter was used, strict bed rest was required for only 3 hours and patients were allowed to discharge on the same day.
Results: FFR was measured in 145 patients (156 lesions) using a 7F guiding catheter (n=54) or a diagnostic catheter (n=91): 5F(n=46) and a 4F(n=45). Results of the quantitative coronary analysis and of FFR are displayed in the table. Feasibility of pressure guide wire placement was similar through diagnostic or guiding catheter and there was no difference in pressure curve quality. 31(20%) lesions were submitted to immediate angioplasty, 5(3%) delayed angioplasty, 9(6%) delayed surgery. All 107(74%) patients not requiring additional procedure were candidates for early discharge. When a 4 or 5F catheter was used, ambulation was allowed after 3 hours and half of these patients were discharged at the same day. No angiography or FFR measurement-related complication occurred.

	7F	5F	4F
N of pts (lesions)	54 (55)	46 (51)	45 (50)
DS (mm)	0.53±0.08	0.43±0.06	0.45±0.12
FFR	0.86±0.06	0.91±0.08	0.87±0.21
Protamine post FFR	7 (16%)	19 (40%)	25 (56%)
Outpatients	1/54 (2%)	3/46 (6%)	20/45 (44%)

Conclusion: FFR measurement through 4 or 5F diagnostic catheter is feasible and safe and therefore is possible during outpatient coronary angiography.

P472 Intravenous adenosine during coronary flow reserve assessment: is 90-second infusion sufficient for maximal coronary vasodilatation?

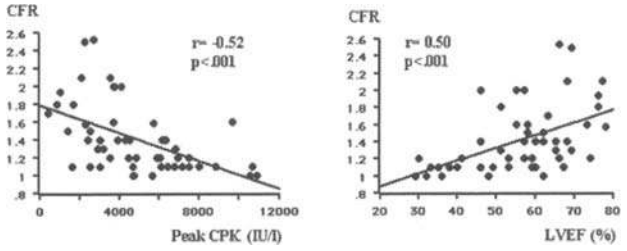
L.J. Chen[1], P. Colonna[1], R. Montisci[2], A.H. Selem[1], C. Caiati[1], C. Cadeddu[1], L. Meloni[2], S. Iliceto[1]. *[1]University of Padua, Division of Cardiology, Padua, Italy; [2]University of Cagliari, Division of Cardiology, Cagliari, Italy*

Background: The timing of i.v. adenosine infusion during coronary flow reserve (CFR) evaluation varies among different studies. Recent studies have used a 90-second i.v. adenosine for CFR assessment. We sought to test if CFR measured within 90 seconds after adenosine infusion can induce maximal coronary vasodilatation, when compared with standard 5-minute protocol.
Methods: Two-hundred twelve patients suspected of coronary artery disease were studied. Flow velocity in the distal left anterior descending coronary artery (LAD) was noninvasively evaluated at rest and during i.v. adenosine (140μg/kg/min in 5 minutes) by transthoracic Levovist enhanced harmonic Doppler echocardiography. The maximum hyperemic peak flow velocity averaged over 3 cardiac cycles within 90 seconds and 5 minutes were calculated, and CFR values within 90 seconds (CFR-90s) and 5 minutes (CFR-5m) were determined respectively.
Results: Three patients (1.4%) could not achieve flow signal in the LAD and 12 (5.6%) could not finish 5-minute adenosine infusion because of chest pain (5), ECG ST depression>1mm (4) or hypotension (3). CFR-90s and CFR-5m were successfully acquired in 197 patients (92.9%). In 186 patients (94.4%) the highest hyperemic response during 5-minute adenosine infusion was occurred within the first 90 seconds, i.e., CFR-5m equals to CFR-90s; whereas in 11 (5.6%) CFR-5m was significantly higher than CFR-90s (2.46 ± 0.70 vs. 2.12±0.57, p<0.01). Among these patients, 7 (63.6%) had a pattern of fluctuating flow during adenosine infusion. Heart rate and blood pressure were not significantly different within 90 seconds and 5 minutes.
Conclusions: Although in majority of patients the maximum hyperemic response appeared within the first 90 seconds after adenosine infusion, in approximately 5% of patients CFR was significantly underestimated when calculated within 90-second infusion. Therefore, when no severe side effects are present, 5-minute adenosine infusion should be preferred for CFR assessment.

P473 Coronary flow reserve immediately after reperfusion predicts infarct size in patients with acute myocardial infarction without diabetes mellitus

T. Takahashi, Y. Hiasa, T. Nada, T. Ogata, S. Hosokawa, K. Kishi, R. Ohtani. *Tokushima Red Cross Hospital, Cardiology, Komatsushima, Japan*

Background: The aim of this study was to examine the clinical value of coronary flow reserve (CFR) measured immediately after reperfusion in predicting infarct size.
Methods: We studied 73 patients (pts) with a first anterior wall myocardial infarction who underwent primary coronary angioplasty successfully. By using a Doppler guidewire, CFR was assessed immediately after primary coronary angioplasty. The patients were divided into two groups: diabetic group (n=19) and non-diabetic group (n=54). We used peak CPK and left ventricular ejection fraction (LVEF) at 2-3 weeks follow-up as markers of infarct size.
Results: By regression analysis, CFR significantly correlated to peak CPK and LVEF in non-diabetic pts (r= -0.52 and r=0.50, respectively, p<.001), whereas there was no correlation in diabetic pts (r= -0.36 and r=0.06, respectively, p=NS).



CFR and infarct size in non-diabetic pts.

Conclusion: CFR measured immediately after reperfusion can predict infarct size in pts with non-diabetic anterior AMI.

P474 Coronary artery fistulas in adults: blood flow pattern and effect on myocardial perfusion

K.E. Vardakis[1], G.E. Kochiadakis[1], E.N. Simantirakis[1], N.E. Igoumenidis[1], E.I. Skalidis[1], M.I. Hamilos[1], P.E. Vardas[2]. [1]*Heraklion University Hospital, Cardiology Dept., Heraklion, Crete, Greece;* [2]*Heraklion University Hospital, Cardiology, Heraklion, Greece*

Background: Congenital fistulae are the most common coronary arterial malformation and are being recognized with increased frequency with the widespread use of selective arteriography.
In this study we assess for first time the effect of these malformations on coronary circulation and myocardial perfusion in adults.
Methods: Of the 830 patients who underwent diagnostic catheterization in our laboratory, 11 (1.3%) had coronary artery fistulas. All of them performed exercise stress myocardial perfusion scintigraphy. In 6 patients, whose fistulas had diameters greater than 2mm, we placed a 0.014" Doppler guidewire a) at the vessel where the fistulae was originated from and b) into the fistula itself to estimate coronary blood flow. Volumetric flow was calculated as the product of flow velocity integral (systolic, diastolic or total by the estimation of respective flows), heart rate and cross-sectional area (CSA) of the vessel at the tip of the wire.
Results: Seven fistulas originated from the right, 3 from the circumflex and 1 from the left anterior descending coronary artery. None of these vessels had coronary artery disease. The mean ratio of pulmonary to systemic flow was 1.12±1.55 and both right and left heart chambers pressures were within normal range. No one of the patients had a thallium myocardial scintigraphy with evidence of a perfusion defect at the region supplied by the vessel where fistulae originated from. In all cases, the flow through the fistula occurred mainly during systole [diastolic to systolic flow ratio (DSFR): 0.3±0.2] while the flow in the vessel where the fistulae originated from was mainly during the diastolic phase of the cardiac cycle (DSFR: 3.2±0.5).
Conclusions: Coronary artery fistulas do not seem to impair myocardial perfusion in adults, confirming the view of their good prognosis. The main reason seems to be that the blood flow through the fistula occurred mainly during the systolic phase of the cardiac cycle, minimally affecting coronary perfusion, which takes place during diastole.

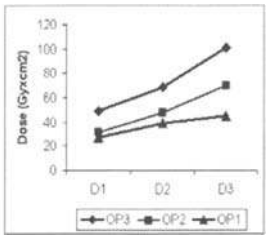
P475 X-ray exposure during coronary angiography: importance of lowering RX emission protocols

O. Bar, D. Blanchard, S. Chassaing. *Clinique Saint-Gatien, Tours, France*

Radiation dose received by the patient during invasive cardiology procedures is multifactorial, depending on the duration of procedures, body surface area and application of X-Ray rules (frames/sec, fluoroscopy dose, cine dose, collimation, intensifier-patient distance, field size), and is cumulative.

In order to evaluate the influence of different X-Ray protocols on patient radiation, we analyzed 2488 consecutive patients (mean age: 65.8 years, 75% males) for whom a diagnostic coronary angiogram was performed by 3 high-volume operators (OP1,OP2,OP3). For each patient, body surface area (BSA), total X-Ray dose (analyzed by Diamentor®), radiation time, type of fluoro (low, medium or high), type of cine dose (A,B,C,D from the lowest to the highest), cine frame rate (8 or 12.5 frames/sec), were collected.X-Ray protocols were significantly different between the 3 operators, leading to significant differences in radiation doses.In order to avoid the influence of radiation time, patients were equally divided into 3 equal groups according to the radiation time (D1: <171 sec; D2: 172-290 sec, D3 >290 sec). BSA was not different between the 3 groups and between operators, but a significant difference in total X-Ray doses was observed between operators for each duration; the shorter procedures performed by OP3 were as irradiating as the longer procedures performed by OP1.

	OP1	OP2	OP3
% 8 fr/sec	64.0%	31.6%	24.6%
% low fluo	91.5%	39.8%	62.6%
% cine A/B	41.9%	33.3%	38.6%
Dose (Gyxcm2)	33+-24	64+-40	64+-41



Protocols and dose.

Conclusion: lowering frame rate and lowering X-Ray emission can dramatically decrease X-Ray exposure for the patient, independently of body mass area and of duration of X-Ray exposure. As this strategy has no consequence for the accuracy of the diagnosis, operators should be encouraged to change their protocol in order to reduce radiation as low as possible, especially in longer procedures.

P476 Appropriatness of invasive coronary investigation: a prospective single centre analysis on 875 consecutive patients

G. Pedrazzini, M. Moccetti, M. Fleisch, A. Maggioni, E. Pasotti, T. Moccetti. *Cardiocentroticino, Cardiology, Lugano, Switzerland*

Evaluations of the appropriatness of medical care are important to monitor the quality of care and to contain costs and enhance safety by reducing inappropriate care. Investigators at RAND have developed a specific method for clinical experts to rate the appropriatness of medical care. It consists of a panel of physicians who, following medical guidelines in the different fields to evaluate, use a scoring system to classify the procedures into three categories: appropriate, uncertain and inappropriate. Following the RAND appropriatness method, criteria were developed for the appropriate use of coronary angiograms and coronary revascularisation procedures (PCI=percutaneous coronary intervention, CABG = coronary artery bypass graft)in Switzerland. Based on the Swiss RAND criteria a system prototype has been implemented on the basis of Internet/database technology. The SOS (second opinion system) allows to compare one's own results with an Internet panel. By connecting our computerized database with the Swiss SOS we were able to evaluate in a prospective manner the appropriatness of our diagnostic and therapeutic procedures. We report the first 6 months analysis performed at our institution from January to June 2001 over 875 consecutive angiograms and 442 revascularisation interventions (292 PCI and 150 CABG). The results are summarized in the table and divided, following the RAND recommendations into the three categories: appropriate, uncertain and inappropriate

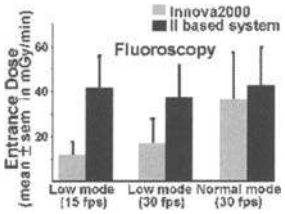
	Appropriatness		
	Angiograms N (%)	PCI N (%)	CABG N (%)
Appropriate	727 (85)	281 (96)	149 (98)
Uncertain	107 (12)	11 (4)	1 (2)
Inappropriate	41 (5)	0	0
Total	875 (100)	292 (100)	150 (100)

Conclusions: 1. Internet decision-making tools for indications and therapeutical decisions may be a valuable tools in medical quality management and represents an interesting method to evaluate the on line appropriatness for invasive procedures.
2. Our analysis contains several intrinsic and procedurale bias and the results, although very convincing, must be interpreted very carefully

P477 Radiation dose reduction with digital flat panel cardiac x-ray imaging

S.V. Raman[1], L. Niklason[2], K. Benali[2], C.A. Bush[1]. [1]*Heart & Lung Research Institute, The OSU Heart Center, Columbus, Ohio, United States of America;* [2]*GE Medical Systems, Buc, France*

Background: The growing use of coronary angiography and percutaneous interventions highlights the importance of minimizing radiation exposure to patients undergoing cardiovascular x-ray angiographic procedures. Excess radiation doses may produce significant acute and late effects, ranging from cutaneous manifestations to carcinogenesis. Fully digital cardiovascular x-ray imaging systems have recently been developed using flat panel detector technology (DFP); the theoretical reduction in dose afforded by this technology has not been largely documented in comparison with a traditional image intensifier (II) system.
Methods: Entrance dose measurements were made using a DFP cardiac system (Innova 2000, GE) and a non-GE II-based system. For each system, the dose was measured using an ionization chamber for 10, 15, 20, 25 and 30 cm of Plexiglas with the center of the Plexiglas phantom maintained at the isocenter of the image system gantry. Dose measurements were made for each system in all dose modes available for both fluoroscopy and record modes, for all frame rates available, and for each magnification mode. Entrance dose measurements are corrected to the entrance surface of the phantom and include backscatter.
Results: On fluoroscopy mode, the DFP system compared favorably to the II based system for each dose settings, i.e 15 and 30 frames per second (fps), in "Low" and "Normal" modes (table 1). Similar results were obtained on record mode at both 15 and 30 fps. On average, the DFP system resulted in significantly lower entrance exposure dose compared with the II system.



Conclusion: This study demonstrates that the DFP based cardiac system has the potential to significantly decrease radiation exposure during fluoroscopy and cine angiography.

P478 Is gridless angiography a dose-saving alternative on a Digital Flat Panel cardiac system?

J. Partridge[1], A. Lowe[2], C. Casey[2], K. Benali[2]. [1]*Harefield Hospital NHS Trust, Dpt of Radiology, Harefield, United Kingdom;* [2]*GE Medical Systems, Buc, France*

Background: The anti-scatter grid is widely used in general X-ray imaging techniques. Its primary purpose is to reduce secondary radiation and improve contrast in the image. However, the use of a grid results in much more radiation being delivered to the patient. This study seeks to evaluate whether the removal of the grid on the newly introduced Digital Flat Panel (DFP) system could be an alternative for a daily routine practice.
Methods: Thirty three randomly selected patients underwent an angioplasty procedure with a fixed grid whilst 35 patients underwent an angioplasty procedure after the grid had been removed from the system and replaced by the air-gap technique. All procedures were performed on a DFP cardiac system (Innova 2000, GE). For each patient sex, BMI, fluoroscopy and record times as well as X-ray dose (expressed as Dose Area Product: DAP) were monitored. Three experienced cardiologists were asked to rate the image quality (IQ) on an 11-point scale (1=Excellent; 6=Satisfactory; 11=Poor IQ).
Results: The group "With Grid" was comparable to the one "Without Grid" in terms of sex, BMI, fluoroscopy and record times. However, a significantly lower dose was delivered to patients undergoing procedures without a grid in comparison to those procedures with a grid (table). The relative dose saving was 31.6% after grid removal (on log-transformed data). Even though the IQ was rated as slightly better for the "With Grid" group (p=0.04), images without the grid were rated as significantly better than a satisfactory IQ (p=0.01).

	"With Grid" (n=33) Mean±SD	"Without Grid" (n=35) Mean±SD	p-value	
Sex (M/F)	27/6	26/9	0.5	NS
BMI (kg/m^2)	27.7±3.2	26.7±3.7	0.3	NS
Fluoroscopy time (min)	7.9±5.2	7.3±6.0	0.3	NS
Record time (sec)	45.4±26.9	38.5±20.2	0.3	NS
DAP (cGy cm^2)	5177.6±3223	3735.5±2848	0.01	S
Image quality	4.11±0.9	5.12±1.1	0.04	S

Conclusion: This study demonstrates that the removal of the grid on a DFP cardiac system has the potential to significantly decrease the radiation dose to the patient with an image quality that is more than satisfactory.

P479 Should follow-up angiography be routine in asymptomatic patients after stenting of unprotected left main coronary stenosis?

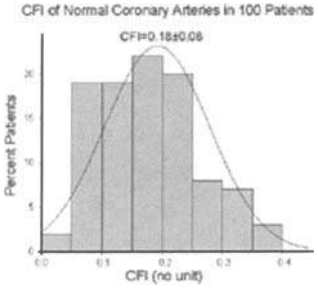
S.K. Sharma, A. Kini, C.A. Mitre, M. Kim, M. Kamran, J.D. Marmur. *The Mount Sinai Medical Center, Cardiology Dept., New York NY, United States of America*

Background: Selected patients with unprotected left main coronary artery (ULMCA) stenosis can safely undergo stenting. Clinical restenosis after stenting of ULMCA occurs in 8-15%. Earlier studies predominantly utilizing non-stent devices revealed approximately 10% incidence of death at follow-up, perhaps due to rapidly progressive restenosis. This led to the recommendation of routine angiography at 3-4 months after ULMCA intervention. However, its practical utility after ULMCA stenting is controversial. We present complete one-year follow-up of first 120 consecutive high-risk cases of ULMCA stenting deemed unsuitable for CABG.
Methods: Baseline: mean age 82±6 yrs, female 42%, mean LVEF 31±14%, GP inhibitors in 76%, and elective IABP in 34%. Stenosis location: ostium in 25%, body/distal in 60%, and bifurcation in 15%. All patients underwent stenting, 89% after rotablation.
Results: Procedure was successful in all patients without any major in-hospital complications. Vascular complications occurred in 3%. Mean reference vessel diameter was 3.81±0.81 mm, MLD pre-procedure 1.12±0.36 mm and post-procedure 3.67±0.52 mm. CK-MB elevation occurred in 21%, with >5x normal in 4%. All patients were discharged alive at a mean duration of 6±5 days. At one-year follow-up there have been 16 deaths: 8 cardiac (4 CHF, 2 MI, 1 arrhythmia, 1 stent thrombosis), 8 non-cardiac (3 CVA, 3 pneumonia, 1 hyperkaliemia, 1 neoplasm). A total of 14 patients (12%) required repeat intervention for recurrence of angina, heart failure, or positive non-invasive testing. On multivariate analysis, bifurcation lesion intervention (OR 4.2; 95% CI 2.2-6.8) and diabetes (OR 2.4; 95% CI 1.8-3.2) were independent predictors of restenosis. No patients underwent CABG or had sudden death at follow-up. Protocol mandated angiography was done in 42 asymptomatic patients and none had >70% stenosis of LMCA.
Conclusion: Present prospective careful observation suggests that ULMCA in-stent restenosis always manifests clinically. Extremely low incidence of sudden death at follow-up may obviate the need of routine follow-up angiography in these high-risk ULMCA patients. Whether this observation can be generalized to all ULMCA stent patients needs to be determined.

P480 Is there collateral flow in normal coronary arteries?

K. Wustmann, S. Zbinden, F.R. Eberli, B. Meier, C. Seiler. *Inselspital Bern, Swiss Cardiovascular Centre, Bern, Switzerland*

Background: Pathologic studies in the past hundred years have described the human coronary circulation to be with or without anastomoses between different vascular regions. In time of first experiences in therapeutic arteriogenesis in the human coronary circulation, it is unknown if there is collateral flow via pre-existing anastomoses in vivo among patients (pts) with angiographically normal coronary arteries.
Methods: In 100 pts collateral flow index (CFI, no unit) was measured in coronary arteries without any stenoses. CFI was determined by simultaneous measurement of mean aortic pressure, central venous pressure and coronary wedge pressure via sensor-tipped guidewire at the end of 1-minute occlusion. Patients were subdivided into two groups according to angiographically determined absence (51 pts) or presence (49 pts) of stenotic lesions in vessels other than that undergoing collateral measurement.
Results: CFI in 100 pts (61 ± 10 years, men/women 69/31) averaged 0.18±0.08 in a normal gaussian pattern, figure. In the two groups differences in CFI (0.19 ± 0.10 vs. 0.17 ±0.07), absence of angina (13/51 vs. 13/49) and pathological intracoronary ECG-changes during measurement (10/51 vs. 7/49) were not significant (ns). CFI in the recipient vessels LAD/LCX/RCA was 0.17 ± 0.08/0.19 ± 0.09/0.17 ± 0.08 (ns).



Conclusions: These findings suggest, that there is flow in preexisting collaterals even in pts with angiographical entirely normal coronary arteries. This is in contradiction to common knowledge indicating that coronary anastomoses develop de novo in a myocardial area jeopardized by ischemia.

P481 Collateral pathway anatomy and collateral function: a new angiographic grading validated by invasive measurement of collateral function

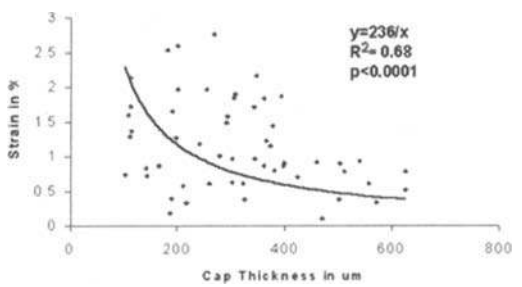
G.S. Werner, R. Surber, S. Heinke, B.M. Richartz, M. Ferrari, H.R. Figulla.
Friedrich-Schiller-University, Klinik Innere Medizin III, Jena, Germany

Background: A valid angiographic characterization of collaterals would be of clinical relevance for the evaluation of new therapeutic modalities to induce collateral growth. These semiquantitative angiographic gradings require a validation through invasive parameters of collateral function.
Methods and Results: In 78 patients with total chronic occlusion (TCO) of a major coronary artery (duration>2 weeks) collaterals were assessed angiographically according to their anatomical location, the apparent size of the visible collateral connection (grade 0 no continuous connection, 1 fathom-like continuous connection, 2 side-branch-like connection), and the criteria of recipient segment filling (Rentrop grading). Collateral function was quantitatively assessed by simultaneous Doppler flow (average peak velocity APV) and coronary pressure (PD) recording distal to the occlusion before recanalization. A collateral resistance index (RColl) was calculated. After antegrade flow was restored for at least 30 minutes recruitable collateral flow was measured during a final balloon inflation. There was no difference in RColl with respect to the anatomical location. Rentrop grade 3 filling was associated with a lower RColl than grade 2 (5.79±2.21 vs. 9.66±6.47 mmHg/cm/s; p=0.011). The 3 collateral connection grades could discriminate collaterals with distinctly different collateral function (0: 14.71±7.27; 1: 7.75±4.42; 2: 5.07±2.22 mmHg/cm/s; p<0.001). Also the recruitable collateral function was better preserved in collateral connections of grade 2 with a lower RColl (0: 34.33±20.41; 1: 18.78±12.08; 2: 8.96±5.16 mmHg/cm/s; p<0.001).
Conclusions: The collateral size, and not the anatomical location, is the best predictor of collateral function. Side-branch like sized collaterals are also those which remain immediately recruitable after recanalization of a TCO, whereas smaller collaterals may not provide protection during acute reocclusion.

P482 Intravascular elastography detects the weak vulnerable plaque

J A. Schaar[1], C.L. de Korte[1], F. Mastik[1], C. Strijder[2], G. Pasterkamp[3], R.A. Baldewsing[1], P.W. Serruys[1], A.F.W. van der Steen[1]. [1]*Erasmus University, Thoraxcenter, Department of Cardiology, Rotterdam, Netherlands;* [2]*Institute of the Netherlands, Department of Interuniversity Cardiology, Utrecht, Netherlands;* [3]*University Medical Center, Department of Cardiology, Utrecht, Netherlands*

The cap of a vulnerable plaque is the weakest link, which can rupture due to increased strain. Intravascular elastography is a new technique to measure local strain in a plaque. Finite element modeling of cap thickness related to stress showed an inverse relationship between these components. Since stress and strain are closely related, a relationship between strain and cap thickness should exist.
Methods: Coronary artery specimens, collected after autopsy, were evaluated for their morphological properties in a water-tank at different intraluminal pressures (80 and 100 mm Hg)with standard intravascular ultrasound catheters and an elastographic workstation.
Selected segments were stained on the presence of collagen and fat, smooth muscle cells and macrophages. In histology a vulnerable plaque was defined as plaque with a thin cap with moderate/heavy macrophage infiltration and a plaque that consisted for at least 40% of atheroma. In elastography, vulnerable plaque was defined as a high strain region on the surface of the plaque with an adjacent low strain region.
Results: In 24 diseased coronary arteries, we studied 54 crossections. 23 vulnerable plaques and 31 non-vulnerable plaques were found in histology. The relation between cap thickness and strain is inverse. A curve estimation, based on finite element modeling, showed a R^2=0.68 with a p <0.0001 (see fig). It should be notified that a cap > 400 μm results in a strain < 1%, while the data are more scattered for lower cap thickness.



Relation strain vs. cap thickness.

Conclusion: Intravascular elastography detects high strain regions in vulnerable plaques, which correlate with the thickness of the cap of plaques. This is the in vitro proof of a former described finite element model on human coronary vessels.

P483 What is the pathophysiological significance of myocardial bridging in patients with chest pain but normal coronary arteries?

H. Teragawa, K. Matsuda, Y. Fukuda, K. Ueda, H. Hirao, T. Yamagata, H. Matsuura, K. Chayama. *Hiroshima Univ. School of Medicine, First dept. of Internal Medicine, Hiroshima, Japan*

Background: Myocardial bridging (MB) is occasionally observed by coronary angiography in patients with chest pain despite having normal coronary arteries. However, the pathophysiological significance of MB is unclear. Therefore, we investigated whether the occurrence of MB was associated with any clinical or angiographic parameters, in such patients. Methods: One hundred fourteen patients with chest pain despite having normal coronary arteries were evaluated. On echocardiography, the left ventricular mass index (LVMI) was calculated according to the formula of Devereux and Reichek, and left ventricular hypertrophy was defined as on LVMI >110 g/m^2 for women and >134 g/m^2 for men. On coronary angiography, a spasm-provocation test was performed by infusing acetylcholine into the left coronary artery. The test result was defined as positive when the diameter of the coronary artery decreased by 50% and ST segment changes were documented. MB was defined as a >15% reduction in coronary arterial diameter during systole after intracoronary injection of nitroglycerin. The patients were divided into two groups based on whether MB was present (Group I) or not (Group II). Results: MB was observed in 41 patients (36%) (Group I) and was located at the mid-segment of the left anterior descending coronary artery in all of them. The percentage of men was greater (Group I 78% vs. Group II 45%: p = 0.0007) and the body mass index was smaller (Group I 23.6±0.3 vs. Group II 25.1±0.4: p = 0.0169) in Group I than in Group II. LVH tended to be less common in Group I (29% vs. 47% in Group II: p = 0.0707). Coronary spasm was induced more frequently in Group I (30/41, 73%) than in Group II (29/73, 40%) (p = 0.0006). Multivariate regression analysis using these factors demonstrated that a positive spasm-provocation test (p = 0.0035) and male gender (p = 0.0037) were associated with the presence of MB
Conclusions: These results suggest that MB correlates with a positive spasm-provocation test, independently of gender difference, in patients with chest pain despite having normal coronary arteries. Thus, MB may increase the risk of coronary spasm in such patients.

P484 Haemodynamic effects of aqueous nitric oxide solutions applied directly into human coronary circulation

M. Kelm[1], J. Rath[1], P. Kleinbongard[1], T. Rassaf[2], M. Preik[1], B E. Strauer[1]. [1]*Universitätsklinikum Düsseldorf, Kardiologie, Pneumologie, Angiologie, Düsseldorf, Germany;* [2]*LSU Health Sciences Center, Dep. of Molecular and Cellular Physiol, Shreveport, United States of America*

In saline perfused isolated heart models nitric oxide (NO) has been shown to dilate vessels and to inhibit platelet function, both effects highly desirable during percutaneous intervention (PCI) in patients with coronary artery disease (CAD). Whether or not NO applied directly into human coronary circulation exerts biological effects is unknown so far. Therefore, the aims of our study were: (i) to develop a method for reproducible production of sterile solutions containing authentic NO, (ii) to find a save mode of intracoronary (ic.) application, and (iii) and to characterize potential dilatory effects in conduit and resistance coronary arteries. Methods: Changes in coronary blood flow (CBF) were quantified by quantitative coronary angiography (QCA) and intracoronary Doppler guide wires (ICD) in 13 patients without flow limiting CAD after application of either saline controls, aqueous NO solutions (NO,1 – 6 μmol), adenosin (ADO, 2.4mg/min) or isosorbiddinitrate (ISDN, 0.3 mg) in random order. Results: NO dilated epicardial arteries in a dose-dependent manner up to 10+1%, equivalent to that seen upon ISDN. In parallel average peak velocity (APV) increased from 21 to 51+4 cm/s. Thus NO dilated coronary microvasculature to almost the same degree as seen after infusion of adenosine, whereas ISDN increased APV only slightly. Consequently, coronary blood flow increased according to the following rank order: NO and ADO > ISDN, whereas saline controls were without effect. Surprisingly, NO induced increases in CBF lasted much longer than expected from its biochemical life span in human blood. Systemic parameters such as heart rate or blood pressure remained unaffected after ic. application of aqueous NO solutions. Conclusions: Aqueous NO solutions can be applied directly into human coronary circulation and dilate uniformly epicardial and resistance arteries increasing coronary blood flow severalfold. These findings offers the avenue to selectively increase local NO stores within the coronary circulation without exerting systemic side effects, representing a new and attractive approach during percutaneous coronary interventions in patients with CAD.

P485 Impaired dilator response to atrial natriuretic peptide of coronary resistance vessel in patients with hyperinsulinaemia

T. Ashikaga[1], M. Nishizaki[2], M. Arita[2], N. Yamawake[2], H. Fujii[2], M. Hiraoka[3], Y. Kishi[4], M. Isobe[4]. [1]Kanagawa-ken, Japan; [2]Yokohama Minami Kyosai hospital, Department of Cardiology, Kanagawa-ken, Japan; [3]Tokyo Medical and Dental University, Department of Cardiovascular Diseases, Tokyo, Japan; [4]Tokyo Medical and Dental University, Department of Cardiology, Tokyo, Japan

Background: Hyperinsulinemia (HI) was suggested as one of risk factors in coronary artery disease. We investigated whether functional abnormality exists in coronary reactivity in HI without any significant coronary stenosis.
Methods: We performed 75g oral glucose tolerance test (OGTT) and coronary flow study in 32 patients with angiographically normal coronary arteries. Epicardial artery vasoactivity to acetylcholine was used to assess endothelial function. Coronary blood flow responses were evaluated by intracoronary Doppler flow velocity recordings and quantitative angiography. HI was diagnosed as a fasting serum concentration exceeding 20mU/L or as a peak serum concentration exceeding 150mU/L during the OGTT. 50ug of adenosine triphosphate (ATP), 1mg of isosorbide dinitrate (ISDN) and 0.05mg/kg of atrial natriuretic peptide (ANP) were intracoronary administered in the middle segment of left anterior descending coronary artery in patients with HI (N=10, 57± 8yrs, 5 males) and normoinsulinemia (NI) (N=22, 61±7yrs, 16 males).
Results: Arterial blood pressure was not changed during the study. Epicardial artery vasoactivity to acetylcholine was reduced in HI, but statistically not significant. Resting average peak velocity (APV) and coronary flow reserve with ATP (13.6±3.8 cm/s, 3.1±0.9) were similar to HI group (12.5±2.2cm/s, 3.3±0.4). In NI group, APV with ISDN (37.6±8.7cm/s) and ANP (36.3±9.7cm/s) were similar. In contrast, APV with ANP (27.6±10.2cm/s, $p<0.001$) was significantly blunted compared to ISDN (40.0±10.5cm/s) in HI group. Epicardial artery vasoactivity to ISDN and ANP did not differ between the two groups.
Conclusion: These results indicate the impaired dilator response to ANP not ISDN on coronary resistance vessel in HI. ANP receptor may be impaired even in the stage of mild endothelial dysfunction in HI.

CONGENITAL HEART DISEASE IN GROWN UP

P486 Pulmonary artery root dilatation in Marfan syndrome: quantative assessment of an unknown criterion

G.J. Nollen[1], K.E. van Schijndel[2], J. Timmermans[3], M. Groenink[1], J.O. Barentsz[4], E.E. van der Wall[5], J. Stoker[6], B.J.M Mulder[1]. [1]Academic Medical Center, Cardiology Dept., Amsterdam, Netherlands; [2]Academic Medical Center, Cardiology Dept., Amsterdam, Netherlands; [3]University Medical Center St Radboud, Cardiology, Nijmegen, Netherlands; [4]University Medical Center St Radboud, Radiology, Nijmegen, Netherlands; [5]Leiden University Medical Center, Cardiology Dept., Leiden, Netherlands; [6]Academic Medical Center, Radiology Dept., Amsterdam, Netherlands

Background: Dilatation of the main pulmonary artery is one of the established criteria for the diagnosis of Marfan syndrome. However, the prevalence and prognosis of pulmonary artery dilatation in Marfan syndrome is still unknown. Purpose of this study was to assess main pulmonary artery dimensions in normal subjects and in patients with Marfan syndrome.
Methods: Fifty Marfan patients (mean age 33 (10) years, 34 men, 16 women) and 15 matched control subjects (mean age 28 (4) years, 9 men, 6 women) underwent cardiac magnetic resonance imaging. Pulmonary artery dimensions were obtained on axial spin echo images at two different levels: 1) the level of the pulmonary artery root, and 2) the level of the pulmonary artery bifurcation.
Results: Upper limits of normal (mean + 2 SD) at the pulmonary root and at the pulmonary artery bifurcation were 34.8 mm and 28.0 mm, respectively. Pulmonary artery dilatation was demonstrated in 37 (74%, root) and 38 (76%, bifurcation) of the 50 Marfan patients. There was a good correlation between pulmonary and aortic root diameter in non-operated Marfan patients ($r=0.76$). Dimensions of pulmonary root were larger (38.4 mm, range 28.3 - 50.7 mm) than dimensions at the pulmonary bifurcation (30.7 mm, range 21.4 - 38.5 mm, $p<0.001$). Marfan patients with aortic root replacement (n=35, root 39.7 mm, bifurcation 31.7 mm,) had significantly larger pulmonary artery dimensions than non-operated Marfan patients (n=15, root 35.5 mm, bifurcation 28.5 mm, $p<0.01$).
Conclusion: In the majority of Marfan patients the main pulmonary artery, particularly the pulmonary root, was dilated. Pulmonary artery dimensions were significantly larger in Marfan patients with aortic root replacement than in non-operated Marfan patients. These findings suggest that dilatation of the pulmonary root increases with progressive involvement of the cardiovascular system in Marfan patients. Although, until now, main pulmonary artery aneurysm and dissection are rare, they may become of more clinical relevance in the near future because of increased longevity in Marfan patients.

P487 Pregnancy among women with ASD: objective versus subjective quality of life

J. Roos-Hesselink[1], E.H.M van Rijen[2], A.E. van den Bosch[3], E.M.W Utens[2], F.J. Meijboom[3]. [1]Academic hospital Dijkzigt, cardiologie, BA 308, Rotterdam, Netherlands; [2]Erasmus Medical Centre, Child Psychiatry, Rotterdam, Netherlands; [3]Erasmus Medical Centre, Cardiology, Rotterdam, Netherlands

Background: The long-term outcome after surgical ASD closure in childhood studied in our "Rotterdam Quality of life" study is excellent. There are no cardiac-related deaths and we found a very low morbidity after long-term follow-up. As the female patient enters adulthood, questions arise on the different aspects of pregnancy.
Aim: The purpose of this study is to analyse pregnancy data of women with ASD closure compared to the normal Dutch population.
Methods: We investigated the long-term outcome (20-35 years) of a cohort of 90 consecutive patients operated in the period 1968-1980 in our centre, with ASD closure in childhood (< 15 years) with respect to pregnancy and psychological aspects concerning pregnancy and compared these results with the Dutch population.
Results: From the 53 female patients participating in the study, 27 patients had child(ren) (50.9%). In total there were 69 pregnancies, which resulted in the birth of 50 children, 18 miscarriages and 1 abortion. One child was born with congenital heart disease (ASD). Pregnancy data of the normal Dutch population is derived from the Central Bureau for Statistics (CBS). In table 1, percentages of first successful pregnancy are shown for both female ASD patients and the Dutch female population.

Age (yr.)	<24	25-29	30-34	>35	Total
ASD	3.8%	32.0%	15.1%	0%	50.9%
CBS	13.4%	30.4%	27.7%	8.5%	80%

Of the 26 female patients who had not had children, 14 (54%) had negative expectations for having children in the future. Of all female patients, 25% felt their heart defect to be a limiting factor in having children; the greatest concern was that their offspring also would have a congenital heart defect. Of the 37 male patients, only 35% had child(ren) until now.
Discussion: Only 50.9% of our female patients had children compared to 80% in the normal Dutch population ($p<0.0001$). Since the objective health is very good, psychological aspects may play an important role in this striking difference in occurrence of pregnancy, especially the fear for congenital defects in the offspring seems important and needs further attention. Conclusion: Although the survival and long-term physical outcome is excellent after surgical closure of ASD at young age, psychological barriers exist, resulting in significantly less pregnancies than expected.

P488 Mid-term follow-up of haemodynamic effects of pulmonary valve replacement in adults late after repair of tetralogy of Fallot

A. van Straten[1], H.W. Vliegen[2], A. de Roos[1], J. Ottenkamp[3], E.E Van der Wall[2], M.G. Hazekamp[4]. [1]Leiden University Medical Center, Radiology, C2-S, Leiden, Netherlands; [2]Leiden University Medical Center, Cardiology, Leiden, Netherlands; [3]Leiden University Medical Center, Pediatric Cardiology, Leiden, Netherlands; [4]Leiden University Medical Center, Cardiothoracic Surgery, Leiden, Netherlands

Background: Pulmonary regurgitation (PR) late after total correction for tetralogy of Fallot may lead to progressive right ventricular (RV) dilatation and an increased incidence of severe arrhythmias and sudden death. Pulmonary valve replacement (PVR) long after repair of Tetralogy of Fallot (TOF) leads to rapid improvement of RV function. Whether further improvement after 6 months from PVR occurs, is unknown. In this study, magnetic resonance imaging (MRI) was used to assess the effect of PVR on RV function and PR up to 18 months after PVR.
Methods and Results: Nineteen consecutive adult patients who underwent PVR in our institution between 1998 and 2001 were studied. Median age at initial repair was 5.0 ± 4.2 years (range 0.4 to 21.0) and median age at PVR was 29.2 ± 9.0 years (range 17.0 to 45.6). Cardiac MRI was performed 6.1 ± 3.4 months before and 7.9 ± 2.4 months and 13.8 ± 5.9 after PVR. Preoperative PR was 46% (range 25-64%). After PVR, 4 out of 19 patients (21%) showed mild residual PR. One year later, 6 out of 19 (32%) patients had mild PR. RV end-diastolic volume (RVEDV) decreased from 308 ± 99 ml to 206 ± 53 ml ($p<0.001$) to 193 ± 54 ml ($p=0.25$) and RV end-systolic volume (RVESV) decreased from 177 ± 70 ml to 113 ± 37 ml ($p<0.001$) to 103 ± 36 ml ($p=0.12$). RVEF increased slightly from 44 to 45 to 49% (not significant).
Conclusion: In adult patients late after total correction of TOF, improvement of right ventricular function is predominantly achieved in the first year after PVR.

P489 Right ventricular function before and after pulmonary valve replacement in adults late after repair of tetralogy of Fallot

A. van Straten[1], H.W. Vliegen[2], A. de Roos[1], J. Ottenkamp[3], E.E. Van der Wall[2], M.G. Hazekamp[4]. [1]*Leiden University Medical Center, Radiology, C2-S, Leiden, Netherlands;* [2]*Leiden University Medical Center, Cardiology, Leiden, Netherlands;* [3]*Leiden University Medical Center, Pediatric Cardiology, Leiden, Netherlands;* [4]*Leiden University Medical Center, Cardiothoracic Surgery, Leiden, Netherlands*

Background: Pulmonary regurgitation (PR) late after total correction for tetralogy of Fallot (TOF) may lead to progressive right ventricular (RV) dysfunction and an increased incidence of severe arrhythmias and sudden death. Timing of pulmonary valve replacement (PVR) is subject to discussion since the effect on RV function in adults is unclear.
Purpose: In this study, magnetic resonance imaging (MRI) was used to assess the effect of PVR on RV function and PR. Clinical improvement was established by means of the NYHA classification
Methods and Results: 26 Adult patients who underwent PVR in our institution between 1998 and 2001 were studied. Median age at initial repair was 5.0 ± 4.2 years (range 0.4 to 21.0) and median age at PVR was 29.2 ± 9.0 years (range 17.0 to 45.6). Cardiac MRI was performed at a median of 5.1 ± 3.4 months before and 7.4 ± 2.4 months after PVR. Mean preoperative PR was 46 ± 10% (range 25-64%). After PVR, 20 out of 26 patients (77%) showed no residual PR, one patient had moderate residual PR and 5 patients mild PR. RV end-diastolic volume (RVEDV) decreased from 305 ± 87 ml to 210 ± 62 ml ($p<0.001$) and RV end-systolic (RVESV) decreased from 181 ± 67 ml to 121 ± 58 ml ($p<0.001$). No significant change was found in RV ejection fraction (RVEF) (42 vs. 42%). We introduced a new method to correct RVEF for regurgitations and shunting (RVEFcor=pulmonary forward flow-pulmonary regurgitation (ml)/RVEDV). This parameter increased from 25.2 ± 8.0% to 43.3 ± 13.7% ($p<0.001$). Mean validity class increased from 2.0 to 1.3 ($p<0.001$).
Conclusion: In adult patients with PR and RV dilatation, late after total correction of TOF, RVESV decreased and RVEFcor increased dramatically, indicating an overall improvement of RV function. This is in accordance with our finding of improved validity. We therefore advocate a less restrictive management concerning PVR.

P490 QRS duration at rest predicts maximal exercise performance in adult patients with repaired tetralogy of Fallot

W. Budts[1], L. Vanhees[2], R. Fagard[1], F. Van de Werf[1]. [1]*UZ Leuven, Cardiology, Leuven, Belgium;* [2]*UZ Leuven, Cardiac Rehabilitation, Leuven, Belgium*

Background: A right bundle branch block (RBBB) is found in most of the patients with repaired tetralogy of Fallot (TF). When the QRS complex exceeds 180 ms or prolongs progressively over time, the incidence of sudden cardiac death increases. We wondered if QRS duration could predict maximal exercise capacity (Wmax, Watt) or maximal oxygen consumption (peak VO2, ml/min).
Methods: Thirty five TF patients with RBBB were examined. QRS duration on V1 (ms)was measured at rest. The right ventricular diameter in parasternal and apical short axis were measured by transthoracic echocardiography. Via color Doppler pulmonary and tricuspid regurgitation (scale 0-4/4) were quantified. Wmax and peak VO2 were obtained during a bicycle stress test (protocol: 20 Watt + 20 Watt/min). Cardiac output (CO, l/min) at rest and at 100 W were measured by CO2 rebreathing. Stroke volume (SV, ml) was calculated. Simple linear regression analysis was used to describe the correlation between QRS duration and Wmax, peak VO2, CO and SV. Multiple linear regression analysis was used to identify the continuous independent variables obtained by echocardiography and influencing the QRS duration. Kruskal Wallis test was performed to evaluate the relation of the nominal echocardiograhic variables on QRS duration. Statistical significance was defined as $P<0.05$.
Results: Thirty patients (25 male, 5 female; age 25±7 y, mean±SD) were selected; five patients could not pass the anaerobic threshold and were excluded. The right ventricular dimensions (parasternal and apical short axis) were 2.7±0.5 cm and 3.8±0.8 cm, respectively. QRS duration, Wmax and peak VO2 were 156±20 ms, 194±49 Watt and 2191±576 ml/min, respectively. QRS duration correlated with Wmax and peak VO2 ($R^2=0.35$ and $R^2=0.18$, respectively, $P<0,05$). The apical short axis diameter of the right ventricle was identified as a predictable variable of QRS duration. No significant correlation was found between the severity of pulmonary or tricuspid regurgitation and QRS duration. No significant correlations were found between CO at rest and at 100 W (4.6±1.6 and 16.6±3.7 l/min, respectively) and QRS duration. QRS duration and SV at 100 W (134±31 ml) were correlated positively ($R^2=0.55$, $P<0.05$).
Conclusions: Adult patients with repaired TF and RBBB have a reasonable exercise performance. QRS duration itself seems to be a strong predictor of maximal exercise capacity. We suggest that earlier activation of the left ventricle in repaired TF patients can result in maintenance of the exercise tolerance. Further investigation is planned to confirm this hypothesis.

P491 QRS-width longitudinally measured in congenital heart disease

J.W. Roos-Hesselink, F.J. Meijboom, S.E.C Spitaels, R. van Domburg, M.L. Simoons. *Erasmus Medical Centre, Cardiology, Rotterdam, Netherlands*

Background: ventricular arrhythmias play a major role in the morbidity and mortality of patients after surgical correction of congenital heart defects. From the literature it is known that QRS-width is a predictor for ventricular arrhythmias in patients with corrected tetralogy of Fallot. If this is true for other congenital defects is not known. Also the changes over time in the QRS-width may be an important factor in the prediction of these arrhythmias.
Methods: A cohort of 351 patients with diagnosis ASD, VSD, PS, tetralogy of Fallot and transposition of the great arteries is longitudinally studied. All patients were operated in childhood (<15 yr.) in our centre, between 1968 and 1980. Mean age at operation was 5 yr., with a mean follow-up of 26 yr. The QRS-width is measured in 1990 and in 2000.
Results: QRS-width changed from mean 101 (range 60-200) in 1990 to 113 (range 70-200) in 2000.In the tetralogy of Fallot group the increment was larger then in the other groups. Sustained ventricular tachyarrhythmias occurred in 5% between 1990 and 2000, also more in the tetralogy of Fallot group (see table).

	ASD	VSD	PS	TGA	ToF
Number of pts	91	95	37	51	77
QRS 1990 (msec)	88	100	94	95	121
QRS 2000 (msec)	97	113	108	110	137
QRS-increment	9	13	14	15	16
VT '90-2000(%)	4.4	2.1	2.7	7.8	9.1
Mort'90-2000(%)	1	4	3	4	3

Conclusion: QRS-width increases over time, but there were clear differences in the different diagnosis groups of patients with congenital heart disease. In the ASD-group the QRS-width-increment is significantly less, and in the tetralogy of Fallot patients the QRS-width-increment is more pronounced ($p=0.004$). A relation was found between QRS-width-increment and the occurrence of sustained ventricular tachyarrhythmias.

P492 Ventilatory response and pulmonary gas exchange at rest and during exercise in patients after the fontan operation

H. Ohuchi, H. Ohashi, J. Park, A. Miyazaki, Y. Ono, O. Yamada, S. Echigo. *National Cardiovascular Center, Pediatrics, Osaka, Japan*

Background: Although abnormal pulmonary circulation, lung function and respiratory response during exercise are well known characteristics in Fontan patients, the relationships between these impaired functions have not been well established.
Methods and Results: Pulmonary function and cardiopulmonary exercise tests were performed in 95 Fontan patients (mean age = 13.6 years, atriopulmonary connection in 29, total cavopulmonary connection in 66) and 44 controls. Vital capacity (VC) and diffusion capacity were significantly lower in Fontan patients than in controls. VC was associated with the number of surgical procedures and decreased significantly during follow-up, being significantly related to the higher frequency and smaller tidal volume (respiratory pattern) during exercise, while did not relate to the dead space ventilation (VD/VT), ventilatory equivalent for CO2 production (ventilatory efficiency) or peak oxygen uptake. Rest and exercise minute ventilation was accelerated and the VD/VT was higher during exercise in Fontan patients. Lower arterial saturation was related with accelerated ventilation, resulting lower resting PaCO2 and resting arterial gas tensions and alveolar ventilation to CO2 production ratio, not the types of repair or VC, determined PaO2 and PaCO2 dynamics during exercise. Fontan patients with left ventricular type had higher diffusion capacity, superior ventrilatory efficiency and peak oxygen uptake compared with those without.
Conclusions: After the Fontan operation, progressive restrictive ventilatory impairment determines the exercise respiratory pattern. Resting slight but significant hypoxia and high VD/VT during exercise have a great impact on accelerated ventilation. However, the ventricular morphology rather than the lung volume or respiratoty pattern have a greater impact on not only their exercise capacity but exercise ventilatory efficiency.

P493 Quality of life of long-term survivors after Fontan operation for tricuspid atresia: a national study

J. Ottenkamp[1], R. Wolff[1], J.L.M. Strengers[2], A.C. Cromme-Dijkhuis[3], T.M. Hoorntje[4], R. Tanke[5], M. Kamphuis[1,6]. [1]Pediatric Cardiologiy CAHAL, Amsterdam-Leiden, The Netherlands; [2]Groningen, The Netherlands; [3]Rotterdam, The Netherlands; [4]Utrecht, The Netherlands; [5]Nijmegen, The Netherlands; [6]TNO-Prevention and Health Leiden, The Netherlands

Introduction: between 1972 and 1990 86 patients with tricuspid atresia underwent Fontan surgery in The Netherlands. 20 Years survival is 66%. What are the consequences for daily life of the long-term survivors?
Aim of the study: to measure subjective health status and health related quality of life (HRQOL) as well as vocational situation late after surgery (follow-up at least 12 yrs).
Material and Methods: of the 86 patients 29 died and 2 were lost to follow-up. Of the remaining 55 (mean follow-up 20.5 yrs) 27 (15-44 yrs, mean 26.7 yrs, median 26 yrs, 15 male) participated in the study by returning completed SF-36 and TAAQOL (HRQOL with subjective view on physical, emotional, cognitive and psychosocial functioning) questionnaires.
Results: significant lower scores for SF 36 role functioning emotional ($p<0.05$) and physical functioning, role functioning physical, vitality, general health perceptions, social functioning, mental health (all $p<0.001$) were found. Also compared to norm values the TAAQOL showed only significant lower values for vitality ($p<0.05$) and gross motor functioning ($p<0.001$). 37% had a paid job, working more than 15 hrs per week. 41% had complete unemployment benefit.
Conclusion: long-term survivors of Fontan surgery experience a limited health status, but a satisfying subjective quality of life. Employment figures are disappointing. Improved counselling aiming at highest education possible is important and vocational guidance is mandatory.

P494 Cardiorespiratory function in patients with Eisenmenger syndrome

M. Westhoff-Bleck[1], C. Cecconi[1], I. Luhmer[2], J.S. Bleck[3], G.P. Meyer[1], H. Drexler[1]. [1]Medizinische Hochschule Hannover, Cardiology and Angiology, Hannover, Germany; [2]Medizinische Hochschule Hannover, Pediatric Cardiology, Hannover, Germany; [3]Medizinische Hochschule Hannover, Gastroenterologie, Hannover, Germany

Interpretation of cardiopulmonary exercise testing (CPET) in patients with secondary pulmonary hypertension still needs to be elucidated. We evaluated the influence of anemia, reduced ventricular function and pulmonary function on exercise tolerance.
Method: 21 Patients (P) (29.2±8.1 y, 13f, 8m) performed a progressively increasing work rate (WR) (10Watt/2min) CPET to maximum tolerance. Maximum oxygen uptake (PeakVO2), WR, ratio of O2 uptake toWR increase (DVO2/DWR), ventilatory efficiency (ventilationVE/VCO2; VE/ VO2) and minimal O2 saturation during exercise were calculated These parameters were correlated with mean corpuscular haemoglobin concentration (MCH) haemoglobin, haematocrit and with forced vital capacity (VC) and forced expiratory volume (FEV1).
Results: No adverse events occurred. 3 P with echocardiographically assessed severely reduced ventricular function had a significantly reduced PeakVO2 (10.1±1.1 vs 15±2.8ml/kg/min,p=0.018) and DVO2/DWR (20 Watt)(4.9 ±0.6 vs15.3±4.6mlO2/Watt; p=0.009).In P (n=5) with anemia (MCH<28pg) had a significantly reduced PeakVO2 (12.3±1.5 vs 15.1±3.2ml/kg/min,p=0.017), maximum WR (28.8±8 vs. 43.1±16.6 Watt; p=0.02) minimal saturation during exercise (62.8±6.8 vs. 74.1±12.7%: p=0.039). VE/VO2 was significantly increased (49.4±9.9 vs. 35.8±12;p=0.017) whereas DVO2/DWR (20Watt) was not significantly reduced. All P had a slightly reduced VC (67.2±16.7%) and normal FEV1 (72.7±12.7%). Both did not correlate with PeakVO2, WR, DVO2/DWR.
Conclusion: PeakVO2 is manly determined by ventricular function and anemia. DVO2/DWR (20Watt) may be helpful in differentiating both entities. Slightly to moderately reduced pulmonary function does not effect O2-uptake.

P495 Carotid and femoral intima-media thickness in adult patients succesfully operated for aortic coarctation

J.W.J. Vriend[1], E. De Groot[2], H.W. Vliegen[3], G. Veen[4], D. Samson[2], W.J. Stok[5], J.J.P. Kastelein[2], B.J.M. Mulder[1]. [1]Academic Medical Center, Cardiology, Amsterdam, Netherlands; [2]Academic Medical Center, Vascular Medicine, Amsterdam, Netherlands; [3]Leiden University Medical Center, Cardiology, Leiden, Netherlands; [4]Free University Medical Center, Cardiology, Amsterdam, Netherlands; [5]Academic Medical Center, Physiology, Amsterdam, Netherlands

Objectives: Structural changes and abnormal vascular reactivity persist in patients with aortic coarctation despite successful repair. This may be due to previous increased blood pressure in the pre-coarctatial arterial conduits and contributes to the increased late morbidity and mortality in post-coarctectomy patients. B-mode ultrasound imaging can describe status and changes in intima-media complex thickness (IMCT) of carotid and femoral arterial walls. Carotid and femoral IMTC was investigated in normotensive adult post-coarctectomy patients.
Methods: Carotid and femoral IMTC was measured in 26 normotensive (31.7(SD9.1)yrs) successfully operated post-coarctectomy patients. Mean age at operation was 9.5(range 0.8-22.1) years. Normotension was defined as a daytime mean systolic blood pressure under 140mmHg as registered on 24 hour ambulatory blood pressure monitoring. Patients were compared to 26 age and sex matched controls (33.9(9.9)years). A subject's IMTC was defined as the averaged measurements of three right, three left carotid, and two left and two right femoral arterial wall segments. In comparisons of the carotid and femoral arterial IMTC's between patients and controls, the averaged per subject IMTC measurements of each of the arterial conduits were used. Comparisons were done with unpaired Student t-tests.
Results: Overall IMTC of the normotensive post-coarctectomy patients (0.65(0.17)mm) was increased if compared to controls (IMTC=0.59(0.11) mm): DIMT=0.06mm, p=0.002. Carotid IMTC was 0.70(0.10)mm in patients and 0.60(0.09)mm in controls: DIMT= 0.14mm, $p<0.0001$; however the femoral IMTC's were similar: (0.56(0.10)mm in patients and 0.57(0.07)mm in controls: DIMT=0.01mm, p=0.64.
Conclusions: Normotensive, post-coarctectomy patients presented with increased carotid IMTC, where the femoral IMTC is similar to controls. It may be concluded that the vascular damage in post-coarctectomy patients is more apparent in the vascular bed proximal of the former aortic coarctation. This finding reflects the increased risk for cardiovascular and cerebral events in these patients. Moreover, the results illustrate the need to investigate multiple vascular beds according to a standardized protocol in order to describe mechanism of disease and improve disease prevention in those at vascular risk.

P496 Exercise-testing for the detection of hypertension in adult post-coarctectomy patients

J.W.J. Vriend[1], G.A. Montfrans van[2], H.W. Vliegen[3], G. Veen[4], B.J.M. Mulder[1]. [1]Academic Medical Center, Cardiology, Amsterdam, Netherlands; [2]Academic Medical Center, Internal Medicine, Amsterdam, Netherlands; [3]Leiden University Medical Center, Cardiology, Leiden, Netherlands; [4]Free University Medical Center, Cardiology, Amsterdam, Netherlands

Objective: Successfully operated aortic coarctation patients frequently show a marked systolic hypertensive blood pressure reaction at exercise. In view of this typical hemodynamic pattern, the question is warranted whether blood pressure in daily life is normal when office readings are low. We therefore determined whether exercise-testing in presumed normotensive adult patients after successful repair of aortic coarctation can predict hypertension at 24 hour blood pressure measurement.
Design and Methods: Seventy-three presumed normotensive, successfully repaired, adult post-coarctectomy patients (44 male; mean age 30, range 17-53 years; time after operation 22.9 years, SD 7.4) underwent a maximal, symptom limited treadmill exercise test (Bruce protocol). Blood pressure (BP) was measured every 3 minutes by conventional RRK. Daytime BP (7:00-23:00) was assessed by 24 hour ambulatory BP monitoring (Spacelabs 90207). Patients were considered hypertensive when day mean systolic BP was above 140 mmHg. A ROC-curve was constructed using maximal systolic BP during exercise as test variable.
Results: Seventeen patients (23%) had daytime hypertension. Analysis of the ROC-curve (area 0.789) revealed that in our patients a cut-off value of maximal systolic BP during exercise above 188 mmHg had the highest sensitivity (82%) and specificity (71%). Using day time BP above 135 mmHg as cut-off value, did not result in significant better test characteristics (area 0.806).
Conclusions: Hypertension is a common finding even in presumed normotensive and successfully corrected adult post-coarctectomy patients. Exercise-testing can predict hypertension in the absence of 24 hour ambulatory blood pressure measurement, however sensitivity and specificity are not very high. 24 hour ambulatory blood pressure measurement should be regularly performed for early detection of hypertension in these patients, who already are at high risk for cardiovascular complications.

P497 Left ventricular remodelling and mechanics after successful repair of aortic coarctation. Correlation with blood pressure on exercise and ambulatory blood pressure measurement

R. Crepaz[1], C.R. Cristina Romeo[2], E.B. Edoardo Bonsante[2], R.C. Roberto Cemin[2], P.K. Peter Knoll[2], W.P. Walter Pitscheider[2], D.T. Diego Trevisan[3]. *[1]Cardiology, Bolzano, Italy; [2]Regional Hospital Bolzano, Cardiology, Bolzano, Italy; [3]Regional Hopspital Bolzano, Biophysics, Bolzano, Italy*

A good surgical repair of aortic coarctation (AoCo) does not always protect from persistent systemic hypertension and left ventricular (LV) remodelling. In 52 normotensive patients (mean age 21.1 ± 10.5; range 2-40 years) followed up after a successful repair of AoCo (mean age at coarctectomy 11.8 ± 10 years), we evaluated the LV remodelling, endocardial and midwall mechanics by echo-Doppler, the trans-isthmic gradient and the systemic blood pressure at rest/exercise and during ambulatory blood pressure monitoring (ABPM), in order to identify factors that might predispose to persistent abnormalities. Cut-off levels for LV mass index (Mi) and relative wall thickness (RWT) were defined to assess LV geometry. The smallest diameter of the aorta was assessed by magnetic resonance imaging (MRI) and calculated as percent narrowing compared with the diameter of the aorta at the diaphragmatic level. The echocardiographic findings were compared with those of 142 controls (N).
In the AoCo group LV end-diastolic volume index (EDVi), Mi, M/V ratio were increased. The LV systolic chamber function estimated at endocardial (VCFc) and midwall (mwVCFc) level was increased. The LV contractility estimated at endocardial level was increased (Z-score > 95° percentile) in 13/52 (25%), whereas that at midwall remained elevated in 10/52 (21%) patients. Twenty-seven (52%) patients had normal LV geometry; among the other 25 with abnormal geometry, 4 (8%) had a pattern of concentric remodelling, 18 (34%) an eccentric hypertrophy and 3 (6%) a concentric hypertrophy. Compared with those with abnormal LV remodelling, the patients with normal LV geometry are younger, had earlier surgical repaired, have lower systolic blood pressure rest/exercise and during ABPM. Mi, M/V ratio and RWT showed a significant positive correlation with age, age at surgical repair, systolic blood pressure on rest/exercise and ABPM ($p < 0.01$). These parameters are predictive of abnormal LV remodelling by multivariate analysis. In conclusion normotensive patients after successful surgical repair of AoCo may have persistent abnormal LV geometry and a hyperdinamic state. These persistent abnormalities are more frequent in those who have undergone to late repair and who exhibit an elevated systolic blood pressure on rest/exercise and ABPM.

P498 Hypertrofic adaptation of the right ventricle seems important for exercise performance in mustard patients

H. Andersen[1], J.C. Nilsson[2], B.A. Groenning[2], B. Larsson[3], J.R. Jacobsen[1], L. Sondergaard[4]. *[1]H:S Rigshospitalet, Dept of Paediatrics, Copenhagen, Denmark; [2]H:S Hvidovre Hospital, Danish Research Centre of MRI, Copenhagen, Denmark; [3]H:S Bispebjerg Hospital, Team Danmark Test Center, Copenhagen, Denmark; [4]H:S Rigshospitalet, Dep. of Cardiology, Copenhagen, Denmark*

Background Previously, transposition of the great arteries (TGA) was treated by atrial switch procedures after which the right ventricle served the systemic circulation. Although patients who have undergone such interventions are generally considered asymptomatic, it is well established that their exercise performance is below normal values. It is uncertain, whether the ability of the right ventricle to adapt to the systemic blood pressure by myocardial hypertrophy influences exercise performance. The aim of the present study was to compare right ventricular myocardial mass (RVM) with maximal oxygen consumption (VO2max) in patients with TGA corrected by the Mustard procedure.
Patients and methods: Seventeen unselected patients (16 males and one female), age (median (range)) 19 (10 - 29) years, were examined 18 (9 - 25) years after Mustard's procedure for TGA (age at operation 14 (10 - 48) months). RVM was measured by magnetic resonance imaging using breath-hold cinematographic gradient-echo technique with the imaging plane in the true short axis of the right ventricle (slice thickness 6 mm, no inter-slice gaps, TR 55 msec). VO2max was determined by an individualized incremental bicycle ergometer test with continuous measurement of metabolites. Criteria for maximal exercise were exhaustion, VO2 plateau reached or VCO2/VO2 > 1.1.
Results RVM index was (mean (SD)(range)) 94.5 g/m^2 (16.9) (56.3 - 120) and VO2max was 1.90 l/min (0.73) (= 31.6 ml/min/kg (6.95)). Furthermore, we found a positive correlation between RVM index and VO2max ($r = 0.57$, $p = 0.02$).
Discussion In contrast to left-sided ventricular systolic dysfunction, where the degree of myocardial hypertrophy correlates with the severity of heart failure, this study indicates that increased RVM index after atrial switch procedures for TGA results in better ventricular function as measured by exercise performance. However, it is uncertain what causes the large range in RVM index in Mustard operated patients. One explanation could be the angiotensin-converting-enzyme genotype, which is known to be related to the degree of myocardial hypertrophy in other settings of increased ventricular workload.

EVALUATION OF THE RESULTS OF CARDIAC SURGERY

P499 Two-years clinical and angiographic follow-up after a traumatic coronary artery bypass

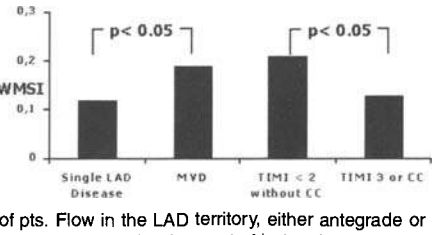
A. gerber[1], M. Cisowski[2], J. Drzewiecki[3], A. Jaklik[3], W. Kruczak[2], M. Trusz-Gluza[3], A. Bochenek[2]. *[1]Katowice, Poland; [2]Silesian University Medical School, Ist Department of Cardiosurgery, Katowice, Poland; [3]Silesian University School of Medicine, Ist Department of Cardiology, Katowice, Poland*

Atraumatic Direct Coronary Bypass (ACAB) is a challenging, quickly developing surgical technique, by which the internal mammary artery (LIMA) is harvested and anastamosed to the left anterior descending artery (LAD), resulting in a minimal cardiothoracic procedure, smaller number of in-hospital complications, and better patients outcome.
A total of 200 patients with anginal symptoms of CCS 2.7 ± 0.4, and significant LAD disease, who underwent coronary artery bypass grafting (with the use of thoracoscopically harvested LIMA) at the 1st Department of Cardiac Surgery since 1998, were included to prospective follow-up study.
Preliminary results comprise 79 patients, who underwent clinical and angiographic control(mean observation period was 1.5 year). Major adverse coronary events were observed in 5 patients (6.3%), and included: myocardial infarction (1 patient, 1.2%), aggravation of anginal status(4 patients, 5.0%). We noted one death due to disseminated neoplasmatic disease, no neurologic event was noted. An avarage patients anginal status was CCS I, ECG excercise test was negative in 64 patients (81%), positive in 13 patients (16.4%), 4 patients were not able to perform stress test due to sceleto-muscular disorders. Seventy eight patients (98%) stated their quality of life as very good and good. Angiographic control of LIMA-LAD graft anastamosis was performed in 72 patients (91%). Patency of grafts was evaluated with the use of Fitz-gibbon scale: 64 patients (88%) had full patency of the graft (score A), in 4 patients (5.5%) we found stenosis reducing distal anastamosis of the trunk more than 50% (score B), only 2 patients (2.7%) had totally occluded grafts (score 0), one was treated with PTCA of LAD. Coronary artery disease progression was observed in 14 patients (19.4%) who were treated with PTCA.
Conclusions: Excellent long term clinical and angiographic results can be achieved with ACAB technique. ACAB is safe and effective method of treatment in proximal LAD lesions, thus it may be the treatment of choice in patients with a high risk of stent restenosis. We believe, that with increasing surgery experience, ACAB approach will have a major impact on the management of coronary patient with type B or C lesion of LAD.

P500 Impact of left anterior descending flow and collateral circulation on myocardial ischaemia during minimally invasive coronary surgery

S. gallina, M. Zimarino, A.L. Iacò, G. Renda, G. Vitolla, R. De Caterina, A.M. Calafiore. *"G. D'Annunzio" University, Dept.of Cardiology and Cardiac Surgery, Chieti, Italy*

Background: Concern has been raised about the effects of ischemia following prolonged left anterior descending (LAD) coronary artery occlusion during minimally invasive direct coronary artery bypass surgery (MIDCAB). In order to evaluate the impact of collateral circulation (CC) and the extent of coronary artery disease on intraoperative ischemia, myocardial function was monitored by intraoperative transesophageal echocardiography.
Methods: Among 92 patients (pts) (80 males, median age 62, range 45-84 years) Wall Motion Score Index (WMSI) was calculated before (baseline), during occlusion and after LAD reopening.
Results: LAD occlusion lasted 22±6min. Contractile impairment began 3.6±2.6min after LAD occlusion. Recovery was documented 4.2±2.1min after reopening. WMSI increased from 1.34±0.32 to 1.48±0.36 ($p<0.001$) during LAD occlusion, and was reverted after LAD reopening (1.30±0.32, $p<0.001$ vs occlusion and p=NS vs baseline). One hour after LAD reopening, contractility was ameliorated in 10 pts (11%), unchanged in 53 pts (58%) and worsened in 28 pts (31%) compared with baseline findings. In all 28 pts with worsened post ventricular function, a 48 hours transthoracic echocardiography documented functional recovery. DWMSI (deterioration in WMSI occlusion over baseline) was related both to the extent of coronary artery disease (MVD=multivessel disease) and the status of coronary flow in the LAD and in CC (Figure 1).
Conclusions:
During MIDCAB with LAD occlusion, anterior wall dysfunction is transient with prompt recovery after completion of the anastomosis. However, myocardial stunning can be documented in a minority of pts. Flow in the LAD territory, either antegrade or retrograde, appears to protect against the development of ischemia.



P501 New evaluation for coronary artery bypass surgery using Doppler guide wire – effect of left internal thoracic artery graft

S. Ito[1], S.I Shin Ishimaru[1], H.S Hiroyuki Suesada[2], G.W Go Watanabe[3].
[1]Tokyo Medical University, Surgery, Tokyo, Japan; [2]Nishitokyo Central Genaral Hospital, Cardiology, Tokyo, Japan; [3]Kanazawa University, Surgery, Kanazawa, Japan

Back Ground: Now we can find a lot of reports about the effects of PTCA for native coronary arteries using a doppler guide wire. However there were no reports about coronary flow reserve(CFR) of native coronary artery before and after coronary artery bypass surgery (CABG). It was estimated only by angiography. The purpose of this study is to evaluate physiologically the efficacy of left thoracic artery (LITA) graft for left anterior descending artery (LAD) before and after CABG with a doppler flowire. Methods: Intracoronary flow verosity was measured at the distal to the target lesion of LAD before CABG and three weeks after operation phasic flow verosity recording were obtained in the native LAD using doppler guide wire in 22 patients who underwent LITA grafting to the LAD. The average peak verosity (APV) and CFR defined as the ratio of APV during hyperemia (10mg of intracoronary papaverine) versus APV at baseline were obtained during Flo Wire measurements. Results: All patients had an uneventful postoperative course. LITA graft had a good patency in 22 cases. CFR of LAD significantly increased from 1.61±0.54 to 2.53± 0.85 ($p<0.0001$) after operation. Only 6 cases we could measure CFR of LAD one year after CABG. It was significantly increased from 1.35 ± 0.47:befor CABG to 2.01±0.50:afterCABG and 2.50±0.96:one year after CABG.Conclusions: LITA graft significantly improved coronary flow reserve and may recover myocardial viability in early time after CABG. CFR measurement is useful to evaluate the efficacy of CABG except angiography.

P502 ^{123}I-MIBG SPECT scintigraphic evidence of cardiac denervation after transmyocardial laser revascularisation

R. Tukkie[1], M. Huikeshoven[2], H.J. Verberne[3], B.L.F. van Eck-Smit[3], J.A.P. van der Sloot[1], J. van der Meulen[4], M.J.C. van Gemert[2], J.F. Beek[2].
[1]Academic Medical Centre, Cardiology, Amsterdam, Netherlands; [2]Academic Medical Centre, Laser Centre, Amsterdam, Netherlands; [3]Academic Medical Centre, Nuclear Medicine, Amsterdam, Netherlands; [4]Academic Medical Centre, Cardiothoracic Surgery, Amsterdam, Netherlands

Transmyocardial laser revascularisation (TMLR) is an invasive therapy used to treat patients with severe refractory angina pectoris in whom standard reatment is insufficient or not possible. Randomised trials have reported a clear clinical benefit (relief of angina and improvement of QOL) of CO2 or Holmium:YAG TMLR compared to maximal medical treatment. Furthermore, initial results of a prospective randomised trial performed by our group also show a reduction in angina and improvement of quality of life (QOL) after XeCl excimer TMLR. The aim of the study described here was to investigate cardiac denervation as a working mechanism of stand-alone TMLR using 123-I-MIBG SPECT scintigraphy (MIBG and noradrenalin have similar molecular structures and both utilise the same uptake and storage mechanisms in sympathetic nerve endings) in combination with an algorithm for quantification of SPECT (Germano et al., J Nuclear Med 2000;41:712-9).
In 8 patients, TMLR was performed using a Ho:YAG (n=3) or XeCl excimer laser (n=5). In all patients angina was reduced by at least 2 classes (classification of the NYHA) at 3 to 12 months follow up, QOL was significantly improved and 123-I-MIBG SPECT scintigraphy showed decreased uptake up to 16 months follow up, indicating sympathetic myocardial denervation after TMLR ($P=0.00002$). Average summed defect scores were 13.4±3.9 pre-operative vs. 23.9±4.3 post-operatively. Pre- and post operative myocardial perfusion scintigraphy did not differ significantly. Our results indicate that relief of angina may be explained by destruction of nociceptors or cardiac neural pathways, resulting in a change in the perception of anginal pain after TMLR.

P503 Coronary artery bypass surgery and risk of sudden death in patients with ischaemic heart disease

G. Gandelman[1], R. Chessky[1], V. Boyko[2], S. Behar[2], A. Caspi[1]. *[1]Kaplan Medical Center, Institute of Cardiology, Rehovot, Israel; [2]Neufeld Cardiac Research Institute, Tel Hashomer, Israel*

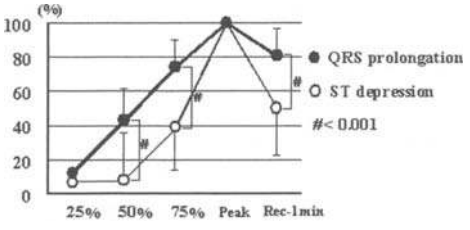
Patients with ischemic heart disease remain at constant risk of sudden cardiac death (SCD). SCD accounts for approximately 50% of all death from cardiovascular causes. The aim of this study was to analyze the influence of surgical coronary artery revascularization on the incidence of SCD in patients without a history of previous CABG who were included in the Bezafibrate Infarction Prevention (BIP) Study (n=2535). During a 7-9 year follow-up period, 541 (21.3%) patients (pts) underwent CABG (mean time from inclusion in study to operation – 2.6 years). Mean age was similar in both groups (CABG + gr. ~59.6 years vs. CABG – gr. ~60.0 years). Patients referred to surgical revascularization included more men (CABG +gr. ~93.3% vs. CABG – gr. ~89.8%) and had a higher prevalence of angina pectoris, heart failure and diabetes (71.5% vs. 57.1%; 32.1% vs. 23.8%; 12.2% vs. 8.4%, respectively). Counterparts without CABG included a higher percentage of smokers (CABG – gr. ~14.4% vs. CABG + gr. ~10.5%), had a higher rate of previous myocardial infarction (81.0% vs. 77.4%, respectively), and received medical therapy with beta-blockers, nitrates and calcium antagonists more frequently (45.3% vs. 38.1%; 66.4% vs. 54.9%; 60.4% vs. 55.7%, respectively). The total cardiac mortality (5.5%) and incidence of SCD (2.4%) among patients who had undergone surgery were significantly lower than in patients without surgical revascularization (10.7% and 6.1%, respectively). After adjustment for different baseline characteristics including the timing of surgery performance, CABG was associated with a 33% reduction in the risk of any cardiac death (RR= 0.67; 95% CI 0.44-1.01) and a 42% reduction in the risk of SCD (RR= 0.58; 95% CI 0.32-1.04).In the group of patients who underwent CABG, an age-dependent increase in death rate from SCD was not observed.
Conclusion: In patients with ischemic heart disease, surgical revascularization was associated with reduction in mortality from SCD.

EXERCISE TESTING/MICELLANEOUS TOPICS

P504 QRS width prolongation precedes ST-segment depression on exercise electrocardiogram in patients with inducible ischaemia

Y. Takeda[1], H. Takaki[2], K. Iida[2], S. Tsunoda[2], S. Watanabe[2], T. Kawada[2], K. Sunagawa[2]. *[1]Tokyo Teishin hospital, cardiology, Tokyo, Japan; [2]National Cardiovascular Center, Cardiology, Suita, Japan*

It is well known that exercise-induced ST depression (STD), representing repolarization abnormality, manifests after cardiac workload exceeds an ischemic threshold, and then advances progressively. We, however, have little information about such a time-course of exercise-induced QRS prolongation (QRS-P) representing depolarization abnormality caused by inducible ischemia. This study addressed this issue.
Methods: We examined 31 patients with documented coronary artery disease who had exercise-induced significant STD and visually identifiable QRS-P in treadmill-electrocardiogram (ECG; 25mm/sec). Using digitized 12-lead ECGs (500Hz), we serially measured QRS width and STD at 25, 50, 75, and 100% of total exercise time.
Results: The magnitudes of STD and QRS-P at peak exercise were -4 ± 1 mm and 13 ± 5 msec, respectively. STD did not increase until at 75% of total exercise time, while QRS-P was identifiable at 50%. At 75%, %change to total was 74 ± 16% in QRS-P, but only 39 ± 28% in STD ($p<0.001$).



Time-course of QRS-P and STD.

Conclusion: In patients with inducible ischemia, the time-courses of depolarization (QRS prolongation) and repolarization (ST depression) abnormality in response to exercise differed from each other. QRS prolongation precedes ST depression, possibly serving as an early sign for inducible ischemia without necessitating maximal efforts.

P505 Complex ventricular arrhythmias and myocardial ischaemia during exercise testing in master athletes: prevalence, correlates and outcome

F. Colivicchi[1], F. Ammirati[1], C. Racani[2], A. Biffi[3], M. Santini[1]. *[1]S. Filippo Neri, Cardiology Dept., Rome, Italy; [2]ASL RM D, Cardiology, Rome, Italy; [3]CONI, Sports Medicine, Rome, Italy*

Between January 1993 and September 2001, 658 consecutive, apparently healthy, asymptomatic, male, competitive athletes (mean age of 57±6 years) underwent a preparticipation cardiovascular evaluation, which included: history, physical examination, 12-lead ECG and maximal ECG exercise testing (cycle ergometer).
During exercise testing, 21 subjects (3,1%) had one or more episodes on non-sustained ventricular tachycardia (NSVT), 14 subject (2,1%) showed asymptomatic ECG abnormalities consistent with myocardial ischemia (MI; horizontal or downsloping ST segment depression >0,1 mV for >80 msec) and 7 subjects (1,0%) showed both episodes of NSVT and MI. All subjects showing NSVT, MI or both during exercise testing were temporarily disqualified from participation in competitive sports and referred for coronary angiography. This diagnostic procedure was performed in 35 of 42 subjects (83,3%), while 7 subjects refused to undergo the procedure and received permanent disqualification (5 with NSVT and 3 with MI). Coronary angiography revealed the presence of significant coronary artery disease (CAD; >50% luminal diameter narrowing in one or more coronary vessels) in 24 of 35 subjects (74,2%). In particular, 7 of 16 subjects with NSVT (43,7%), 10 of 11 subjects with MI (90,9%) and all subjects with both NSVT and MI (100%) showed significant CAD. During follow-up (mean duration 62 months), no major adverse events were noted in athletes who had a negative exercise testing at the initial preparticipation screening. One of the athletes with MI who refused coronary angiography died suddenly while jogging 10 months after disqualification. Necropsy findings were consistent with an acute myocardial infarction in the presence of triple vessel coronary artery disease. Fifteen of 24 subjects with angiographic evidence of CAD underwent myocardial revascularization (11 PTCA and 4 by-pass surgery).
Preparticipation cardiovascular evaluation of male master competitive athletes has a high negative predictive value for subsequent adverse cardiac events. Abnormal findings during exercise testing in such subjects deserve further clinical and laboratory assessment.

P506 Independent association of heart rate response to exercise with cardiac events. An exercise echocardiographic study of 3221 patients

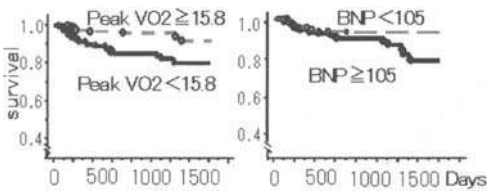
A. Elhendy, B. Khandheria, D. Mahoney, K. Burger, P. Pellikka. *Mayo Clinic, Cardiovascular Division, Rochester, United States of America*

Objectives: To study the association between heart rate response to exercise and the risk of cardiac death and myocardial infarction after adjustment to the severity of left ventricular dysfunction and the extent of exercise induced myocardial ischemia.
Methods: We studied 3221 patients (age 59 ± 12 years, 1701 men) with known or suspected coronary artery disease, who underwent treadmill exercise echocardiography. Chronotropic incompetence was defined as inability to achieve 85% of the maximal predicted heart rate or a low (<0.8) chronotropic index. The independent association between heart rate response to exercise and endpoints (cardiac death and myocardial infarction) was evaluated by an adjusted risk model, which takes into account clinical parameters, resting ejection fraction and both the presence and severity of ischemia (exercise induced wall motion abnormalities).
Results: The target heart rate was not achieved in 495 (15%) patients. A low chronotropic index was observed in 793 (25%) patients. There were 41 cardiac deaths during a median follow up of 3.2 years. Myocardial infarction occurred in 65 patients. After adjustment for clinical, exercise stress and echocardiographic data, a lower chronotropic index was associated with an increased risk of cardiac death (adjusted risk [AR] 0.65 [CI 0.49-0.85], p = 0.002) and myocardial infarction (AR 0.73 [CI 0.59-0.92], p = 0.007). Failure to achieve 85% of the maximal heart rate was independently associated with increased risk of cardiac death (AR 0.47 (0.24-0.91, p = 0.03).
Conclusion: Impaired chronotropic response to exercise is associated with an increased risk of cardiac death and myocardial infarction even after adjusting for resting ejection fraction and the severity of exercise-induced myocardial ischemia.

P507 Peak VO_2 is more potent than brain natriuretic peptide (BNP) as a prognostic parameter in cardiac patients

T. Kubozono, A. Koike, T. Maeda, A. Tajima, Y. Akashi, M. Kato, L.T. Fu, H. Itoh. *The Cardiovasculer Institute, Tokyo, Japan*

Background: It is known that BNP and peak VO2 are not only indices for severity but also independent predictors of mortality in patients with heart failure, however, there were no data compared the power of these parameters in terms of predictor for survival.
Purpose: We investigated the prognostic significance of BNP and peak VO2 in cardiac patients prospectively.
Methods: Three hundred and ten consecutive patients (male:246, female:64, age:62±37 years) with cardiac disease entered the study. They performed cardiopulmonary exercise tests with a cycle ergometer to determine peak VO2. BNP was measured just before the exercise test.
Results: During 704±422 days of follow-up period, 32 patients died of any causes and 9 were unknown. Peak VO2 was higher in survivors than nonsurvivors (18.5±4.7 vs 13.5±3.7 ml/min/kg, p<0.0001). BNP was lower in survivors than nonsurvivors (112±1537 vs 326±445 pg/ml, p<0.0001) In the univariate Cox proportional hazards analysis, both of peak VO2 and BNP were found to be significant prognostic indices for survival. The multivariate analysis revealed peak VO2 as an independent predictor for all cases mortality (Chi-square:23.9, p<0.0001) and BNP as a significant but slightly weaker predictor (Chi-square:8.6, p<0.005). The Kaplan-Meier curves for the groups categorized by the median values of peak VO2 and BNP were shown in the figure.



Kaplan-Meier Curves for peak VO2 & BNP.

Conclusion: These results indicated that BNP and peak VO2 are independent predictors for survival, while peak VO2 is a more potent parameter than BNP for assessing the mortality in patients with cardiac disease.

P508 Physical fitness does not protect from the prothrombotic effects of acute dynamic exercise in a middle aged population

E. Mackie[1], M. Dawson[2], A. McKenzie[3], W.S. Hillis[3]. *[1]University of Glasgow, Medicine and Therapeutics, Glasgow, United Kingdom; [2]WesternInfirmary, Department of Haematology, Glasgpw, United Kingdom; [3]Glasgow University, Dept. Medicine and Therapeutics, Glasgow, United Kingdom*

Acute dynamic exercise stimulates coagulation, fibrinolysis and thrombocytosis.However the benefits of physical fitness on the balance of haemostasis is controversial.This study aimed to assess the haemostatic changes with exercise in a group of trained subjects in the age group at risk of acute coronary events. Methods: 21 soccer referees peformed a ramp protocol exercise test. Blood sampling was performed pre, immediately post and 30 mins post exercise. Samples were analysed for platelet count, Prothrombin time(PT), Activated Partial Thromboplastin Time(APTT), Fibrinogen, Tissue Plasminogen Activator(tPA). Flow cytometry using CD62(p-selectin) and antifibrinogen antibodies was used to assess platelet activation at rest and in response to ADP, collagen and epinephrine. Results: Expressed as mean(SEM).Statistical analysis was performed using paired t-tests. The mean age of participants was 39.2(5.1)years. Total platelet count increased immediately post exercise (228.2(40.5),278.6 (48.9), p=0.001) remaining elevated at 30 minutes. APTT was reduced immediately post exercise (32.15(3.1),29.7(3.94)p=0.001) with further reduction seen at 30 minutes (32.15(3.1),28.4(3.31),p=0.001). %CD62 expression increased post exercise (0.688(0.52),1.42(1.3)p=0.008) with no significant difference seen at 30 minutes.%Anti-fibrinogen expression increased post exercise (5.19(4.31), 13.01(14.24)p=0.017) with a further increase seen at 30 minutes (5.19 (4.31), 20.47(26.8) p=0.02). Significant increases were seen post exercise in response to epinephrine. tPA increased immediately post exercise (0.47(0.85),6.28(4.45)p=0.001) returning to baseline by 30 minutes. Conclusion: Despite the protective effects of fibrinolysis, the changes in coagulation and platelet activation persist at 30 minutes when tPA has returned to baseline levels. In contrast to previous studies in young athletes, this suggests that in an older population, physical fitness does not protect against the prothrombotic effects of acute dynamic exercise and that the potential risks persist well into the recovery period. Further research should be carried out in an ischaemic heart disease population as haemostatic markers may further improve risk stratification with exercise testing.

P509 Cardiac troponin I (cTnI) and exercise test: correlation with myocardial ischaemia

C. Bendavid[1], A. Le Helloco[2], B. Laviolle[3], E. Garin[4], S. Giraud[4], A. Le Treut[1] on behalf of Dade Behring. *[1]Pontchaillou Universitary Hospital, Biochemistry Federation, Rennes, France; [2]Pontchaillou Universitary Hospital, Cardio Pneumologic Center, Rennes, France; [3]Pontchaillou Universitary Hospital, Public Health Departement, Rennes, France; [4]Eugène Marquis Center, Nuclear Medecine Departement, Rennes, France*

The aim of this study was to assess the variation in cTnI, mass CPK MB and CPK activity during an exercise test and to compare these results with thallium 201 tomoscintigraphy.

Methods: 161 subjects (76% male, 63 ± 10 years) with initial (H0) cTnI of <0.4ng/ml were studied.

Blood samples were withdrawn 15 minutes before the exercise test (H0) and 4 hours after (H4). All subjects underwent myocardial tomoscintigraphy after cycle ergometer testing (15 derivations with CM5, CC5 and ML) with an increase in workload every 3 minutes to maximal exercise test and with redistribution imaging at H4.

For the exercise test myocardial tomoscintigraphy, subjects were divided in five groups:

– ischaemic group (77 subjects): without previous acute myocardial infarction (AMI) (28 subjects), with jeopardized myocardium in the territory of AMI (32 subjects) or in a remote territory (17 subjects).

– non ischaemic group (84 subjects): with normal tomoscintigraphy (46 subjects) or previous AMI without ischaemia (38 subjects).

Results: cTnI increased significantly after exercise ($p<0.0001$, Wilcoxon rank test). The means of the ischaemic and non ischaemic groups were compared using the Mann-Whitney U test (table below).

Differences between the five groups were determined by ANOVA for cTnI.H4 ($p=0.005$) and cTnI.H4-H0 ($p=0.021$).

Multiple comparison of means by the Scheffe F test showed that only subjects without previous AMI but with exercise myocardial ischaemia, and normal subjects, differed for these variables ($p=0.0053$ and $p=0.0223$ respectively).

Quantification of the ischaemic myocardial by scintigraphic scores did not show any correlation with the cTnI rates or their variations.

The other markers tested did not show statistically significant variations.

Unit: ng/ml	cTnIc.H0	cTnIc.H4	cTnIc.H4-H0
Ischaemic group (77 subjects)	0.051	0.107	0.056
Non ischaemic group (84 subjects)	0.034	0.063	0.029
p	0.1802	0.0123	0.0252

Conclusion: cTnI showed a statistically significant increase, dependent on exercise, particularly in the ischaemic group, but there was no correlation with tomoscintigraphic extent of exercise ischaemia. In the absence of AMI, the difference in the increase in cTnI between ischaemic and non ischaemic groups was significant, which was not the case in presence of AMI.

P510 Modelling left ventricular dysfunction in the community setting

G. Galasko, R. Senior, A. Lahiri. *Northwick Park Hospital, Cardiology, Middlesex, United Kingdom*

Background: With the increasing prevalence of heart failure, community-based programmes to screen for and treat left ventricular systolic dysfunction (LVD) have recently been advocated. However, who best to screen has not been fully elucidated. This study was undertaken to assess this further.

Methods: 1403 subjects ≥45 years old were chosen at random from 7 representative local general practices and invited to undergo a symptom questionnaire, clinical examination, ECG, echocardiogram, urinalysis, spirometry and fasting plasma glucose, N-terminal proBNP (NTP) and lipid profiles.

Results: 732 subjects (52%) attended, 516 (70%) Caucasian and 216 (30%) from ethnic minorities, the majority S. Asian. An ejection fraction was calculable by echocardiography using Simpson's apical biplane method in 703 cases (96%). 38 subjects (5.4%) (3.8-7.2%) were found to have LVD. Multivariate predictors of LVD included prior myocardial infarction, diabetes, a history of heavy alcohol usage, male sex, an abnormal ECG and plasma NTP levels. A multivariate model to predict LVD using these factors was developed. This model gave an area under the ROC curve of 0.95 for predicting significant LVD (left ventricular ejection fraction <45%). A risk-score above 2.83 gave a sensitivity of 92% and specificity of 89% for predicting significant LVD, requiring only 14% of the population to be screened with a one-in-four pick up rate.

Conclusion: Thus simple clinical and biochemical markers of LVD can be combined to create a model that successfully predicts left ventricular systolic dysfunction in the community setting, potentially allowing cost-effective echocardiographic screening, with 86% of the population not requiring echocardiography.

P511 Lean tissue-adjusted versus body weight-adjusted peak oxygen consumption and mortality prediction in chronic heart failure

M. Cicoira[1], C. Davos[2], L. Zanolla[3], L. Franceschini[3], M. Piepoli[2], A.J.S. Coats[2], P. Zardini[3], S.D. Anker[2]. *[1]Divisione Clinicizzata di Cardiologia, Dip scienze biomediche e chirurgiche, Verona, Italy; [2]National Heart & Lung Institute, Cardiac Medicine Dept., London, United Kingdom; [3]Divisione Clinicizzata di Cardiologia, Verona, Italy*

Background: peak oxygen consumption (peak VO2) is an important prognostic marker in chronic heart failure (CHF) patients. Peak VO2 reflects oxygen extraction from the metabolically active tissues (i.e., the skeletal muscles); nevertheless, peak VO2 is expressed in mL/min/kg of body weight (peak VO2-weight). We assessed, whether the adjustment of peak VO2 for lean tissue (peak VO2-lean) might provide better prognostic information than peak VO2–weight in CHF patients. Methods and Results: Prospectively, 272 CHF outpatients in stable clinical conditions (mean age 61±12 years, NYHA class 2.3±0.8) underwent a symptom-limited cardiopulmonary exercise testing, and evaluation of body composition with dual-energy X-ray absorptiometry (DEXA). Peak VO2-weight averaged 17.6±5.7 mL/kg/min and peak VO2-lean 25.6±8.1 mL//kg/min. During follow-up (mean 878±777 days), 60 patients died (12-month survival: 89% [95% CI 85-93]). Cox proportional hazard analyses showed that peak VO2-weight and peak VO2-lean predicted survival (both $p<0.0001$), but at the log-likelihood ratio test peak VO2-lean was significantly stronger than peak VO2-weight in predicting survival ($p=0.002$). The receiver operating characteristic area under the curve for peak VO2-lean was significantly greater than for peak VO2-weight at 12, 15, 18 and 21 months follow-up (all $p<0.03$). In patients with mild CHF (NYHA class I and II), peak VO2-lean significantly predicted outcome ($p=0.03$), while peak VO2-weight lost its prognostic power. Conclusions: Adjustment of peak VO2 for lean tissue instead for body weight provides a stronger prognostic parameter. This correction might be particularly useful in mild CHF and in subgroups of patients, such as in women and obese patients, in whom the prognostic value of peak VO2 is less obvious.

P512 Contribution of alveolar and serial dead space to the hyperpnoea of exercise in chronic heart failure

R. Wensel[1], P. Georgiadou[1], D.P. Francis[2], S. Bayne[3], W. Doehner[1], S.D. Anker[1], A.J.S. Coats[1], M.F. Piepoli[1]. *[1]National Heart and Lung Institute, Clinical Cardiology, London, United Kingdom; [2]Chelsea&Westminster Hospital, Cardiology, London, United Kingdom; [3]Royal Brompton Hospital, Noninvasive Cardiology, London, United Kingdom*

An increased ventilatory response to exercise is an important feature of chronic heart failure (CHF) and relates to poor prognosis. Increased physiological dead space and low arterial pCO_2 are causative mechanisms. Physiological dead space consists of alveolar and anatomical dead space. Whether the increase in physiological dead space results from an increase in alveolar or anatomical dead space has not been directly investigated yet.

We performed cardiopulmonary exercise testing in 26 patients with CHF (age: 66±11, LVEF: 31±13%, peakVO2: 16±4mL/kg/min, VE/VCO2-slope: 35±7). At rest and during each stage of the test arterial pCO_2 was measured and physiological dead space was calculated. Anatomical dead space was measured by a modified Fowler technique. Consecutively, alveolar dead space and the dead space to tidal volume ratios were calculated.

Of the resting parameters only the anatomical dead space to tidal volume ratio correlated with the VE/VCO2-slope ($r=0.4$, $p<0.05$). At peak exercise, the physiological dead space to tidal volume ratio ($r=0.66$, $p<0.001$), alveolar dead space to tidal volume ratio ($r=0.55$, $p<0.01$), anatomical dead space to tidal volume ratio ($r=0.4$, $p<0.05$) and arterial pCO_2 ($r=-0.58$, $p<0.01$) correlated with VE/VCO2-slope.

On multivariate regression analysis the alveolar dead space to tidal volume ratio ($p=0.01$) but not the anatomical dead space to tidal volume ratio ($p=0.14$) was independently related to VE/VCO2-slope. Alveolar dead space to tidal volume ratio and anatomical dead space to tidal volume ratio were not correlated with each other ($r=0.1$, $p=0.96$).

Our findings confirm that the VE/VCO2-slope is dependent on the physiological dead space to tidal volume ratio during exercise. The increase of the physiological dead space is caused by both an increase in alveolar and anatomical dead space. However, alveolar dead space seems to be more important for VE/VCO2-slope. This suggests a role for an abnormal pulmonary perfusion in the development of exercise hyperpnoea in CHF.

P513 Can natriuretic peptides screen for left ventricular diastolic dysfunction in the community?

G. Galasko[1], A. Lahiri[1], R. Senior[1], J. Trawinski[2], M. Baumann[2]. [1]*Northwick Park Hospital, Cardiology, Middlesex, United Kingdom;* [2]*Roche Diagnostics, Basel, Switzerland*

Background: Natriuretic peptides (NPs) have recently been shown to accurately predict left ventricular systolic dysfunction (LVSD) in the community. However, controversy exists as to their ability to predict left ventricular diastolic dysfunction (LVDD) in the absence of LVSD, which may occur in up to half of all heart failure cases. We assessed this further for N-terminal atrial natriuretic peptide (NTA), and N-terminal pro-brain natriuretic peptide (NTB), a newly detectable NP.
Methods: Accordingly, 1403 subjects ≥ 45 years old were chosen at random from 7 representative local general practices and invited to undergo a symptom questionnaire, echocardiography and venesection for plasma NTA and NTB assays. Echocardiographic measures of diastolic dysfunction included mitral inflow peak E and A wave velocities, E/A ratio and E wave deceleration time (DT), isovolumic relaxation time (IVRT) and left atrial diameter (LA).
Results: 732 subjects (52%) attended. Significant correlation was seen between plasma NTB levels and A, E/A, IVRT and LA and between plasma NTA levels and LA only. 187 subjects (26%) had symptoms of dyspnoea. 47 subjects had symptomatic LVDD with either impaired relaxation or restrictive filling patterns on echocardiography, dyspnoea and normal systolic function. Mean plasma levels for those with vs those without symptomatic LVDD but no LVSD were 77.4 and 32.2 pmol/l for NTB ($p<0.0001$) and 2170 and 1760 fmol/ml for NTA ($p=0.001$), respectively. Areas under the ROC curves for NTB and NTA to predict symptomatic diastolic dysfunction were 0.76 and 0.65, respectively ($p=0.04$).
Conclusion: Thus although both NTA and NTB predict LVDD in the absence of LVSD in the community, NTB is a more discriminatory marker, with a greater potential role in screening for LVDD.

P514 Contribution of ergoreflex to respiratory control in chronic heart failure – the reproducibility and the clinical implications of the method

A. Kaczmarek[1], E.A. Jankowska[1], T. Witkowski[1], A.C. Scott[2], D. Francis[2], W. Banasiak[1], M.F. Piepoli[2], P. Ponikowski[1]. [1]*Military Hospital, Cardiology, Wroclaw, Poland;* [2]*Royal Brompton Hospital, National Heart and Lung Institute, London, United Kingdom*

The overactivation of ergoreceptors (afferents sensitive to metabolic products of skeletal muscle work) is presumed to contribute to the enhanced ventilation and exercise intolerance in patients with chronic heart failure (CHF). The relationships between the ergoreflex activity (the ventilatory response to exercise) and the clinical state of CHF patients have not been comprehensively established, moreover the reproducibility of the applied method has not been tested yet.
Material and Methods: The ergoreflex activity was measured in 53 men with CHF (63.5±12.5 years, NYHA class I/II/III/IV - 8/27/16/2 subjects, EF = 30.5±6.6%) and compared with 17 healthy age-matched men (60.9±11 years, EF = 58.1±4.5%). All subjects underwent maximal cardiopulmonart exercise testing to assess peak oxygen uptake (peak VO2) and ventilatory response to exercise VE/VCO2 slope).
The ergoreflex activity was assessed by 2 runs the 5-minute dynamic handgrip, one run followed by the 3-minute post-handgrip regional circulatory occlusion (PH-RCO), with the continuous measurement of ventilation [l/min-1]. The contributions made specifically by ergoreflex to ventilatory responses were estimated by calculating the differences of ventilation between PH-RCO and the recovery period without PH-RCO (during 1 and 2 minute - ERGO 1-2, during 2 and 3 minute - ERGO 2-3). We also compared the reproducibility of the method in the group of 13 men with CHF.
Results: The advanced clinical state of CHF patients was related to augmented ergoreflex activity: ERGO 1-2 for controls vs NYHA I vs NYHA II vs NYHA III/IV were 0.72 vs 1.82 vs 2.03 vs 4.05 l/min-1, respectively ($F=18.74$, $p<0.0001$). ERGO 2-3 for controls vs NYHA I vs NYHA II vs NYHA III/IV were 0.08 vs 1.08 vs 1.51 vs 3.21 l/min-1, respectively ($F=20.67$, $p<0.0001$). Among CHF patients the significant correlations between ERGO and NYHA class were revealed ($r=0.53$, $p<0.0001$ for ERGO 1-2; $r=0.55$, $p<0.0001$ for ERGO 2-3). CHF patients when compared to controls revealed lower peak VO2 (16.23±4.32 l/kg/min; $p<0.0001$) and higher VE/VCO2 slope (40.98±12.61; $p<0.001$). Variability coefficients for ERGO 1-2 and ERGO 2-3 were 36.1% and 21.5%, respectively.
Conclusions: Our results confirmed that the ergoreflex activity constituted a significant factor discriminating CHF patients and the ergoreceptors overactivation was related to the deterioration of clinical state of CHF patients. The applied method for assessing ergoreflex activity appeared to be moderately reproducible with VC ranging from 21.5% to 36.1%.

P515 Is there any difference in long-term left ventricular pacing compared to biventricular pacing in patients with severe congestive heart failure?

J. Heintze[1], B. Lamp[1], J. Vogt[1], B. Hansky[2], L. Krater[1], F. Warzok[1], R. Koerfer[2], D. Horstkotte[1]. [1]*Heart Center North Rhine-Westphalia, Department of Cardiology, Bad Oeynhausen, Germany;* [2]*Heart Center North Rhine-Westphalia, Dept Thorac Cardiovasc Surgery, Bad Oeynhausen, Germany*

Cardiac resynchronisation therapy (RT) is a therapeutic option in patients (PTS) with severe systolic heart failure (HF) and conduction abnormalities. According to the PATH I data, left ventricular (LV) stimulation resulted in similar improvement as biventricular pacing during acute hemodynamic testing in PTS with advanced HF and left bundle branch block (LBBB). Potential differences between permanent LV versus biventricular (BiV) stimulation during long-term follow up are not well studied yet.
Until mid 2001 we treated 149 consecutive PTS with severe HF, LBBB and sinus rhythm with RT. Pacing configuration was tailored according to the preimplant hemodynamic testing, which has been described earlier. Baseline characteristics of LV- and BiV-stimulated PTS were comparable. During follow-up 4 PTS died (2 LV, 2 BiV) and 4 were transplanted successfully due to worsening heart failure (1 LV, 3 BiV). All parameters characteristic of HF improved significantly during 6 and 12 months follow-up (FU) (see table below). No significant differences were observed between the LV- and BiV-stimulated groups.
Conclusion: In contrast to published data in this patient cohort the pacing site was chosen according to a preoperative hemodynamic testing. No difference in improvement of clinical and echocardiographic parameters was observed up to 12 month of follow-up.

Abstract P515 – Table

Parameter	Baseline LV	Baseline BiV	LV 6 mo	BiV 6 mo	LV 12 mo	BiV 12mo
n	46	103	35	81	23	51
CAD/DCM/other	18/26/2	29/59/5	13/20/2	27/49/5	16/7	35/14/2

P516 The use of brain natriuretic peptide in the diagnosis of heart failure in the community: a randomised, controlled, effectiveness study

S.P. Wright[1], R.N. Doughty[2], G.D. Gamble[2], A. Pearl[3], J. Pomfret[2], G.A. Whalley[2], H.J. Walsh[2], T. Yandle[4], A.M. Richards[4], N. Sharpe[2]. *[1]Dept of Medicine, Auckland 1001, New Zealand; [2]University of Auckland, Division of Medicine, Auckland, New Zealand; [3]University of Auckland, Division of General Practice, Auckland, New Zealand; [4]University of Otago, Dept of Medicine, Christchurch, New Zealand*

Background: Patients commonly present to general practitioners (GPs) with symptoms of suspected heart failure (HF). However, diagnosis is often difficult in the community setting. Brain natriuretic peptide (BNP) has been shown to be an accurate diagnostic tool in patients with dyspnoea presenting to hospital, but the diagnostic utility of BNP when used by GPs in a community setting is uncertain.
Methods: The study included patients presenting to their GP with symptoms of dyspnoea and/or oedema. Each patient underwent full clinical assessment including ECG, chest radiograph, echocardiography and N-terminal BNP measurement, by an independent study investigator. Patients were randomised as to whether their referring GP received their BNP result (BNP group) or not (control group). All patients were subsequently reviewed by their referring GP who made a diagnosis of HF or not based on clinical grounds alone or with the addition of the BNP. The gold standard diagnosis of HF was the decision of an independent expert panel using ESC criteria. A correct diagnosis was one that agreed with the expert panel, and included correct diagnoses of HF and not HF.
Results: 304 patients were included, mean age 72 yrs (SD 11.4), 65% female; 80% Caucasian; 148 (49%) presented with dyspnoea only, 36 (12%) with oedema only and 119 (39%) with both symptoms. 77 patients (25%) met the case definition for HF; these patients had a significantly higher N-terminal BNP, 286 (SD 319) vs 61 (SD 67) pmol/l, p=0.0001. The percentage agreement of each GP's final diagnosis with the panel diagnosis is shown in the table.The diagnostic accuracy in the BNP group improved 20% compared with 6% in the control group, p=0.002.

Agreement of GP and panel diagnoses

	Control group (no BNP)	BNP group	
Initial GP diagnosis	52%	49%	
Final GP diagnosis (with BNP or clinical review alone)	59%	70%	
Absolute change in accuracy of GP diagnosis	+7%	+21%	p=0.002

Conclusions: In the first prospective, randomised controlled effectiveness trial based in the community, BNP improved diagnostic accuracy of HF by general practitioners. This study supports the availability of N-terminal BNP for the evaluation of patients with symptoms suggestive of heart failure in the community.

P517 Effect of carvedilol on myocardial ischaemia, hibernation and viability in patients with left ventricular systolic dysfunction due to CAD

J.G.F. Cleland[1], D. Pennell[2], S. Ray[3], A. Coats[4], A. Lahiri[5], J. Dalle Mule[6], Z. Vered[7] on behalf of the CHRISTMAS Steering Committee and Investigators. *[1]Academic Cardiology, Kingston upon Hull, United Kingdom; [2]Royal Brompton Hospital, MRI Unit, London, United Kingdom; [3]Wythenshawe Hospital, Department of Cardiology, Manchester, United Kingdom; [4]National Heart & Lung Institute, Department of Cardiac Medicine, London, United Kingdom; [5]Northwick Park Hospital, Department of Cardiac Research, Harrow, United Kingdom; [6]Pieve di Cadore Hospital, Cardiology Unit, Pieve di Cadore, Italy; [7]Asaf Harofeh Hospital, Heart Institute, Zriffin, Israel*

Background: Both the myocardial substrate and the ventricular ejection fraction response to beta-blockers are heterogeneous in patients with heart failure and left ventricular systolic dysfunction (LVSD) secondary to coronary artery disease (CAD). The two may be related.
Aims: To determine whether the increase in left ventricular ejection fraction (LVEF) in response to carvedilol amongst patients with heart failure and LVSD secondary to CAD reflects the volume of myocardium affected by hibernation and/or ischaemia.
Methods: An international, multi-centre, double-blind, randomised, parallel-group study was conducted. Patients with systolic dysfunction were initially identified using echocardiography (wall motion index $\leq$ 1.3 (9 segment model), corresponding to a LVEF $\leq$ 39%). In eligible patients, LVEF (radionuclide ventriculography) and myocardial perfusion (MP) (nitrate-enhanced sestamibi at rest and after exertion) were further assessed and reported in a blinded fashion in a core laboratory. Hibernation was defined as an impaired regional echocardiographic wall motion at rest with preserved MP; myocardial ischaemia was defined as a stress-induced MP defect in a segment that had preserved myocardial perfusion at rest. Patients were randomised to placebo or carvedilol (titrated to a target dose of 25 mg bid or 50 mg bid if >85 kg) and then followed for 4 months on maintenance doses (Total duration of treatment about 6 months).
Results: 305 patients were included in the intention to treat analysis. 90% were men, mean age was 62 years, 63% were angina-free during daily activity and 23% were diabetic. 61% were in NYHA class II and 27% in class III. Mean baseline LVEF was 30+11% (SD). 181 (59%) were classified as hibernators. LVEF was unchanged after 6 months on placebo in patients with or without hibernation but rose by 3.3% ($P < 0.0001$) (placebo-subtracted) with carvedilol overall. However, in patients without evidence of viable or ischaemic myocardium carvedilol did not increase ejection fraction, whereas it rose by >5% in patients with 4 or more affected segments.
Conclusions: These data suggest that the effect of carvedilol on LVEF may be mediated by resuscitation of hibernating myocardium and protection from myocardial ischaemia. Medical therapy may be an important adjunct or alternative to revascularisation for these patients. Patients without myocardial ischaemia or hibernation may benefit from beta-blockers by mechanisms other than an improvement in LVEF.

P518 Interleukin-6 and tumor necrosis factor-a levels increase in response to maximal exercise in patients with chronic heart failure

T. Kinugawa, M. Kato, Y. Tomikura, S. Osaki, K. Ogino, O. Igawa, I. Hisatome, C. Shigemasa. *Tottori University Faculty of Medicine, Div of Cardiology/1st Dept Int Med, Yonago, Japan*

Background: Chronic heart failure (CHF) is characterized by the activation of neurohormones and cytokines. Strenuous exercise causes activation of both systems, but the effect of exercise on cytokine is not known in patients with CHF. This study determined whether maximal exercise induces activation of cytokines in patients with CHF.
Methods: Plasma interleukin-6 (IL-6), tumor necrosis factor (TNF)-a, epinephrine, norepinephrine, and atrial & brain natriuretic peptide (ANP & BNP) were determined before and after symptom-limited cardiopulmonary exercise testing in 80 patients with CHF (age=58±1 years, LVEF=38±1%, peak VO2=18.8±0.5 ml/min/kg) and age-matched 33 normal controls.
Results: Resting IL-6 (Controls vs CHF: 1.3±0.2 vs 2.4±0.3 pg/ml, $p<0.001$) and TNF-a (2.7±0.2 vs 3.8±0.2 pg/ml, $p<0.01$) were elevated in CHF. IL-6 and TNF-a were positively correlated (r=0.35 and r=0.28, respectively) with plasma norepinephrine, and were negatively correlated (r=-0.28 and r=-0.31, respectively) with peak VO2. Maximal exercise increased IL-6 and TNF-a in controls (by 92% and by 12%, respectively) and in patients with CHF (by 59% and by 13%, respectively) (all $p<0.01$). Changes in IL-6 (delta-IL-6) was correlated with delta-epinephrine (r=0.63, $p<0.0001$) and delta-norepinephrine (r=0.57, p=0.0006) in controls, but not in patients with CHF. Delta-TNF-a was correlated with delta-ANP (r=0.28, p=0.01) only in patients with CHF.
Conclusions: Cytokine activation at rest was associated with high plasma norepinephrine and low exercise capacity. Maximal exercise caused increases in IL-6 and TNF-a concentrations. Sympathetic activation seems to be important for the IL-6 increase during exercise in controls. In patients with CHF, changes in ANP during exercise was associated with the exercise-induced increase in TNF-a, but still unknown mechanisms are involved for the cytokine activation during exercise.

P519 Predictive value tissue Doppler echocardiographic findings on positive left ventricular remodelling induced by cardiac resynchronization therapy

L. Faber[1], B. Lamp[1], J. Vogt[1], J. Heintze[1], B. Hansky[2], R. Koerfer[2], D. Horstkotte[1]. [1]*Heart Center North Rhine-Westphalia, Cardiology Dept., Bad Oeynhausen, Germany;* [2]*Heart Center North Rhine-Westphalia, Dept of Thorac Cardiovasc Surg, Bad Oeynhausen, Germany*

Background and Introduction: Resynchronization of left ventricular (LV) contraction is considered a mechanism for the clinical benefit observed in heart failure patients (CHF-pts.) with a wide QRS complex treated by cardiac resynchronization (CRT). We analyzed whether mechanical LV asynchrony as assessed by tissue Doppler echocardiography (TDE) and its evolution after CRT is predictive for echocardiographic measures of LV function (LVF) during follow-up.

Methods and results: 49 CHF-pts treated with CRT were studied. Pt. selection for CRT was based on clincal and ECG criteria plus invasive hemodynamic testing. TDE curves of septal and lateral wall segments were obtained 144±94 (30-390) days after CRT, and were superimposed on each other, to allow analysis of timing and direction of movements. Timing was measured in ms (corrected for a cycle length of 1000 ms). Pts. were classified as TDE-responders (TDE-R: asynchrony at baseline, corrected by CRT) vs. non-responders (TDE-NR: either not asynchronous at baseline, or persisting asynchrony despite CRT) and LVF responders (LVF-R: diameter reduction of >10%) vs. nonresponders (LVF-NR). Results are summarized in the table.

Variable	TDE-R (n=29)	TDE-NR (n=20)	p-value
Baseline LV diameter (mm)	79±9	82±11	0.2
LV diameter reduction (mm)	9±11	3±9	0.08
Baseline LV-EF (%)	23±8	20±12	0.2
LV-EF gain (%)	9±10	2±12	<0.05
LV-R (n; %)	19/29 (66%)	5/20 (25%)	<0.01
LV filling time gain (ms)	70±103	30±168	0.3
Baseline QRS width (ms)	191±20	200±26	0.2

Conclusions: The remodeling effect of CRT is largely limited to TDE-R, although TDE-NR also demonstrated some benefit. TDE evaluation should therefore be routinely performed in pts. considered for CRT. Traditional selection criteria including hemodynamic testing do not reliably predict the success of CRT with respect to echo measures of LVF.

P520 Clinical characteristics and prognosis of patients with heart failure and preserved or reduced left ventricular ejection fraction

J.R. González-Juanatey, A. Varela, P. Basanta, J.M. García Acuña, A. Virgos, I. Gomez Otero, P. Mazón. *Hospital Clínico Universitario, Unidad de Investigación, Santiago de Compostela, Spain*

Objectives: To determine the clinical and prognostic differences between heart failure patients with preserved and deteriorated systolic function, defined as possession of left ventricular (LV) eiection fractions > 50% and < 50%, respectively.

Patients and Methods: We studied the records of 229 conqestive heart failure (CHF) patients aged 66.7± 11.7 years (95 women, 134 men) who had been admitted to a Cardioloqy Service for CHF in the period 1991-1994, and whose LV systolic function had been echocardio-graphically evaluated within 2 weeks of admission. Data were collected on the main clinical findings, supplementary examinations, treatment, and duration of hospitalization; the patient's situation in the spring of 1999 was evaluated by searching the general archives of the hospital and by telephone survey.

Results: LV systolic function was preserved in 29% of patients. The preserved and deteriorated groups differed significantly as regards the female/male sex ratio (greater in the preserved group), and the presence of third sound, cardiomegaly, alveolar oedema, ischaemic cardiopathy and treatment with angiotensin-converting enzyme inhibitors (all more prevalent in the deteriorated group). There were no statistically significant differences as regards age; NYHA functional class; the presence of sinus rhythm, fibrillation or LV hypertrophy; treatment with drugs other than ACE inhibitors; or survival. In the group as a whole, the survival rates after 3 months and 1 and 5 years were 92.6%, 80% and 48.4%.

Conclusion: In view of the poor prognosis of CHF patients with preserved LV systolic function (currently treated empirically), controlled clinical trials should be carried out to optimize their treatment.

Key words: congestive heart failure. Systolic function. Prognosis,

P521 Response to multisite pacing in ischaemic cardiomyopathy: which site to choose

L C.M.C. van Campen, F.C. Visser, C.C. de Cock, H.S. Vos. *VU Medical Center, cardiology, Amsterdam, Netherlands*

Introduction: As multisite pacing is a promising new therapy for heart failure patients in class III and IV, still not a lot of knowledge is available on the optimal pacing site and why some patients do not respond and what kind of patient will not respond

Objective: in temporary multisite pacing we tried to establish how many pts are responders to what pacing combination.

Methods: in 24 pts with ischemic cardiomyopathy with QRS duration over 120 msec and EF below 35% (21 male/3 female, age 71±8 yrs) we used temporary multisite pacing to establish the best position for each patient. We used temporary 6Fr pacing lead V116 and specially prepared PTCA Galeo wires (Biotronik) through an Amplatz L2 guiding catheter to position in RV apex, RV outflow tract, right atrium for VDD pacing and anterior and posterolateral branches of the coronary sinus. We then used Doppler flow over the aortic valve to measure Cardiac Index (CI). A responder was defined as an increase of 10% or more.

Results: At bifocal right postion (RV apex + outflow tract) 10 (59%) pts were nonresponders and 7 (41%) were responders. The delta CI (maximal CI minus baseline CI) was 5.5±2.5 and 16.7±4.1% resp. (p<0.0001). Cs postlat+apex had 8 (47%) nonresponders and 8 (47%) responders with delta cardiac index 4.5±4.9 and 15.6±4.3% resp (p<0.0001). Cs postlat+rvot had 11 (65%) nonresponders and 5 (29%) responders with delta cardiac index 5.6±3.8 and 17.1±8.2% resp (p<0.0002). Cs ant+apex had 9 (53%) nonresponders and 8 (47%) responders with a delta cardiac index of 2.1±5.9 and 15.2±3.1% resp (p<0.0002). Cs ant+rvot had 14 (58%) nonresponders and 6 (35%) responders with a delta cardiac index of 3.6±4.9 and 14.1±3.9% resp (p<0.001).

Conclusion: this study shows clearly that definite LV lead positioning should be individually tailored for each patient. How to determine with easier methods than with this lengthy temporary pacing procedure to know where to be has yet to be determined.

P522 Neurohumoral activation predicts enhanced ventilatory response to exercise in patients with chronic heart failure

T. Kinugawa, K. Ogino, S. Osaki, M. Kato, Y. Tomikura, O. Igawa, I. Hisatome, C. Shigemasa. *Tottori University Faculty of Medicine, Div of Cardiology/1st Dept Int Med, Yonago, Japan*

Background: Chronic heart failure (CHF) is characterized by the activation of neurohormones and elevated slope of ventilatory response to exercise (VE/VCO2). Patients with an enhanced VE/VCO2 slope reported to have exercise intolerance, abnormal hemodynamics, augmented chemoreceptor sensitivity, and poor prognosis. However, the relation between the enhanced ventilatory response to exercise and multiple neurohumoral factors has not been studied. This study determined whether neurohumoral activation is a predictor of VE/VCO2 slope in patients with CHF.

Methods: Plasma concentrations of norepinephrine, renin-angiotensin system activity, atrial & brain natriuretic peptide (ANP & BNP), and endothelin-1 were determined in 71 patients with CHF (age=61±1 years, NYHA functional class I/II/III: 24/31/16, left ventricular ejection fraction=35±1%, peak VO2=17.9±0.9 ml/min/kg) and age-matched 25 normal controls. VE/VCO2 slope was calculated by the relation between ventilation and carbon dioxide production at cardiopulmonary exercise testing.

Results: Patients with CHF had significant neurohumoral activations with increased plasma norepinephrine (Controls vs CHF; 201±11 vs 302±28 pg/ml), ANP (23.7±4.3 vs 74.9±8.0 pg/ml), BNP (19.7±3.5 vs 218.2±29.1 pg/ml) and endothelin-1 (2.32±0.12 vs 2.64±0.13 pg/ml) levels compared to normal controls (all p<0.05). VE/VCO2 slope (Controls vs CHF; 27.5±0.6 vs 34.6±0.9, p<0.01) was higher in CHF. At the univariate analysis, age (p<0.01), body weight (p<0.01), NYHA functional class (p<0.0001), plasma norepinephrine (p<0.0001), plasma ANP (p<0.0001), plasma BNP (p<0.0001), and plasma endothelin-1 (p<0.0001) significantly related with VE/VCO2 slope among patients with CHF. Both plasma ANP (r=0.59, p<0.0001) and plasma norepinephrine levels (r=0.55, p<0.0001) had significant positive correlation with VE/VCO2 slope in CHF. Multivariate analysis revealed plasma levels of ANP and norepinephrine predicted VE/VCO2 slope independent of NYHA functional class and body weight (overall R=0.80, p<0.0001).

Conclusions: Plasma ANP and norepinephrine levels are independent predictors of VE/VCO2 slope in patients with CHF. These findings suggest that neurohumoral activation significantly contributes to the enhanced ventilatory response to exercise in patients with CHF.

P523 Effects of carvedilol therapy on exercise tolerance in patients with chronic heart failure

F. Al-Nasser[1], M. yousufuddin[1], M. piepoli[1], F. al-nozha[2], S. anker[1], A. coats[1], P. ponikowski[1]. [1]Royal Brompton Hospital, Clinical Cardiololgy Dept., London, United Kingdom; [2]king faisal hospital, cvardiology, Riydah, Saudi Arabia

Background: Recent clinical trials have clearly demonstrated that beta-blockers (BB) prolong survival in chronic heart failure (CHF), but whether BB improve pts exercise tolerance remains controversial. In this study we assessed the effect of 3-month therapy with carvedilol on functional capacity in pts with mild to moderate CHF.

Methods and Results: Among 50 consecutive CHF pts referred to our institution for initiation of BB therapy (carvedilol), 42 pts met the entry criteria (>1 month stability, NYHA class II-III, optimal treatment obligatory with ACE inhibitor) and were included into the study. Carvedilol (3.125mg od) was started and titrated up to a maximal tolerated dose (aim: 25 mg bd). Ten pts did not tolerate carvedilol and were excluded. The remaining 32 Pts (28 men, 62±9 years, NYHA class II/III: 19/13) completed the 3-month study period. At baseline and after 3-month therapy cardiopulmonary exercise testing was performed and the following parameters were analysed (table): total exercise duration (Texer), peak oxygen consumption (peakVO2), ventilatory response to exercise (VE/VCO2 slope), anaerobic threshold (AT), and respiratory quotient (RQ) (mean ± SD, * p<0.05):Baseline(n=32)vs End of the study (n=32): NYHA class (I/II/III) 0/19/13 vs 3/24/5*, Texer (s) 457±140 vs 488±164, Peak VO2 (ml/min/kg) 20.9±5.9 vs 21.4±6.1, VE/VCO2slope 35.4±13.4 vs 32.6±6.1, AT (ml/min/kg) 12.4±4.7 vs 13.9±4.6, RQ 1.08±0.06 vs 1.09±0.04.

In pts treated with carvedilol, subjective improvement in functional capacity as evidenced by NYHA class was not paralleled by objective changes in cardiopulmonary indices. Pts were further divided into 2 groups, based on the presence (n=12) or absence (n=20) of left ventricular restrictive filling pattern (defined as mitral E/A ratio > 1 and deceleration time <120ms) at baseline ECHO-2D recordings. In those with restrictive filling pattern, carvedilol significantly decreased VE/VCO2 slope (41.9±17.2 vs 32.3±10.3, p=0.03) and increased AT (11.8±4.4 vs 14.1±2.4, p=0.06, baseline vs after 3-month therapy, respectively) with concomitant restoration of transmitral flow in 9/12 Pts.

Conclusion: In this study carvedilol therapy exerted neutral effects on objective indices of exercise tolerance in Pts with CHF. Whether in Pts with restrictive LV filling pattern BB may be particularly effective in improving exercise intolerance warrants further investigation.

P524 Tool for prediction of match between positive exercise treadmill test and need for revascularization

O. Kalpak, J. Davcheva-Pavlovska, B. Petrovski, V. Kotevski, S. Kedev, S. Antov, M. Kaev. *Institute for Heart Diseases, Skopje, F.Y. Rep. of Macedonia*

Objectives: Can true positive test be predicted using risk score as tool developed from coefficients using multivariate logistic regression risk-prediction model. Therefore we analyze total of 4268 exercise treadmill tests performed between 01/1999 and 01/2000 using a multivariate logistic regression analysis to identify predictors. The final model vas validated on an independent data set from 836 positive treadmill test results and angiography findings (performed in period from 10/2000 to 09/2001). Match between positive test and need for revascularization assessed by angiography finding was considered as true positive test. A tool for predicting an individual patients risk was developed using a risk prediction score representing the rounded coefficients of the logistic regression model to the closest half-integer.

Results: False positive test occurred in 17.6% of patients. Multivariate regression analysis identified: previous myocardial infarction (odds ratio [OR] 11.5, 95% confidence interval [CI] 9.4-13.8; p<0.001); previous positive test (OR 7.7, 95% CI 5.1-9.2; p<0.001); previous angioplasty (OR 2.7, 95% CI 1.8-3.4; p<0.001); male gender (OR 2.2, 95% CI 1.5-3.4; p<0.001); age 55-60 years (OR 1.8. 95%CI 1.3-2.6; p<0.001) age 61-65 years (OR 2.3, 95% CI 1.6-3.2) over 66 years (OR 2.9, 95% CI 2.1-4.2; p<0.001); exercise below 60% of cardiovascular capacity (OR 2.4, 95% CI 1.3-3.4; p<0.001) Hypotensive response (OR 5.5, 95% CI 3.7-6.3);Symptom limited exercise (OR 3.1, 95% CI 1.6-4.5; p<0.001) as independent predictors of true positive test. Analysis identified Female gender (OR 1.8, 95% CI 1.2-2.2; p<0.001); Hypertensive response to exercise (OR 3.7, 95% CI 2.2-5.2; p<0.001); dispnoe (OR 2.3, 95% CI 1.2-3.2; p<0.001) as independent predictors of false positive test.

Conclusions: We conclude that risk-score tool can facilitate accuracy of positive exercise test.

P525 Patients with coronary stenoses show abnormal regional strain and backscatter despite normal function

S. Yuda[1], Y. Satoshi[2], T. Marwick[1]. [1]University of Queensland, Department of Medicine, Brisbane, Australia; [2]University of Queensland, Department of Medicine, Brisbane, Australia

Background: Although structural and functional changes have been reported in hypoperfused myocardium with left ventricular (LV) dysfunction, it is not known whether such changes occur even in hypoperfused myocardium with normal LV function. We sought whether regional myocardial structural and functional abnormalities in coronary artery disease (CAD) patients with normal LV systolic function could be detected using integrated backscatter (IB) and strain rate (SR) imaging.

Methods: Forty-nine CAD pts (defined by ≥50% stenosis) and 18 controls without significant CAD were studied. All pts had normal wall motion (LV ejection fraction; >55%) and no LV hypertrophy (LV mass index; <131 g/m^2 in men and <100 g/m^2 in women). Gray scale and color tissue Doppler imaging from 3 apical views were stored and analyzed off line and all pts underwent coronary angiography within 6 months. Wall thickness at end-diastole (WT) and percent wall thickening (%WT) were measured in each of 12 segments (excluding apical segments) using anatomical M-mode echocardiography. Cyclic variation (CV) of IB was measured in all 16 segments, and peak strain and SR was calculated in each wall. Calibrated IB intensity (CIB), corrected for pericardial IB intensity, was measured in the septum and posterior wall.

Results: Segments (n=470) subtended by significant stenoses were divided according to stenosis seveity into 3 groups; mild (50-69%, n=170), moderate (70-98%, n=230) and severe (≥99%, n=70). Each parameter in each group was compared with that in control segments (n=288) from pts without CAD (Table). Segments with severe stenosis showed significantly lower CV than that in control segments (p<0.05), with no difference in WT or %WT.

Strain and IB parameters vs stenosis

	Control	Mild	Moderate	Severe
CV (dB)	7.6±2.8	7.7±2.8	7.5±2.6	6.7±2.8*
CIB (dB)	-24.9±7.4	-21.9±7.0	-23.9±6.3	-20.7± 5.9
Peak strain (%)	-26.6±5.2	-27.2±4.8	-26.4±5.6	-26.8± 6.7
WT (mm)	8.6±1.1	8.7±1.4	8.6±1.5	8.7±1.2
%WT (%)	44.5±14.0	45.7±14.7	46.1±12.3	43.5±10.6

Conclusions: Regional myocardial function is impaired in segments with severe coronary stenosis, even without overt infarction and with preserved systolic function.

P526 Trans-ulnar coronary interventions: a feasibility study

O. Bertrand, R. De Larochellière, G. Proulx, R. Lemay, S. Plante, G. Barbeau, O. Gleeton, L. Roy. *Quebec Heart Institute/Laval hospital, Cardiology, Quebec City, Canada*

Since trans-radial coronary catheterisation is not always possible, we have explored the possibility of using the ulnar artery (UA) as an alternative route for coronary intervention.

Percutaneous trans-ulnar coronary catheterisation has been attempted in 43 patients after positive oxymetry (reverse modified Allen test). Reasons for UA approach was operator preference in 41 cases and failed radial artery puncture (n=2). There were 25 men and 18 women. Mean age was 63±12 years. Mean height was 170±7 cm and mean weight was 81±17 kgs. Body surface area was 1.9 ± 0.2 m^2. In 5 cases, the UA could not be canulated due to spasm. In 1 case of planned left main PTCA, we had to change from left UA to right femoral route due to lack of back-up support. Sheath size was 4Fr (n=1), 5Fr (n=26), 6Fr (n=10), 7Fr (n=1). The right UA was used in 35 cases and left UA in 3 cases. There were 25 diagnostic angios (2 previous CABG) and 13 angios followed by adhoc PTCAs. To canulate the left main, we used Multipurpose (n=20), Judkins left (n=16) or left Amplatz (n=2). To canulate the RCA, we used Multipurpose (n = 20), Judkins (n=16) or left Amplatz (n=2) catheters. For PTCA, left main was canulated with an extra-back up (n=10) catheter and RCA with Barbeau (n=2) or right Judkins (n=1) catheters. Abciximab was used in 4 cases and Eptifibatide in 3 cases. Intravascular ultrasound was performed in 5 cases and brachytherapy in 1 cases. The mean duration of the procedures was 40 ±22 minutes. There was no clinical complication.

Trans-ulnar catheterisation may be an elegant substitute for trans-radial approach in selected cases.

P527 Does nitroglycerin mask a warm-up phenomenon in patients with coronary artery disease?

V. Todosiychuk[1], V. Kuznetsov[2], O. Nochrina[1]. [1]Institute of Clinical & Prevent. Card., Tyumen, Russian Federation; [2]Institute of Clinical & Prevent. Card., Tyumen, Russian Federation

The aim of this study was to assess the effects of nitroglycerin on a warm-up phenomenon (i.e. attenuation of myocardial ischemia during repeat exercise testing) in patients with stable angina pectoris.

Methods: Twenty males (52±6 years) with 1-2-vessel coronary artery disease and positive baseline treadmill exercise test (TET) were randomized in a double-blind, 3 day cross-over period study to receive 0,5 mg sublingual nitroglycerin or placebo immediately prior each of two consecutive TET with at 15-minute recovery intervals.

Results: Significantly improvement in some parameters of myocardial ischemia was observed during second TET compared to the first TET after placebo. The duration of exercise was prolonged from 312±160 to 387±165 seconds ($p<0.001$), the maximal ST depression was decreased from 2.1±0.43 to 1.7±0.57 mm ($p=0.003$), as well as the recovery time from 349±106 to 233±86 seconds ($p<0.001$) and the number of ECG leads with 1 mm ST depression from 3.2±1.7 to 2.7±1.6 ($p=0.037$). The heart rate at onset of ischemia increased from 120±18 to 126±21 beats/min ($p=0.001$), the double product at 1,5-mm ST depression increased from 17.54±3.4 to 19.53±4.3 mm Hg/second ($p<0.001$). However, these parameters of two consecutive TET did not change after nitroglycerin administration with a significantly drug test interaction ($p=0.009$, at two-way ANOVA).

Conclusion: Nitroglycerin with 0,5 mg sublingual dose increased anti-ischemic tolerance but it should mask the warm-up phenomenon during repeat exercise tests.

P528 The serum hydroxyproline level, a maker for collagen, is a biochemical marker in patients with vulnerable plaque or plaque disruption

B.S. Yoo, J. Yoon, J.Y. Ko, K.H. Lee, M.S. Ahn, S.H. Lee, S.O. Hwang, K.H. Choe. *Yonsei University, Cardiology Department, Wonju, Korea, Republic of*

Background & Objectives: The activated macrophage secretes proteinases that can break down both collagen and elastin to peptides and eventually amino acids.Evidence from several laboratories suggests that collagen breakdown in coronary artery disease is important for identification of vulnerable plaque or disruption. This breakdown of these structural molecules of the extracellular matrix can weaken the fibrous cap, rendering it particularly susceptible to rupture and precipitation of acute coronary syndromes. Hydroxyproline released in the serum used as an evidence of collagen breakdown or synthesis. Our objective was to compare these collagen markers among patients with stable angina, patients with unstable angina or AMI and healthy individuals.

Methods: Venous blood sampling was obtained at the time of admission. We examined the serum levels of hydroxyproline in 15 patients with stable angina, in 15 patients with unstable angina (Braunwald II or III), in 20 patients with AMI and in 10 healthy subjectes. Serum hydroxyproline level was measured by the amino acid analysis system (HPLC: Pico-Tag system, Waters). Serum c-reactive protein (CRP) was measured in same samples.

Results: There was significant difference in serum hydroxyproline level in patients with acute myocardial infarction (4.92±1.89 μg/L), unstable angina (2.92±0.81 μg/L), stable angina (2.22±1.29 μg/L) and normal control group (2.35±0.92 μg/L). There was no significant difference in serum hydroxyproline level between the stable angina and normal control group ($p>0.05$). However, there was significant elevation of serum hydroxyproline in the patients with unstable angina ($p=0.045$) and AMI ($p<0.01$) compared to the patients with stable angina. There was no relationship between serum hydroxyproline and CRP level ($p>0.05$).

Conclusion: Serum hydroxyproline level in the acute coronary syndrome was significant elevation. So, we think that serum hydroxyproline could be a good biochemical for vulnerable plaque in the coronary artery disease.

P529 Plasma interleukin-6 levels are increased in coronary artery ectasia

L. Tokgozoglu[1], O. Ergene[2], O. Kinay[2], C. Nazli[3], G. Hasçelik[4], Y. Ucarci[2]. [1]Hacettepe University, Cardiology Dept., Ankara, Turkey; [2]Suleyman Demirel University, Cardiology Dept., Isparta, Turkey; [3]Izmir, Turkey; [4]Hacettepe University, Microbiology, Ankara, Turkey

Objective: Coronary artery ectasia is a relatively rare abnormality which is considered to be congenital or acquired in origin. Acquried coronary ectasias have been most commonly attributed to atherosclerosis and less frequently to inflamatory diseases. Recent studies have suggested a cytokine-induced tissue inflamation in the pathogenesis of abdominal aortic aneurysms, depending on the demonstration of increased levels of circulating interleukin-6 (IL-6) in these patients. The aim of this study was to investigate whether a similar association also exists for patients with coronary ectasia, which may also be regarded as an abnormal dilatation of the arterial system.

Method: The study group was composed of 43 patients (58±9.4 years, 26 males) with coronary ectasia and the control group consisted 48 consecutive patients (55±11 years, 20 males) with angiographically normal coronary arteries. Coronary diameters were measured as the maximal diameter for each segment by quantitative angiography. A coronary diameter index was defined for each segment as the coronary diameter divided by the body surface area (BSA). In the study group, a coronary segment with a diameter index of more than 1.5 fold of the control group was defined as ectatic. IL-6 levels were measured from the venous blood samples.

Results: There were no significant differences between the two groups with regard to baseline characteristics such as age, sex, BSA, hypertension, diabetes, smoking and lipid profile. Coronary ectasia was present in a single vessel in 28 patients and in two coronary vessels in 12 patients in the study group. Diffuse ectasia in 3 vessels was observed in 3 patients. Serum IL-6 levels were significantly higher in patients with coronary ectasia compared with the control group (5.18±2.04pg/ml vs 4.13±0.5pg/ml,$p=0.002$). The mean serum IL-6 levels in patients with single vessel,two vessel and diffuse ectasia were as follows: 5.37±2.03pg/ml,4.68±2.04pg/ml and 5.57±2.71pg/ml, respectively. There was no significant correlation with the maximal diameter of the most dilated coronary segment and IL-6 levels in patients with coronary ectasia ($r=0.10$,$p=0.50$).

Conclusion: Results of this study have demonstrated increased levels of circulating IL-6 in patients with coronary ectasia which might indicate a possible role of inflamatory process in the pathogenesis of dilated coronaropathy. Absence of a significant correlation between the dimensions of the ectatic segments and IL-6 levels might be due to the narrower range of the diameters of the coronary arteries compared with the abdominal aorta.

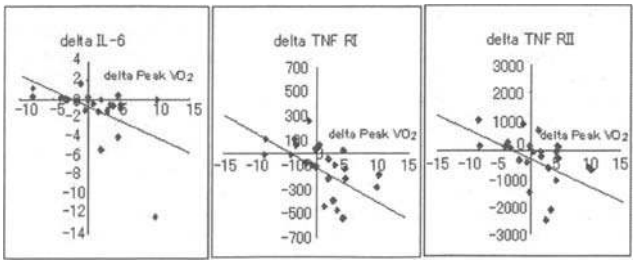
P530 Changes in the cytokine levels reflect the that of functional capacity in patient with heart failure

H. Itoh[1], N. Osada[2], A. Koike[1], A. Tajima[1], T. Maeda[1], Y. Akashi[1], M. Kato[1], L.T. Fu[1]. [1]The Cardiovascular Institute, Cardiology, Tokyo, Japan; [2]St. Marianna Univ, School of Med., Cardiology Dept., Kawasaki, Japan

Recently several investigators have reported that pro-inflammatory cytokines such as tumor necrosis factor (TNF) and its receptors are not only indices for severity but also predictors of mortality in patients with heart failure. We investigated the relationship between cytokine revels and peak VO2, which is a conventional parameter for the prognosis, in the time course of medical treatment in heart failure patients.

Methods: Twenty-three patients with stable chronic heart failure (average ejection fraction: 28.9±9.2%, 60.3±10.7 years) who performed cardiopulmonary exercise testing (CPX) using a cycle ergometer with a ramp protocol were enrolled in this study. Nine months after the initial CPX, the second exercise testing was performed. Plasma concentrations of brain natriuretic peptide (BNP), TNF-soluble receptors I and II (TNFR-I and R-II), and interleukin-6 (IL-6) were measured at the same time.

Results: In the initial CPX, peak VO2 was 17.8±6.6 ml/min/kg. Peak VO2 was did not change as an average at the second CPX (18.9±5.6), while 13 patients out of 23 showed an increase in peak VO2 (4.7±2.9). The plasma cytokine levels in the initial test were as follows; IL-6:2.0±3.2 pg/ml, TNFR-I:1046±336 pg/ml, TNFR-II:2545±1193 pg/ml, and BNP:158±120 pg/ml. And they correlated negatively to peak VO2. The change in peak VO2 (the second-the initial) correlated negatively to those of IL-6 ($r=0.52$, $p=0.01$), TNFR-I ($r=0.54$, $p=0.008$), TNFR-II ($r=0.45$, $p=0.03$), and BNP ($r=0.55$, $p=0.01$).



Delta values of cytokine and peak VO2.

Conclusion: The changes of plasma cytokine levels related to that of exercise capacity. This result suggests that cytokine measurements are useful in predicting improvements or deteriorations in functional capacity in ambulatory patients with chronic heart failure.

P531 The relationship between functional impairment and neurohormonal abnormalities

N. Osada[1], K. Omiya[2], K. Inoue[2], M. Tamura[2], N. Suzuki[2], Y. Akashi[2], A. Seki[2], F. Miyake[2]. [1]Yokohama, Japan; [2]St. Marianna University, Cardiology, Kawasaki, Japan

Peak VO2 is an established parameter for evaluating the severity of heart failure. On the other hand, investigators have recently reported that neurohormonal parameters are useful for the same purpose. This study was designed to evaluate the relationship between peak VO2 and neurohormonal abnormalities.

Methods: We performed cardiopulmonary exercise testing (CPX) in 105 patients with acute myocardial infarction at 1 month after the onset. Plasma concentrations of noradrenaline (NA), brain natriuretic peptide (BNP), and tumor necrosis factor-alpha soluble receptors (TNFR-I and TNFR-II) were measured. Patients were classified into the following three groups: very low capacity (VL: peak VO2<18 ml/min/kg, n=11), low capacity (L: peak VO2=18 to 24 ml/min/kg, n=44), and preserved capacity (P: peak VO2 >24 ml/min/kg, n=50).

Results: Ejection fraction was similar in the three groups. NA was higher in the VL group than in the L group (451±249 vs 341±207pg/ml), and NA was higher in the L group than in the P group(341±207 vs 239±127pg/ml). BNP was also higher in the VL group than in the L group (256±178 vs 85±84pg/ml), and BNP was higher in the L group than in the P group (85±84 vs 49±41pg/ml). While TNFR-I (1257±496 vs 1043±365 pg/ml) and TNFR-II (3566±759 vs 2778±786pg/ml) were higher in the VL group than in the L group, their levels were similar in the L and P groups.

Conclusion: Among heart failure patients, NA and BNP increase even in those with mild exercise intolerance, while TNFR-I and TNFR-II increase in those suffering from more severe cardiac conditions.

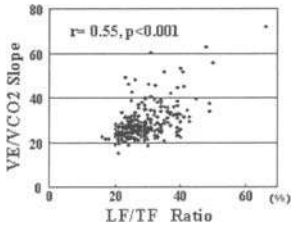
P532 Low-frequency components of exercise VO_2 are coupled to VE/VCO_2 slope in patients with heart failure

E. Hirose[1], H. Takaki[2], O. Tsukamoto[1], Y. Ino[1], Y. Goto[1], K. Sunagawa[2]. [1]National Cardiovascular Center, Division of Cardiology, Suita, Japan; [2]National Cardiovascular Center, Cardiovascular Dynamics Dept., Suita, Japan

Although elevated VE/VCO2 slope (exercise hyperventilation) measured at exercise testing with respiratory gas analysis (CPX) has been shown to have important pathophysiological and prognostic implications in patients with heart failure, the responsible mechanisms are incompletely understood. Similarly, we have few available data explaining the origin of abnormal slow oscillations in ventilation and VO2 seen in these patients. If the same mechanism such as enhanced CO2 chemosensitivity may operate in the manifestation of these two abnormalities, there should be a close relationship between them. We therefore examined the hypothesis that these two abnormalities are coupled to each other. Since we have no available method for quantifying slow oscillations, we estimated VO2 low-frequency components measured at CPX.

Methods: We performed symptom-limited CPX on bicycle ergometer (ramp protocol) in 184 consecutive patients with mild to severe heart failure due to dilated cardiomyopathy (DCM). By using VO2 data (every 6 sec) from rest to peak exercise, we computed low frequency power (LF) in the range of 0.5-1.25 cycles/min and total power of VO2 (TF) with serially performing FFT (4-min time-window, overlapping every 30 sec). VE/VCO2 slope was measured according to the standard method.

Results: LF/TF ratio was significantly correlated with VE/VCO2 slope (r=0.55, p<0.001) as shown in the figure.



LF/TF Ratio vs. VE/VCO2 slope.

Conclusion: Predominant low-frequency components of VO2 were associated with elevated VE/VCO2 slope, suggesting the possibility that the same mechanism, such as enhanced CO2 chemosensitivity, contributes to the genesis of elevated VE/VCO2 slope and slow oscillations in VO2.

P533 Effect of a home based telecardiology on chronic heart failure outcomes: a case control pilot study

S. Scalvini, E. Zanelli, M. Volterrani, O. Buscaya, D. Domenighini, A. Giordano. Cons for Res and Devel of Telemedicine, Dept of Cardiology S Maugeri IRCCS, Gussago, Italy

Chronic heart failure (CHF) remains a common cause of disability and death and the extensive requirement for hospital admission represents a major burden to health-care system. Previous investigations suggest that home-based intervention has the potential to decrease the rate of hospital readmission, prolong event-free and total survival and improve quality of life.

Aim of our study was to analyse a home based intervention with a telecardiology system in CHF patients (pts).

Seventy four CHF pts, aged 59±9 years in stable conditions and with optimised therapy were enrolled. The program consists in a transtelephonic follow-up and ecg monitoring (HBT: home based telecardiology) followed by paramedical and medical team. The pts received a portable device, transferring by a mobile or fixed telephone a one lead trace to a receiving station where a nurse was available for reporting and interactive teleconsultation (providing information on health status, symptoms, weight, diuresis, drug adjustment and optimization). The patient can call the centre when he need (teleassistance), while the team call the patient with scheduled appointment (telemonitoring). Comparison of one-year clinical outcomes were made between HBT patients and a control group of 74 patients matched 2:1 to HBT patients on age, sex, NYHA class, EF% and VO2 peak (UC). A significant reduction in instabilisations (55.4% vs 23.9%; p<0.0001; RRR 0.57; CI 0.12-0.59) and hospitalisations (36.5% vs 18.3%; p<0.01; RRR 0.5; CI 0.18-0.83) and were observed in HBT group in comparison with UC group. No significant difference was found on mortality between groups. These results suggest that a telecardiology service could detect and prevent clinical instabilisations and reduce rehospitalisation in CHF patients.

THE PERIPHERY IN CHRONIC HEART FAILURE

P534 Chemical mediators of the muscle ergoreflex in chronic heart failure: a putative role for prostaglandin in reflex ventilatory control

A.C. Scott[1], C.H. Davos[1], A. Kaczmarek[2], R. Wensel[1], P.P. Ponikowski[2], A.J.S. Coats[1], M. Piepoli[3]. [1]Imperial College School of Medicine, Cardiac Medicine, London, United Kingdom; [2]Medical Academy, Cardiology, Wroclaw, Poland; [3]Piacenza, Italy

Background: The overactivity of ergoreceptors (intra-muscular afferents sensitive to products of skeletal muscle work) may be responsible for the abnormal responses to exercise and symptoms of exercise intolerance in chronic heart failure (CHF); however little is known of the chemical nature of the stimuli involved. We investigated biochemical factors (H^+, PvCO2, PvO2, HCO3, K^+, Phosphate, Lactate, PGE2, PGF1alpha, bradykinin) potentially involved in ergoreceptor activation.

Methods and Results: Sixteen stable CHF patients (64.9±2.7years, peakVO2 15.8±0.7ml/kg/min) and 10 age-matched normals were studied. The ergoreceptor test involved two 5-minute handgrip exercises. On one occasion the subjects recovered normally (control recovery), while on the other a post handgrip regional circulatory occlusion (PH-RCO) was induced in the exercising arm, isolating the stimulation of the ergoreceptor after exercise. The ergoreflex was quantified as the difference in ventilation between the PH-RCO and the control recovery periods. During the protocol the local muscular blood effluent concentrations of metabolic mediators were assessed. Patients had an ergoreflex effect on ventilation greater than normals (4.8±1.4 vs. 0.4±0.1L/min, p<0.01). During the ergoreflex test in patients, the following metabolites were elevated with respect to resting values in comparison with normals: PGE2 (3.7±0.7 vs. 1.1±0.2pg/ml), PGF1alpha (16.2±2.8 vs. 7.2±1.2pg/ml) and bradykinin (2.1±0.3 vs. 1.0±0.1pg/ml), p<0.05 for all comparisons. Only the increases in prostaglandin were predictors of the ergoreflex response (r>0.41, p<0.01). Eight patients on aspirin vs. those eight not on aspirin presented lower ergoreflex activity in the control of the ventilatory response (2.1±0.6 L/min vs. 7.5±2.3 L/min, p<0.05), associated with reduction of blood concentration of PGF1a (10.7±2.9 pg/ml vs. 21.1±3.2 pg/ml, p<0.05) and not significant changes in PGE2 (3.1±0.8 pg/ml vs. 4.6±0.8 pg/ml, p=NS).

Conclusion: Although multiple metabolites are concentrated in exercising muscle in CHF, only prostaglandin correlated with ergoreflex activity suggesting these factors as potential triggers to the exaggerated ergoreflex which is characteristic of CHF. This may have important implications for novel therapies to improve exercise tolerance.

P535 Desmin-free cardyomyocytes and myocardial dysfunction in end-stage heart failure

S. Di Somma[1], M.P. Di Benedetto[2], G. Salvatore[2], M.I. Scarano[3], S. Montagnani[3], G. Cudemo[2], L. Agozzino[4], G. Caputo[2]. *[1]S.Andrea Hospital La Sapienza Roma, Cardiology, Rome, Italy; [2]University "FedericoII", Clinical Experimental Medicine, Naples, Italy; [3]University Federico II, Biomorphology and Functional Science, Naples, Italy; [4]Second University, Patology Department, Naples, Italy*

In previous paper we demonstrated that in mild dilatative cardiomyopathy in humans, cardiomyocyte desmin disarray was associated "in vivo" with reduced actin-myosin contractile function.
The objective of this study has been to evaluate the role of desmin on myocyte contractility in end-stage heart failure.We studied 18 hearts explanted from patients undergoing heart trasplantation (10 for coronary artery disease and 8 for dilatative cardiomyopaty).Cardiac biopsies from donor's heart rapresented the control myocardium.
Immunoflorescence with desmin antibody was performed on paraffin-embebbed sections of cardiac specimens and evaluated by confocal mycroscopy.On the same samples Actin-myosin in vitro motility assay was performed in order to obtain cellular contractile function.Moreover PCR analysis of desmin in normal and pathological heart was obtained on frozen myocardial tissue.
Results: Compared to healthy cardiac tissue, in end-stage heart failure myocardium there was a significant($p<0.01$)presence of desmin -free myocytes at immunostaining with non difference between dilatative and ischemic cardiomyopathy.At PCR analysis there was a significant($p<0.03$)reduction of desmin content in disesed hearts compared to controls.Moreover there was a significant reduction of in vitro actin-myosin coupling rate in heart failure myocardium conpared to normal heart.A significant negative ($r=-0.65$; $p<0.05$) relation-ship between number of desmin-free myocytes and actin-myosyn contractile rate was found.
Conclusion: In end-stage heart failure, both fron ischemic or idiophatic origin ,compared to normal hearts,there is the presence of desmin -free myocytes. This finding is related to myocardial cellular dysfunction and could rapresent a marker of prognosis in the decision making for patients in waiting list for heart trasplantation.

P536 Left ventricular hypertrabeculation/noncompaction in 62 patients: prevalence and association with other cardiac and neuromuscular disorders

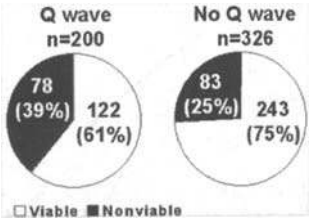
C. Stöllberger[1], J. Finsterer[2], G. Blazek[3], W. Kopsa[4]. *[1]Wien, Austria; [2]Rosenhügel, Neurologisches KH Dept, Vienna, Austria; [3]Hanusch Krankenhaus, Cardiology Dept., Vienna, Austria; [4]Radiologische Abteilung, KA Rudolfstiftung, Vienna, Austria*

Background and objectives: Few data are available about the prevalence of left ventricular hypertrabeculation/noncompaction (LVHT), the number of investigations necessary to diagnose LVHT and the rate of associated cardiac and neuromuscular disorders (NMD). Aim of the study was thus to assess 1. the prevalence of LVHT, 2. the number of echocardiographic examinations necessary to diagnose LVHT, 3. cardiac abnormalities are associated with LVHT and 4. the rate of NMD in patients with LVHT.
Methods: LVHT was diagnosed if in one plane >3 trabeculations apically to the papillary muscles were seen and Doppler imaging visualized intertrabecular spaces perfused from the ventricular cavity. All patients in whom LVHT was diagnosed between June 1995 to December 2001 underwent a clinical cardiological examination. It was noted, after how many examinations LVHT was diagnosed. All LVHT-patients were invited for a neurological examination.
Results: LVHT was diagnosed in 62 (12 female) patients with a mean age of 50 (18-75) years. The prevalence of LVHT was 0.24%/year. In 47% of the patients LVHT was diagnosed at the first echocardiographic examination, in 25% >3 examinations were necessary. In 97% of the patients LVHT was associated with echocardiographic abnormalities, ECG abnormalities in 92%, cardiac symptoms in 89%, heart failure in 73% and arrhythmias in 65%. Among the 49 LVHT-patients who underwent a neurologic examination, 82% had a NMD and 18% were neurologically normal.
Conclusions: LVHT is a heterogeneous echocardiographic finding which is often overlooked, more prevalent than previously believed and associated with NMD in the majority of patients.

P537 Assessment of viable tissue in Q-wave regions by metabolic imaging using single-photon emission computed tomography in ischaemic cardiomyopathy

A.F.L. Schinkel, J.J. Bax, A. Elhendy, E.C. Vourvouri, M.A. Bountioukos, F.B. Sozzi, J.R.T.C. Roelandt, D. Poldermans. *Erasmus Medical Center Rotterdam, Cardiology Dept., Rotterdam, Netherlands*

Aim: Chronic electrocardiographic Q waves are often believed to reflect irreversibly scarred, transmurally infarcted myocardium. The aim of this study was to evaluate whether residual viable tissue persists in dysfunctional myocardial regions related to chronic Q waves on the surface electrocardiogram in patients with heart failure.
Methods: A total of 148 patients with healed myocardial infarction and impaired left ventricular (LV) function presenting with heart failure symptoms underwent electrocardiography and metabolic imaging using Tc-99m-tetrofosmin/F18-fluorodeoxyglucose (FDG) single-photon emission computed tomography (SPECT). Patients with primary cardiomyopathy, significant valvular disease or left bundle branch block were excluded. The LV was divided into 4 major regions to compare myocardial viability in regions with and without chronic Q waves on surface electrocardiography.
Results: According to FDG SPECT metabolic imaging, residual viable tissue persisted in a high proportion (61%) of dysfunctional myocardial regions with chronic Q waves. Regions with chronic Q waves were more often dysfunctional than regions without Q waves. Moreover, dysfunctional regions with chronic Q waves were less frequently viable compared to dysfunctional regions without Q waves on the electrocardiogram.



Viability in infarcted regions.

Conclusion: This study demonstrates that chronic Q waves on electrocardiography in patients with heart failure do not necessarily imply irreversibly scarred myocardium. Residual viable tissue persists in a high proportion of dysfunctional ventricular regions according to FDG SPECT metabolic imaging.

P538 Human urotensin II and big endothelin in patients with chronic heart failure

S. Krüger[1], J. Graf[1], U. Janssens[1], T. Stickel[1], D. Kunz[2], P. Hanrath[1]. *[1]University clinic, Medical Clinic I, Aachen, Germany; [2]Clinical chemistry, University clinic, Aachen, Germany*

Background: Human urotensin II (hU-II) is the most potent mammalian arterial vasoconstrictor identified so far, but it has also vasodilating properties. HU-II receptors are predominant in the human heart and arterial vessels, suggesting to be of importance as a cardiovascular mediator. Aim of this study was to measure hU-II plasma concentrations in patients with and without chronic heart failure (CHF) at rest and exercise, to examine its correlation with exercise capacity and to compare it with the vasoconstrictor big endothelin.
Methods: We prospectively studied 32 patients (pts) with CHF (60 ± 12 years, 7 women, LVEF 26 ± 6%) and 10 healthy controls (54 ± 12 years, 5 women, LVEF 60 ± 4%). All CHF pts had a LVEF < 35%. Cardiopulmonary exercise testing was performed in all CHF pts and controls. Serum levels of hU-II (enzyme immunoassay, Immundiagnostik, Bensheim, Germany) and big endothelin (ELISA, Immundiagnostik, Bensheim, Germany) were measured prior to symptom-limited bicycle exercise and at peak exercise.
Results: Peak VO2 was significantly lower in CHF pts than in controls (14.7 ± 3.6 vs. 19.8 ± 3.8 ml/min/kg, $p < 0.01$). HU-II concentrations at rest were comparable in CHF pts (2990 ± 1104 pg/ml, range 1730 - 7010 pg/ml) and controls (3290 ± 508 pg/ml, range 2710 - 3750 pg/ml, n.s.). At peak exercise hU-II plasma levels were still not significantly different in CHF pts and controls (3063 ± 1185 vs. 3213 ± 1188 pg/ml, n.s.). HU-II concentrations at rest and at peak exercise showed no significant alterations in pts with CHF and controls. HU-II concentrations at peak exercise correlated better with peak VO2 in controls ($r = -0.61$, $p <0.01$) than in CHF patients ($r = 0.25$, $p <0.01$). Resting hU-II levels demonstrated no correlation with peak VO2 in controls or CHF patients. Big endothelin levels were significantly higher in CHF pts compared to controls at rest (2.8 ± 1.8 vs. 1.7 ± 0.1 fmol/ml, $p < 0.01$) and after exercise (2.7 ± 1.7 vs. 1.6 ± 0.2 fmol/ml, $p <0.005$).
Conclusions: This is the first report about in vivo studies of hU-II plasma concentrations in CHF. HU-II levels allowed no discrimination between patients with and without CHF. Physical exercise did not lead to significant changes in circulating hU-II neither in CHF patients nor in controls. In contrast, big-endothelin, an established vasoconstrictor, demonstrated significant elevation in CHF patients compared to controls at rest as well as after exercise.

P539 Why are patients with congestive heart failure due to systolic dysfunction discharged without angiotensin-converting enzyme inhibitors?

M. Martínez-Sellés[1], J.A. García Robles[1], L. Prieto[2], J.A. Serrano[1], R. Muñoz[1], E. Frades[3], J. Almendral[1]. *[1]Madrid, Spain; [2]Universidad Complutense, Biostatistics Dept., Madrid, Spain; [3]Gregorio Maranon University Hospital, Cardiology Dept., Madrid, Spain*

Introduction: Although a number of well-designed prospective trials have demonstrated that ACE inhibitors improve survival in pts with heart failure (HF) due to systolic ventricular dysfunction, information exists about the under prescription of ACE inhibitors to these pts.
Purpose: To study the factors that determine prescription of ACE inhibitors in pts with HF and ventricular dysfunction discharged from our hospital
Methods: A total of 1,953 HF or related diagnosis were done among patients older than 15 years consecutively admitted to our institution during 1 year period. Their hospital records were collected and retrospectively checked. We excluded pts: a) in whom the presence of HF could not be objectively determined, b) with acute MI, c) in whom some data were not available. Echocardiography was performed in 706 pts and 381 had LVEF $\leq$0.5 (54%), 355 (93%) were discharged alive. To identify factors that prevented ACE inhibitors prescription a multivariate analysis was done.
Results The number of pts discharged on ACE inhibitors was 244 out of 355 (69%). Pts with ejection fraction < 0.30 received more ACE inhibitors than pts with ejection fraction between 0.3 - 0.4 or 0.4 - 0.5 (77, 66 and 51%, respectively, p < 0.001). Factors that prevented ACE inhibitors prescription are depicted in the table (multivariate analysis).

Variables related with no ACEi treatment

	OR (CI 95%)	p
Renal insufficiency	4.1 (2.3 -7.5)	<0.00001
Aortic stenosis *	1.8 (1.2 - 2.5)	0.002
Ventricular dysfunction**	0.55 (0.41- 0.73)	0.0001

* Codified from no=0 to severe=3.** Codified from ejection fraction 0.4-0.5=1 to ejection fraction <0.30=3Area under ROC curve: 0.77 (0.72 – 0.82)

Conclusions: Hospitalized pts with HF due to systolic dysfunction are more frequently discharged without ACE inhibitors if they have renal insufficiency, aortic stenosis or less severe systolic dysfunction.

P540 Incidence and progression of cardiac lesions in systemic sclerosis

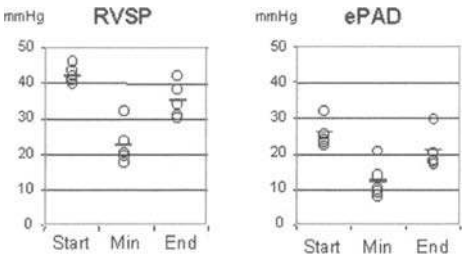
I. Moyssakis[1], V. Vassiliou[1], P. Sfikakis[2], N.J. Pantazopoulos[1], V. Votteas[1], M. Kyriakidis[1]. *[1]"Laiko" Hospital, Department of Cardiology, Athens, Greece; [2]"Laiko" Hospital, Department of Rheumatology, Athens, Greece*

Background: Systenic sclerosis is characterized by fibrous thickening of the skin and associated degenerative disease of the fingers, oesophagus, bowel, kidneys, lungs and heart. This study aimed to echocardiographically investigate the frequency, severity and evolution of cardiac lesions in patients (pts) with diffuse Systemic Sclerosis (SSc).
Material and Methods: Sixty-four (60 females – 4 males, aged 59 ± 11 years) pts with SSc were evaluated with M-mode, 2D and Doppler echocardiography after a follow-up period of 42 ± 12 months. The left ventricular fractional shortening (FS) and the velocity of tricuspid regurgitant jet pius the right atrial pressure served as indices of LV systolic function and pulmonary systolic pressure. Organic valvular involvement was defined as valve thickening and/or regurgitation. Left ventricular mass index was calculated by the Penn convention formula.
Results: Left ventricular systolic dysfunction (FS<29%) was present in 8 pts (12.5%) in the first study and in 11 (17%) in the last. Valvular involvement occurred in 12 pts (18.7%) in the beginning and 17 (26.5%) in the end. Pulmonary hypertension was detected in 13 patients (20.3%) in the first and in 28 (43.7%) in the last study (p<0.05). Left ventricular mass index appeared significantly different between the two measurements (102.5 ± 22 vs 114 ± 26 g/m^2, p<0.01).
Conclusion: Our results show that the evolution of cardiac lesions in SSc is rapid, with most significant changes being pulmonary hypertension and left ventricular mass index.

P541 Haemodynamic response to dialysis in patients with chronic renal failure and impaired ventricular function

F. Braunschweig[1], N. Clyne[2], K. Larsson[2], B. Kjellström[3], C. Linde[1]. *[1]Karolinska Hospital, Dept of Cardiology, Stockholm, Sweden; [2]Karolinska Hospital, Dept of Nephrology, Stockholm, Sweden; [3]Medtronic Inc, Bakken Research Center, Maastricht, Netherlands*

Background: Cardiovascular complications are the major cause of morbidity and mortality in patients with chronic renal failure and seem to become exacerbated after the start of maintenance dialysis. Repeated volume overload between dialysis sessions and pressure drops during hemodialysis may contribute to this.
Methods: Five patients on maintenance hemodialysis, age 53-76, with systolic and/or diastolic heart failure (EF 20-50%) received an implantable hemodynamic monitor (IHM, Chronicle® model 9520, Medtronic). The IHM consists of a memory device implanted subcutaneously and a transveneous right ventricular (RV) lead carrying a pressure sensor placed in the RV outflow tract. It continuously records heart rate, RV systolic (RVSP) and diastolic pressures (RVDP), pulse pressure, dP/dt and an estimate of pulmonary artery diastolic pressure (ePAD).
Results: RVSP and ePAD dropped by 35-45% during all dialysis sessions in each patient, irrespective of systolic and diastolic LV dysfunction. This drop occurred immediately after start of dialysis and was partly restored at termination. Between dialysis sessions, cardiac filling pressures reached levels typically seen in heart failure (RVSP at start of dialysis 42 ± 3 mmHg). The figure shows mean RVSP and ePAD values during dialysis (min = minimum pressure).



Pressure changes during dialysis.

Conclusion: The observed cyclic changes in right ventricular pressures during dialysis could have a detrimental effect on ventricular performance. Whether the pressure recordings from the monitor may help in optimising the dialysis protocol to avoid these pressure changes remains to be determined.

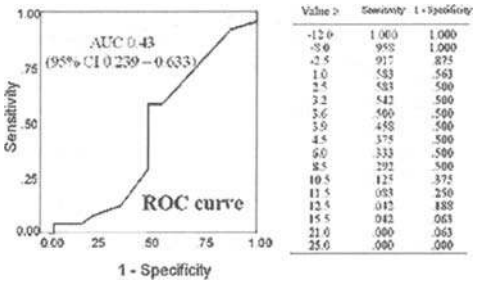
P542 Fail of non-invasive evaluation of flow-mediated vasodilation in the differentiation between ischaemic and non-ischaemic dilated cardiomyopathy

R. Moreno[1], J. Zamorano[1], A. D Ovidio[1], C. Almeria[2], J.L. Rodrigo[2], L. Alvarez[1], D. Herrera[2], L. Sánchez-Harguindey[2]. *[1]Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain; [2]Hospital Gregorio Marañón, Interventional Cardiology Dept., Madrid, Spain*

Recently, high frequency transducers have been introduced in the Echo Labs to non-invasively measure flow-mediated endothelial function. Aim of the study was to evaluate whether endothelial dysfunction assessed by this method could differentiate ischemic from non-ischemic dilated cardiomyopathy (DC).
Methods: 40 patients with DC undergoing cardiac cath were studied. Flow-mediated brachial artery vasodilation was measured using high-frequency transducers (Agilent 5500 or Aloka SSD 870 equipments). ROC curves were constructed in order to identify whether any cut-off could differentiate between ischemic and non-ischemic DC.
Results: Out of the 40 patients, 24 (60%) had ischemic, and the remaining 16 (40%) non-ischemic DC. Patients with ischemic DC had a significantly higher basal brachial artery diameter, but there were not significant differences between endothelial function between both groups. Moreover, ROC curve did not provide any cut-off that could be of help in differentiating between both groups (see table and figure).

Ischemic vs non-ischemic DC

	Non-ischemic DC	Ischemic DC	p
Basal brachial artery diameter (mm)	3.97±0.56	4.37±0.60	0.04
Hyperemia diameter (mm)	4.18±0.47	4.54±0.72	NS
% brachial vasodilation	6.00±8.07	3.97±6.25	NS
Endothelial dysfunction	8 (50.0%)	15 (62.5%)	NS



ROC curve.

Thus, the non-invasive evaluation of flow-mediated endothelial function is not useful in the differentiation between ischemic and non-ischemic DC.

P543 Spectrum of risk factors and comorbidity in a hospitalized population with congestive heart failure

M. Martínez-Sellés[1], J.A. Garcia Robles[1], L. Prieto[2], J.A. Serrano[1], R. Muñoz[1], E. Frades[1], J. Almendral[1]. [1]*Madrid, Spain;* [2]*Universidad Complutense, Biostatistics Dept., Madrid, Spain*

Introduction: The progressive aging of population along with increased survival of patients with ischaemic heart disease and high blood pressure, as a result of improvements in treatment, are leading to increasing prevalence of congestive heart failure (CHF) mainly in the elderly. The aim of this study was to investigate the frequency of comorbid diseases in hospitalized CHF patients.
Methods: A total of 1953 CHF or related diagnosis were done among patients older than 15 years consecutively admitted to our institution during 1 year period. Their hospital records were collected and retrospectively checked. We excluded 454 patients that did not fulfill the established criteria of CHF, 69 patients with acute myocardial infarction and 72 patients in whom some data were not available. Therefore we studied 1358 admissions in 1075 patients (1.27 admission per patient).
Results: Mean hospitalization time was 16 ± 15.5 days (median 12 days). Mean age was 74.7 ± 11.6 years and 42% were men.
Risk Factors: Hypertension (43%), diabetes (30%), smoking (16%) and hyperlipidemia (11%).
Comorbidity: A. Cardiovascular diseases: atrial fibrillation (AF)(49%), previous myocardial infarction (15%), previous stroke (12%), left bundle branch block (11%), severe coronary stenosis (9%), right bundle branch block (8%), valvular surgery (7%), pacemaker (7%), peripheral vascular disease (6%) and CABG (4%). B. Systemic diseases: chronic pulmonary disease (CPD)(30%), renal disease (14%), alcoholism (8%), ulcer disease (6%), severe obesity (6%), dementia (6%), liver disease (5%) and cancer (4%).
Conclusions: The majority of our hospitalized patients with CHF are women, and have an advanced age, and long admissions. We found frequent multiple comorbidity, prevalence of AF, CPD, diabetes and renal disease among patients admitted with CHF was particularly high.

P544 Neurohumoral effects of weight loss in surgically treated obese patients

S. Nodari[1], M. Metra[1], A. Dei Cas[2], E. Trussardi[1], N. Pezzali[1], C. Giovanelli[1], G. Milesi[1], L. Dei Cas[1]. [1]*Chair of Cardiology, University of Brescia, Brescia, Italy;* [2]*University of Parma, Medicine Dept., Parma, Italy*

Obesity may cause major changes of the neurovegetative balance with an increase in the sympathetic drive which may have an important role, not only in the pathogenesis of obesity, but also in the development of cardiovascular diseases and cardiac death. In this study we used power spectral analysis (PSA) of heart rate variability (HRV) and plasma levels of catecholamines to test the hypothesis that weight loss may reverse obesity related disturbances in cardiovascular autonomic function.
Thirty-three obese patients (mean body mass index, 47.8; mean age, 38±10 years) were studied by PSA of HRV at baseline and after a 50% loss of the excessive body weight (BW), compared to the ideal one, obtained by surgical therapy. The total power (TP) of HRV, its low frequency (LF) and high frequency (HF) components and the LF/HF ratio were measured in basal conditions, during spontaneous breathing, during vagal stimulation by controlled breathing and during sympathetic stimulation by mental stress test. Plasma levels of norepinephrine and epinephrine were assessed with the patient in the resting condition. During spontaneous breathing, weight loss caused a significant reduction in the LF ($P < 0.001$) with a concomitant increase in the HF ($P < 0.0001$) component and a reduction in the LF/HF ratio ($P<0.001$). Vagal stimulation by controlled breathing caused a significant reduction in the LF ($P<0.005$) and an increase in the HF ($P<0.05$) component of HRV, at baseline, before weight reduction, with a further, highly significant, increase in vagal drive shown by the further reduction in the LF/HF ratio ($P<0.00001$), after weight loss. Sympathetic stimulation by mental stress did not cause any significant change of the LF component, at baseline. In contrast, weight loss was associated with a significant increase in the LF/HF ratio during mental stress ($P<0.0001$). Thus, weight loss was associated with an increase of both the vagal and the sympathetic responses. Assessment of plasma catecholamines showed a significant decrease in both plasma norepinephrine and epinephrine levels after weight loss (from 538±131 to 253±42 pg/ml and from 228±113 to 55±6 pg/ml, respectively, $p<0001$ in both cases).
In conclusion, we have shown that obese patients have an increase in the sympathetic drive at baseline, with a very low response to sympathetic stimulation. Weight loss reduces the LF/HF ratio, with a concomitant increase in the response to both sympathetic and vagal stimulation. These favorable hemodynamic and functional changes are attended by a significant reduction in cathecolamine plasma levels.

P545 Elevated left ventricular filling pressures and impaired alveolar-capillary diffusion capacity in chronic heart failure: any link?

G. Pontone[1], M. Guazzi[2], M.D. Guazzi[2]. [1]*Centro Cardiologico Monzino, IRCCS, Milan, Italy;* [2]*University of Milan, Milan, Italy*

Background: In chronic heart failure (CHF) the occurrence of an impaired alveolar-capillary diffusing capacity, as assessed by carbon monoxide technique (DLco), is well established. Specifically, an increased resistance to gas exchange negatively affects the clinical status and exercise performance of these patients. The relationship between the increased left ventricular filling pressures (FPs) and a reduced DLco has not been characterised before. We aimed at evaluating whether, in CHF, higher FPs are associated with an abnormal DLco.
Materials and Methods: 21 CHF patients (male/female: 19/2; mean age 63±9 years) with an average EF of 36%±11% underwent clinical, echocardiographic and metabolic stress testing evaluation. Alveolar gas exchange was also investigated by measuring DLco, analysing its membrane (DM) and capillary volume (Vc) components. FPs were measured by combining transmitral [(early diastolic flow (E) and late diastolic flow (A)] and pulmonary venous flows and peak velocity of mitral anulus pulsed tissue Doppler velocity-time (TDI) waves (means of septal and lateral velocities) in systolic phase (TDIs), and early (TDIpd) and late diastolic phase (TDItd). Accordingly, patients were divided in 2 groups: group 1, with normal FPs (transmitral peak E/A velocities <1.2 and E deceleration time >150 msec; pulmonary venous systolic/diastolic integrals >1; E/TDIpd ratio <10) and group 2 with high FPs (transmitral peak E/A velocities>1.2 and E deceleration time <150 msec; pulmonary venous systolic/diastolic integrals<1; E/TDIpd ratio >10).
Results: Group 1 compared to Group 2 presented with an higher DLco (25.5±7.0 vs 16.7±6.0 ml/min/mmHg; $p<0.01$), DM (32.7±6 vs 24.5±9 ml/min/mmHg; $p<0.05$), TDIs (12.8±3.3 vs 8.8±1.0 cm/sec; $p<0.05$), TDItd (13.2±5.5 vs 9.3±3.3 cm/sec; $p<0.05$) and a reduced E/TDItd (4.4±2.1 vs 7.6±3.5; $p<0.05$). By using the Receiving Operating Characteristic (ROC) methodology a DLco cut-off of 21 ml/min/mmHg was identified. This cut-off separated group 1 from group 2 with a high specificity (73%) and sensitivity (87%).
Conclusions: CHF patients with higher FPs present with an increased resistance to gas exchange. Putative diastolic mechanisms sustaining an increase in FPs seem to be the same background for the development of gas exchange abnormalities and DLco impairment.

P546 Cardiac calcification is highly predictive for increased mortality in younger patients with congestive heart failure: prospective follow-up study

G. Kamensky[1], E. Piknova[2], R. Sidlo[3], N. Plevova[1], P. Drahos[1], L. Trenèianska[1], E. Polak[4], I. Ondrus[5]. *[1]Ruzinov University Hospital, Dept. Noninvasive Cardiovasc. Diagnost, Bratislava, Slovakia; [2]Ruzinov University Hospital, Dept. Noninvasive Cardiovasc.Diagnost, Bratislava, Slovakia; [3]University of Economy, Department of Statistics, Bratislava, Slovakia; [4]Ruzinov University Hospital, Dept. of Internal Medicine 1, Bratislava, Slovakia; [5]Ruzinov Faculty Hospital, Department of Internal Medicine 2, Bratislava, Slovakia*

Objectives: Multiple cardiac calcifications are much less frequently observed in younger pts and although their presence is generally associated with adverse cardiovascular outcomes, it is unclear whether they increase mortality in younger pts with CHF.
Methods: We prospectively studied 469 consecutive pts (199 males, 270 females, mean age 72±9y) admitted to hospital due to congestive heart failure (NYHA II-IV). Univariate and multivariate analyses were performed to test the association between the presence of aortic valve sclerosis (AVS), aortic root calcification (ARC) and mitral annular calcification (MAC) detected by 2D echocardiography, and total mortality during a follow-up in pts with CHF younger and older than 65y. The mean follow-up was 28±7 months.
Results: 110 pts (23%, mean age 56±6y) were younger than 65y and 359 pts (77%, mean age 76±6y) were older. The younger pts, compared to the older, had significantly higher BMI (30.3 and 27.9, resp., p=0.001), a larger left atrium (4.8 cm and 4.5 cm, resp., p=0.001), a higher uric acid (485.5 and 451.9, resp., p=0.05) and triglycerides (1.67 and 1.44, resp., p=0.05). Older pts had significantly more frequently MAC (p=0.05), AVS (p=0.0001), ARC (p=0.0001), as well as the combination of MAC+AVS+ARC together (0.0001). No diferences were observed in other risk factors including LVEF. In therapy, younger pts had more statins and calcium channel blockers (p=0.005 and 0.05) compared to older pts. During the follow-up 24 (22%) pts died in the younger group compared to 175 (49%) in older group (p=NS). Using the Kaplan-Meier survival curve model there was a 19% increase of total mortality (log rank = 47.3, p=0.0001) in pts with the presence of MAC+AVS+ARC compared to those without this finding. In the younger group, there was an even higher increase of mortality (24%, log rank = 27.6, p=0.0001). After adjusted multivariate Cox proportional-hazard analysis, age (OR 1.06, p=0.0001, 95% CI 1.03-1.08), MAC+AVS+ARC (OR 2.64, p=0.005, 95% CI 1.40-3.47) and uric acid (OR 1.14, p=0.05, 95% CI 1.05-1.23) were the only independent predictors of increased mortality in the whole group of pts. In younger pts OR of MAC+AVS+ARC was much higher (OR 16.0, p=0.0001, 95% CI 5.03-51.17).
Conclusion: Younger pts with CHF and multiple cardiac calcifications have a 16-times higher risk of death compared to those without calcifications. Therefore, multiple cardiac calcifications should be considered as a powerful independent predictor of increased mortality particularly in younger pts with CHF.

P547 Does the degree of hyperglycemia influence diastolic myocardial function in patients with type 2 diabetes?

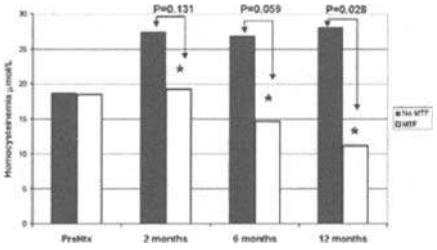
H. von Bibra, V.G. Dounis, A. Hansen, K. Malmberg, L. Rydén. *Karolinska Hospital, Cardiology, Stockholm, Sweden*

Diastolic left ventricular function is impaired in patients with diabetes mellitus. The relationship of glucose control to diastolic function has not been well defined in D patients. We tested the hypothesis, that the degree of hyperglycaemia influences diastolic myocardial function in patients with type 2 diabetes (D).
Methods: 33 D (mean age 59±8 years) had systolic (Vs) and diastolic (Vd) regional myocardial velocities assessed with pulsed Doppler tissue imaging in 12 left ventricular segments. Subgroups were defined according to the diagnosis or exclusion of ischemic heart disease by dobutamine stress echocardiography (SE). 25 D were studied before and after 3 weeks of improved metabolic control and 7 D with unchanged treatment and unchanged metabolic control (C).
Results: In the 9 patients with normal SE, there was a significant negative correlation between Vd and age (r=0.85, p<0.003) and Vd and fasting blood glucose (r=0.76, p<0.02) before and after improved metabolic control (r=0.83, p<0.006 and r=0.87, p<0.002) respectively. The remainders did not demonstrate such correlation as ischemic heart disease impairs Vd independently. In C, fasting blood glucose, Vd and Vs remained unchanged. After improved metabolic control, fasting blood glucose decreased by 3.7±2.7 mmol/L, Vd increased from 7.9±1.6 cm/s to 8.8±1.7 cm/s (p<0.01) and Vs remained unchanged (6.2±1.0 and 6,6±0.9 cm/s). The changes in Vd were significantly correlated to the change in fasting blood glucose after improved metabolic control in all patients: r=0.53, p<0.002.
Conclusion: Diastolic dysfunction in diabetic patients is influenced by the degree of hyperglycaemia and, additionally, ischemic heart disease and by increasing age. Strict glycemic control, however, may augment Vd in all these states.

P548 Effect of folate supplementation on allograft vascular disease after one year from heart transplant: a prospective randomized trial

L. Potena, G. Magnani, F. Grigioni, P. Ortolani, C. Marrozzini, A. Marzocchi, C. Magelli, A. Branzi. *University of Bologna, Institute of Cardiology, Bologna, Italy*

Introduction: Graft vascular disease (GVD) is a major determinant of mortality in heart transplant (HT) recipients. High serum homocysteine (tHcy) levels may enhance GVD progression. Although folate supplementation decreases tHcy, it is unknown whether folate may directly influence GVD progression. This prospective randomized study aimed to examine the effect of calcium 5-n-methil-tetrahydrofolate (MTF) administration on GVD detected by intravascular ultrasound (IVUS).
Methods: 29 consecutive HT recipients (79% males, aged 53±12, 37% with ischemic cardiomyopathy) randomly assigned to receive MTF 15mg. Serum levels of tHcy were determined before HT and 2, 6 and 12 months after HT. Complete lipid panel was also determined. IVUS of left anterior descending (LAD) was performed after 1 and 12 months from HT. Planimetry of intimal area (IA) was performed in serial cross sectional images chosen every 2 mm in proximal 30mm of LAD.
Results: 14 patients received MTF and 15 did not (P>0.1 for all baseline characteristics). Mean tHcy increased after HT only in non-MTF patients, while it decreased significantly in those assuming MTF (Figure; *P<0.05). Average IA increased in patients assuming MTF (1.87±3.26 vs. 3.41±3.31 mm^2; P<0.01) as well as in those not assuming MTF (1.85±2.73 vs. 3.42±3.31 mm^2; P<0.01). LDL serum levels correlated with the increase in IA(P=0.037), while tHcy plasma levels did not (P=0.632).



Homocysteine levels and MTF assumption.

Conclusions: The preliminary results of this prospective randomized trial suggest that although MTF significantly decreased tHcy after HT, it is ineffective in preventing intimal growth in graft coronary arteries after 12 months of follow-up. LDL concentration resulted a major non-immunological determinant of GVD in HT recipients.

P549 Prognostic impact of coronary endothelial dysfunction after heart transplantation

M. Weis[1], M. Kuebrich[1], S. Pehlivanli[2], M. Muscholl[1], H. Fliri[2], J. Koglin[1], B.M. Meiser[3], W. von Scheidt[2]. *[1]University Hospital Grosshadern, Medizinische Klinik I, Munich, Germany; [2]Zentralklinikum Augsburg, Medizinische Klinik, Augsburg, Germany; [3]University Hospital Grosshadern, Cardiac Surgery, Munich, Germany*

Cardiac allograft vasculopathy (CAV) is the most aggressive atherosclerosis in humans. Coronary endothelial dysfunction may predict future progression of coronary intimal thickening in heart transplant patients. We analyzed the prognostic impact of epicardial and microvascular endothelium-dependent and endothelium-independent vasomotor function in 188 human heart transplant recipients. Functional coronary measurements were performed 25±30 months after heart transplantation. Coronary endothelial dysfunction was defined as >10% epicarial vasoconstriction and/or <100% coronary flow increase in response to ACh. Patients were followed up for 36±20 months (1-8 years). Cardiovascular related events (CVRE) and death were analyzed. Over the course of the study, 15 patients developed CVRE (8%) and 19 patients died (10%; n=9 with cardiovascular related death). Patients with coronary endothelial dysfunction at baseline had significant more events during follow-up (CVRE p=0.023; death p=0.019) compared to patients with normal endothelial function. Endothelium-independent vasomotor response was not related to CVRE or death during follow-up.
Allograft coronary endothelial dysfunction predicts CVRE and death after human heart transplantation. Early studies of endothelial function may play an important role in predicting clinical outcomes after transplantation.

P550 Sleep-related breathing disorders in patients with stable heart failure

M. Villa[1], E. Quintana[2], M. Fernández-Quero[1], E. Arana[1], J. Marín[1], F. Capote[2], E. Lage[1], A. Martínez[1]. [1]*HUV ROCIO, Cardiology, Sevilla, Spain;* [2]*HUV ROCIO, Unit of Respiratory Diseases, Sevilla, Spain*

Background: Sleep-related periodic breathing with recurrent episodes of apnea and hypopnea is known to occur in patients with heart failure. Recent data suggest that sleep apnea can also lead to the progression of cardiac dysfunction in patients with chronic heart failure. However, few studies of sleep apnea in heart failure have been reported and studies with historical and physical findings and laboratory examination are needed.
Aims: To analyze the impact of sleep-related breathing disorders (SRBD) in ambulatory patients with stable heart failure.
Method: We consecutively studied 54 patients with stable heart failure due to systolic dysfunction (left ventricular ejection fraction <45%) who were clinically stable (symptoms or signs of heart failure had not changed in the previous 4 weeks) and received standard therapy. Baseline assessment included: specific cardiopulmonary questionnaire, radionuclide ventriculography, shuttle walking test (SWT) and quality of life questionnaires: functional outcomes of sleep questionnaire (FOSQ) and Minnesota living with heart failure questionnaire (MLHQ). All patients underwent a full-night polysomnography. SRBD was defined with an apnea-hipopnea (AHI)>10 in three categories: central (C), obstructive(O) or mixed(M). A SBD in which greater than 50% of events were central was defined as central sleep apnea; if >50% of events were obstructive, it was defined as obstructive sleep apnea.
Results: According to the AIH threshold, 20 patients (37%) had SRBD (AHI 28.4 ± 4.4; 17 (85%) with central apneas and 3 (15%) with obstructive apnea) and 34 patients (63%) had not SRBD (AHI 3 ± 0.5).There were no significant differences between both groups in age, sex, body mass index, left and right ventricular ejection fraction. We found differences statistically significant in MLHQ (29.5 ± 3.6 vs 15.4 ± 5.5. p<0.001), FOSQ (71.6 ± 5.5 vs 84.4 ± 3, p<0.001), SWT (229.4 ± 54.2 vs 445.1 ± 45.4, p<0.05) and hospital admissions due to heart failure (90% vs 39.4%, p<0.001) between the group with SRBD and the group without SRBD.
Conclusions: The prevalence of severe occult SRBD is high in ambulatory patients with stable and optimally treated heart failure. These selected population have less exercise tolerance and worse quality of life than those patients without SRBD.

P551 Prevalence of heart failure and asymptomatic ventricular dysfunction in an urban sample of Portuguese adults – preliminary results

A. Azevedo[1], P. Dias[2], R.A. Rodrigues[2], P.B. Almeida[2], F. Friões[3], P. Bettencourt[3], C. Abreu-Lima[2], H. Barros[1]. [1]*University of Porto Medical School, Hygiene and Epidemiology, Porto, Portugal;* [2]*Hospital de S.João, Cardiology, Porto, Portugal;* [3]*Hospital de S. João, Medicine B, Porto, Portugal*

Objective: To measure the prevalence of heart failure and asymptomatic ventricular dysfunction in a community sample of adults living in Porto, Portugal.
Participants and methods: A cross-sectional study is being conducted to measure the prevalence of heart failure (HF) and asymptomatic ventricular dysfunction in a random sample of adults of both genders, aged 45 years or more and living in Porto. Participants were selected by random digit dialing and attended an interview with a physician, in which a structured questionnaire was used to assess the presence of symptoms, and physical examination, ECG and echocardiogram were performed. Heart failure was diagnosed according to the criteria of the European Society of Cardiology; cardiac dysfunction was defined as left ventricular ejection fraction lower than 45% and/or valvular disease of at least moderate severity.
Results: We have evaluated 354 individuals. In 30 (8.5%) it was not possible to calculate the ejection fraction (EF) due to the bad quality of the acoustic window. Among the remaining 324, we identified 7 with EF<45% and 5 with valvular disease(1 patient fulfilled both criteria). Seven of these individuals were symptomatic yielding a prevalence of HF (95%CI) of 2.2% (0.9%-4.4%) in this population. Of the 7 patients with ventricular dysfunction, 4 had no symptoms (prevalence of asymptomatic ventricular dysfunction of 1.2%, 95%CI 0.3%-3.1%). In the assessed population, 17 participants had EF between 45 and 50% (minimally depressed systolic function), and among these 7 had symptoms (1 had chronic respiratory disease, 1 was obese and 5 had no other cause for symptoms). Thus, the prevalence of HF with minimally depressed systolic function was 1.5% (0.5%-3.6%).
Conclusion: These preliminary results show that in our community the prevalence of HF is similar to that reported in studies conducted in other European populations with similar characteristics. We found a prevalence of HF with minimally depressed systolic function very close to that of HF.

P552 Process-of-care measures and quality-of-care assessment in an heart failure outpatient setting

S. De Feo, M. De Salvo, G. Forni, E. Traversi, C. Opasich, R. Tramarin. *IRCCS FONDAZIONE SALVATORE MAUGERI, CARDIOLOGY, Pavia, Italy*

The achievement of measurable, rapid and sustainable improvement in quality-of-care (QoC) of patients with heart failure (HF) is a challenge for stake-holders and individual health care providers.
In order to assess the QoC provided in an HF outpatient clinic, we evaluated a series of evidence based process-of-care measures in clinical practice.
Methods Medical records of 169 consecutive pts referred to our HF clinic with at least 2 visits have been reviewed. The measures considered were inspired by the Veterans Affairs proposal (CHF QUERY; Circulation 2000;101:e122): left ventricular ejection fraction (LVEF) and aetiology assessment, ACE-inhibitors and beta-blockers (BB) if LVEF <41%, spironolactone if NYHA III-IV, anticoagulants or antithrombotics if atrial fibrillation or if ischemic aetiology, statins if ischemic aetiology and LDL>100 mg/dL, blood pressure control (<140/90 mmHg), patients adherence to prescriptions (daily weight and/or blood pressure monitoring).
Results 121 pts were in NYHA class I-II (63%), 39 in III (23%) and 7 in IV. Aetiology of HF was assessed in 93% pts (56% ischemic, 9% valvular, 12% idiopathic, 15% other). LVEF was measured in all pts (LVEF 33±11%; <41% in 135 pts). Among pts with LVEF <41%, 121 (90%) received ACE-inhibitors; 13 did not for contraindication (creatinine >3.0 mg/dL in 10, hypotension in 3) and 1 for neutropenia onset. In the same group BB were prescribed in 49 pts (64%), but the treatment was withdrawn in 4 pts and was contraindicated in 37 (COPD in 8, severe peripheral vascular disease in 10, hypotension in 12, bradycardia or A-V block in 7). Spironolactone was prescribed in 26 (45%) of the 47 pts in NYHA III-IV; it was contraindicated in 16 pts (hyperkaliemia in 14 and gynecomastia in 2). In 3 out of 95 pts with ischemic aetiology antithrombotics or anticoagulants were not prescribed (contraindicated in 1). Among pts with ischemic aetiology and cholesterol LDL >100 mg/dL, 10 (10%) were not receiving statins; the treatment was withdrawn in 1 for CK, GOT, GPT increase. Atrial fibrillation was present in 29 pts: all were receiving anticoagulants (70%) or antithrombotics (30%). An adequate blood pressure control was achieved in 133 pts (79%). Patients adherence was evaluated in 126 pts (75%) and was considered poor in 42 (33%).
Conclusion Periodic process-of-care assessment is useful in evaluating quality of care and represents a stimulus for continuous quality improvement. Among process-of-care measurements considered, the rate of BB prescription and the degree of patient adherence remain the most defective in clinical practice.

P553 Correlation of morphological and functional parameters of the skeletal muscle with a reduced electromyographic activity in chronic heart failure

P.C. Schulze[1], A. Linke[2], N. Schoene[2], S. Erbs[2], M. Busse[3], V. Adams[2], R. Hambrecht[2], G. Schuler[2]. [1]*BWH, Harvard Medical School, Cardiovascular Research, Cambridge, United States of America;* [2]*University of Leipzig, Heart Center, Department of Cardiology, Leipzig, Germany;* [3]*University of Leipzig, Faculty of Sports Medicine, Leipzig, Germany*

Exercise intolerance and early muscle fatigue are key symptoms in patients (pts) with chronic heart failure (CHF). In advanced stages of the disease, profound metabolic abnormalities have been described finally leading to a catabolic state with a progressive loss of muscle bulk. Aim of this study was to investigate morphological, functional and electromyographical parameters of the skeletal muscle in pts with CHF.
17 patients with CHF and 12 age-matched controls (LVEF 25±2 vs. 68±1%, BMI 26.6±0.8 vs. 28.0±1.0 kg/m^2; p=NS) were included in this study. Cross-sectional area (CSA) of the thigh was assessed by computed tomography. Under electromyographical control, maximal and 30% submaximal isometric strength as well as the relative decrease of muscle strength of the quadriceps muscle over a period of 20 s were determined. Serum levels of TNFalpha were measured by immunoassay.
Pts with CHF showed a significant reduction of muscle CSA (134.8±5.3 cm^2 vs. 165.2±7.4 cm^2, p=0.002) as compared to controls. The maximal quadriceps muscle strength was found to be significantly reduced in patients with CHF (226.7±22.3 N vs. 286.9±17.1 N, p<0.05) who also exhibited a higher extend of muscular fatigability (-2.18±0.33 N/s vs. -0.54±0.20 N/s, p<0.01). Electromyographic activity at 30% submaximal contraction showed a reduced increase in pts with CHF (66±22% vs. 114±36%; p<0.05) indicating an impaired muscle fiber recruitment. Furthermore, a significant correlation between muscular fatigability and reduced electromyographic activity was found in CHF (r=0.84; p<0.001).
Our findings demonstrate an impaired electromyographic activity and muscular function in patients with CHF suggesting a new pathomechanism contributing to functional abnormalities of the skeletal muscle in advanced stages of this disease.

P554 Airways resistance in chronic heart failure measured by impulse oscillometry

K.K.A. Witte, A. Morice, J.G.F. Cleland, A.L. Clark. *Hull, United Kingdom*

Background-Patients with chronic heart failure (CHF) complain of breathlessness and fatigue on exertion and have reduced peak oxygen consumption (pVO2) and an increased ventilatory response (VE/VCO2 slope) when subjected to exercise testing with metabolic gas exchange. These abnormalities correlate with abnormalities of basic spirometry (FEV1 and FVC).
Methods-Impulse oscillometry (IOS) measures airways resistance and lung compliance during normal breathing and is therefore independent of respiratory muscle strength and patient compliance. Sound waves of varying frequencies produced by a loud speaker are sent into the lungs and the amplitude and phase shift of the reflected waves can be measured to give an assessment of airway resistance (R) and reactance (X).
Objective-The aim of this study was to establish whether there is increased airways resistance in patients with CHF using IOS.
Methods-23 patients with CHF and 18 controls underwent peak exercise testing with metabolic gas analysis (Oxycon Record, Jaeger, Germany) and, on a seperate occasion, had airways resistance assessment using the Jaeger (Germany) IOS system before and after a fixed period of exertion on a cycle at 25W.
Results-Patients had a lower pVO2 (18.7 (4.0) v 39.2 (8.3)ml/kg/min $p<0.0001$), elevated VE/VCO2 slope (41.6 (8.1) v 27.4 (2.9)), and lower FEV1 (2.4 (0.4) v 3.2 (0.7)l/min $p=0.0001$) and FVC (3.3 (0.7) v 4.1 (1.1)l $p<0.005$) when compared with controls. Measures of R and X correlated closely with spirometric abnormalities, and were significantly different between patients and controls (R at 5Hz 0.44 (0.16) v 0.30 (0.15)kPa/(l/s) $p<0.005$ and X at 5Hz -0.16 (0.08) v -0.09 (0.08)kPa(l/s) $p<0.05$). They also correlated with pVO2 (0.46 $p=0.0025$) and VE/VCO2 slope (0.43 $p<0.05$). There was no significant deterioration in airways resistance after exercise.
Conclusion Conclusion-Patients with CHF have elevated airways resistance and reduced lung reactance measured with IOS when compared with controls.

P555 Prevention of myocardial fibrosis by inhibition of the ubiquitin-proteasome system

S. Meiners[1], B. Hocher[2], M. Laule[3], C. Guenther[3], A. Mrozikiewicz[4], G. Baumann[3], K. Stangl[3]. *[1]Charité/Humboldt-University, Cardiological Research Laboratory, Berlin, Germany; [2]Department of Nephrology, Charité/Humboldt-University, Berlin, Germany; [3]Charite/Humboldt-University, Medical Department I, Berlin, Germany; [4]Institute of Clinical Pharmacology, Med. Department, University of Poznan, Poznan, Poland*

Background: Myocardial fibrosis is a hallmark of cardiac remodeling contributing to left ventricular dysfunction. The ubiquitin-proteasome system is the major pathway for intracellular protein degradation and plays a key role in degrading central signal mediators, which are likewise involved in the development of cardiac fibrosis. We have investigated whether inhibition of the proteasome may influence myocardial fibrosis.
Methods and Results: Effects of proteasome inhibition on myocardial fibrosis were studied in spontaneously hypertensive rats (SHRs). Long-term treatment over 12 weeks with the specific proteasome inhibitor MG132 (daily 1 mg/kg, n=10/group) was well tolerated and resulted in pronounced inhibition of cardiac fibrosis by -38% as revealed by computer-aided morphometry. Inhibition of myocardial fibrosis correlated with improved left ventricular function in the MG132-treated group, in comparison to control SHRs as analyzed by measuring left ventricular end-diastolic pressure (LVEDP), dp/dtmax, and dp/dtmin. Treatment of rat primary cardiac fibroblasts with MG132 (0.1 and 1 μM) revealed concentration-dependent inhibition of fibroblast growth, as well as specific and concentration-dependent downregulation of collagen I alpha 2 by as much as -73%, and collagen III alpha 1 by as much as -91%, as determined by real-time PCR analysis.
Conclusion: We conclude from these proof-of-principle experiments that inhibition of the proteasome system effectively prevents myocardial fibrosis in SHRs, a result which corresponds to improved cardiac function. These effects are presumably mediated by reduced growth and collagen expression of cardiac fibroblasts.

P556 Prolonged rat heart allograft survival after treatment with pentoxifylline

N.E. El Mokhtari[1], A. Meissner[1], A. Reinecke[1], D. Krueger[1], M. Lins[1], A. Tiroke[1], S. Hirt[2], R. Simon[1]. *[1]University of Kiel, Clinic of Cardiology Dept., Kiel, Germany; [2]Cardiovascular Surgery Dept., Kiel, Germany*

Background: Data from multiple studies suggest that proinflammatory cytokines, such as tumor necrosis factor-alpha (TNF-alpha) are important modulators of allograft rejection. Increased levels of proinflammatory cytokines have been detected in rejecting allografts in both clinical studies and animal models, and inhibition of these cytokines has been associated with prolonged allograft survival. Pentoxifylline, a methylxantine phosphodiesterase inhibitor commonly used to treat peripheral vascular disease, has been shown to decrease the level of proinflammatory cytokines such as IL-12, TNF-alpha and IFN-gamma. We xamined the effect of Pentoxifylline on allograft rejection.
Methods: Heterotopic abdominal transplantation from Fisher 344 rats to Wistar Kyoto rats was used as a model of cardiac allograft rejection (n = 15). Wistar Kyoto to Wistar Kyoto served as controls (n = 15). In the experimental groups, recipients were intraperitoneally injected with Pentoxifylline (25mg/kg) just after operation, followed by daily injection of the drug. Allograft survival was determined by palpating heartbeats.
Results: In the control group, the mean graft survival was 21 $\pm$ 5 days. Pentoxifylline significantly prolonged the survival period (up to 70 $\pm$ 44 days, $p < 0.01$).
Conclusions: These results suggest that Pentoxifylline can be used as an effective agent in preventing graft rejection.

MYOCARDIAL FUNCTION IN HEART FAILURE

P557 Does preservation of radial function of the left ventricle compensate for loss of longitudinal function with age?

C.F. Madler[1], D. Vinereanu[1], N. Payne[1], L.A. Brodin[2], A.G. Fraser[1]. *[1]Welsh Heart Research Institute, Cardiff, United Kingdom; [2]Huddinge University Hospital, Clinical Physiology, Huddinge, Sweden*

Left ventricular (LV) performance is a combination of radial function due to concentric myocardial fibres, and longitudinal function due predominantly to subendocardial fibres. Global diastolic function declines with age, whereas systolic function is thought to be preserved, but the separate contributions of radial and longitudinal fibres are unclear. Tissue Doppler measurements of regional myocardial velocities during contraction and relaxation allow separate assessment of radial and longitudinal, and systolic and diastolic, function.
Aim: To investigate changes in radial and longitudinal function with age, at rest and during stress, in a large normal population.
Method: 110 normal subjects aged 21-84 years (32 normal volunteers, and 78 healthy patients referred for chest pain but with normal exercise ECG and coronary arteriography) were studied at rest and during dobutamine infusion (5-40 μg/kg/min, $\pm$ 1 mg atropine), as part of the MYDISE study. Digital image loops of colour tissue Doppler (GE Vingmed System V) were analysed off-line (Echopac TVI). Myocardial peak systolic velocity (S) and peak early (E) and late (A) diastolic velocities, were averaged from 2 beats. Radial function was assessed from the velocities of the basal posterior wall in a parasternal view, and longitudinal function from average velocities of 4 basal segments (septal, lateral, anterior, and inferior) in apical views. Systolic functional reserve (SFR) was calculated as the absolute increase in velocity from baseline.
Results: Correlation coefficients of resting velocities and SFR against age are given in the table (*$p<0.01$).

Velocities against age

	S wave	E wave	E/A ratio	SFR
Longitudinal	-0.38*	-0.69*	-0.69*	-0.42*
Radial	-0.03	-0.25*	-0.33*	-0.38*

Conclusion: There is a progressive and subclinical decline in systolic longitudinal (subendocardial) function with age. Radial function compensates at rest but not during stress. Diastolic function declines with age more steeply in subendocardial than in subepicardial fibres. These changes may contribute to the pathophysiology of LV dysfunction in the elderly and should be measured as risk factors for the development of heart failure.

P558 The within-subject variability of left ventricular dimensions in patients with left ventricular systolic dysfunction

T.N. Martin[1], B.A. Groenning[1], J.E. Foster[1], T. Steedman[1], A. Elliott[2], H.J. Dargie[1]. [1]*Western Infirmary, Department of Cardiology, Glasgow, United Kingdom;* [2]*Western Infirmary, Department of Clinical Physics, Glasgow, United Kingdom*

Background: The variability of the symptoms of heart failure is well recognized. We hypothesized that this could be due to day-to-day variation in left ventricular (LV) performance that can be measured by cardiac magnetic resonance (CMR) imaging. This would be an important consideration in the evaluation of LV measurements as well as in the design of future studies in patients with systolic dysfunction.
Methods: LV dimensions were evaluated twice, separated by at least 48 hours; by cinematographic (True-Fisp) breath-hold CMR (1.5 Tesla Siemens Sonata Magnetom) using a phased array chest coil in 14 patients with LV systolic dysfunction (heart failure (HF) group) and 20 healthy volunteers (HV). Images were evaluated by four independent and blinded observers.
Results: Mean (range) age in the HV group was 33.1 (23-51) and 69.2 (59-81) years in the HF group. Mean (SD) LV end-diastolic volume (LVEDV) in the HV and HF groups was 137 (24) and 218 (55) ml, respectively ($p<0.0001$). Mean (SD) LV end-systolic volume (LVESV) was 46.8 (12) and 131 (56) ml ($p<0.0001$), mean (SD) LV ejection fraction was 66.0 (5.2) and 38.5 (15) % ($p<0.0001$) and mean (SD) LV myocardial mass was 99.7 (25) and 178 (36) g, respectively ($p<0.0001$). Mean (SD) difference in LVEDV (delta LVEDV) between examinations was 3.08 (11.9) ml in the HV group and -3.90 (23.2) ml in the HF group ($p=0.03$). Mean (SD) delta LVESV was 0.96 (8.15) and -4.87 (15.1) in the HV and HF groups, respectively ($p=0.01$). Mean (range) Bland-Altman limits of agreement for delta LVEDV in the HV group for the 4 observers were -18.6 (-23.6 to -12.1) to 24.5 (10.1 to 38.8) ml and -49.8 (-53.8 to -47.5) to 42.9 (37.4 to 53.5) ml in the HF group. For delta LVESV, Blandt-Altman limits of agreement were -13.8 (-20.9 to -5.72) to 15.6 (5.26 to 21.7) ml in the HV group and -34.0 (-44.6 to -24.3) to 24.3 (20.9 to 29.3) ml in the HF group. Inter-observer variability for LVEDV was 8% in the HV group and 5% in the HF group. For LVESV, the values were 31% (HV) and 6% (HF), respectively. By multiple linear regression analyses, significant differences in LVEDV ($p=0.03$) and LVESV ($p=0.004$) between the two examinations were dependent on the subject type (HF) and not the observer.
Conclusion: The major determinants of LV dimensions measured by CMR in patients with LV systolic dysfunction vary significantly when compared to healthy volunteers. The effect is independent of observer variability and should be taken into account when evaluating LV dimensions in patients with LV systolic dysfunction.

P559 Ability of a novel tissue Doppler index to identify elevated left ventricular filling pressures in patients with abnormal relaxation

T. Poerner, B. Goebel, C. Wolpert, T. Sueselbeck, S. Pfleger, M. Borggrefe, K.K. Haase. *University Hospital of Mannheim, 1st Dept. of Medicine, Mannheim, Germany*

Background: Patients with impaired relaxation may also have elevated filling pressures, without presenting a restrictive or pseudonormal mitral inflow pattern. No echocardiographic criteria for the detection of elevated left ventricular end-diastolic pressure (LVEDP) in the presence of abnormal relaxation are currently available.
Aim of the study was the noninvasive estimation of LVEDP in patients with evidence of delayed relaxation.
Methods: 87 consecutive patients scheduled for coronary angiography presenting with a mitral inflow pattern of impaired relaxation ($E/A < 1$) underwent left heart catheterization with invasive measurement of LVEDP and a Doppler echocardiographic examination, including Doppler myocardial imaging (DMI). Peak transmitral velocities were determined at rest and during the strain phase of a Valsalva maneuver. Peak diastolic velocities of the mitral annulus and the early diastolic myocardial velocity gradient of the posterior basal wall were obtained by DMI. We introduced a new temporal parameter: the myocardial relaxation time (MyoRT), that was calculated between aortic valve closure and the early diastolic velocity peak by DMI at the level of the lateral basal wall.
Results: Elevated filling pressures were found in 32 patients (group 1: LVEDP 20 ± 3 mm Hg, E/A 0.73 ± 0.14), while 44 patients had normal LVEDP values (group 2: LVEDP 7.5 ± 2 mm Hg, E/A 0.7 ± 0.14). A number of 11 patients with borderline LVEDP between 11-14 mm Hg were excluded. There were no differences with respect to clinical or conventional Doppler data between both patient groups. Of all DMI indices only MyoRT correlated significantly ($r = 0.38$, $p = 0.024$) with LVEDP and provided by ROC-analysis an acceptable predictive accuracy for LVEDP > 15 mm Hg (area under ROC-curve of 0.7 with a 95% CI of 0.57-0.82, $p = 0.005$). Prolonged MyoRT > 100 ms had a sensitivity of 63% and specificity of 60% for the prediction of LVEDP > 15 mm Hg.
Conclusions: Noninvasive assessment of LVEDP in patients with delayed relaxation remains a difficult clinical challenge. Only the new DMI-derived temporal index MyoRT enabled in this study a semiquantitative prediction of elevated filling pressures in patients with impaired relaxation.

P560 Contrast-enhanced Doppler echocardiography as an alternative to right-heart catheterization in patients with left ventricular dysfunction

F.L. Dini[1], E. Traversi[2], M. Pozzoli[3]. [1]*Santa Chiara Hospital, Cardiovascular Diseases Unit 2, Pisa, Italy;* [2]*Maugeri Foundation, Pavia, Italy;* [3]*Manzoni Hospital, Cardiology Unit, Lecco, Italy*

Noninvasive assessment of cardiac hemodynamics by Doppler echocardiography requires a reliable detection of flow velocity signals.
We sought to evaluate accuracy and reproducibility of contrast-enhanced Doppler echocardiography in the noninvasive estimation of hemodynamic variables in patients with chronic heart failure (HF) and left ventricular (LV) systolic dysfunction.
Right heart catheterization and Doppler echocardiography were simultaneously carried out in 45 consecutive patients with chronic HF and dilated cardiomyopathy (LV ejection fraction: 29±7%) in sinus rhythm. Doppler evaluation of right-sided regurgitant signals and of pulmonary venous flow (PVF) were performed both at baseline and after enhancement by intravenous injection of Levovist (2.5 grams of at 400 mg/ml). Noninvasive variables were estimated as follows: cardiac output by pulsed-Doppler of LV outflow tract, pulmonary capillary wedge pressure (PCWP) by a regression equation including mitral and PVF variables, right atrial pressure from the inspiratory collapse of inferior vena cava, systolic and diastolic pulmonary artery pressures by adding the estimated right atrial pressure to the peak and the end-diastolic pressure gradients of tricuspid and pulmonary regurgitation. Pulmonary artery mean pressure (PAMP) and pulmonary vascular resistance (PVR) were then calculated from these measurements. The interobsever variability of noninvasive measurements was assessed in 12 randomly selected patients by the physician sonographer and by an independent observer.
After contrast enhancement, optimal or near optimal PVF tracings were achieved in all patients, while measurable tricuspid and pulmonary valve regurgitation signals were obtained in 43 and 41 of 45, respectively. Strong correlations between invasive and noninvasive hemodynamic variables were found: $r=0.90$, SEE 0.45 l/min for cardiac output, $r=0.90$, SEE 3.1 mm Hg for PCWP, $r=0.93$, SEE 3.7 mm Hg for PAMP and $r=0.85$ SEE 1.0 Woods units for PVR. Interobserver measurements of PCWP, PAMP and PVR correlated closely ($r=0.99$, SEE=0.90, $r=0.97$, SEE=0.97 and $r=0.97$, SEE=0.30, respectively). By Bland-Altman analysis, the mean differences in hemodynamic measurements between the two observers were 0.8±1.1 mmHg, 1.4±1.9 mmHg and 0.2±0.3 Wood Units, respectively.
Contrast-enhanced Doppler ultrasound is accurate as well as reproducible in assessing cardiac hemodynamics in patients with chronic HF and LV systolic dysfunction and may constitute an alternative to cardiac catheterization in potential heart transplantation candidates and in critically ill patients.

P561 Atrio-left ventricular pacing for heart failure acutely improves diastolic filling by relieving diastolic ventricular interaction

R.A. Bleasdale[1], C.E. Mumford[1], M.S. Turner[1], G. Middleton[1], V. Paul[2], J.A. Morris-Thurgood[1], M.P. Frenneaux[1]. *[1]Wales Heart Research Institute, Cardiology, Cardiff, United Kingdom; [2]St. Peter's Hospital, Cardiology, Chertsey, United Kingdom*

Although acute haemodynamic improvement, has been demonstrated in response to atrio-left ventricular pacing (LVP) in patients with congestive heart failure (CHF), the mechanisms underlying these benefits remain unclear. Mechanical and electrical resynchronisation are the more popular explainations. Our group has shown non-invasively that a significant proportion of patients with congestive heart failure have impaired left ventricular filling because of diastolic ventricular interaction (DVI). This physiological phenomenon wass assumed to be present when a paradoxical increase in left ventricular end diastolic volume (LVEDV) occurred in response to a reduction in right ventricular end diastolic volume (RVEDV). In health a reduction in LVEDV is seen in response to reducing RVEDV. We hypothesised that LVP would relieve diastolic ventricular interaction by inducing a phase shift allowing the left ventricle to fill prior to the right ventricle. We studied 8 male subjects with permanent LVP systems implanted for the treatment of heart failure and left bundle branch block on ECG. Using the same well-validated technique, of applying lower body negative pressure (LBNP) to reduce RVEDV, we compared the changes in ventricular volumes in response to LBNP with the pacing system turned on versus off. We measured right ventricular and left ventricular volumes simultaneously by radionuclide ventriculography. Of the group studied 4 out of 8 (50%) showed diastolic ventricular interaction as evidenced by an 18.8 ± 24.5% increase in LVEDV in response to reducing RVEDV by applying LBNP. This contrasted with a decrease of 21.9 ± 10.6% (p=0.037) seen in the 4 without DVI. In the sub-group with DVI, in the absence of LBNP, LVP increased LVEDV by 16.2 ±23.8% from baseline implying an improvement in diastolic filling. The left ventricular ejection fraction did not change (18 ± 8.4% vs., 18.3 ± 8.8%, p=0.89)indicating an increase in stroke volume. Furthermore in LVP mode the 'paradoxical' increase in LVEDV during the application of LBNP was almost abolished (0.1 ± 20.7%, p=0.038). We therefore conclude that LVP relieves diastolic ventricular interaction allowing improved diastolic filling at rest. Whether this benefit improves exercise tolerance in response to chronic LVP remains to be established.

P562 Intraventricular pressure gradients along the cardiac cycle: effects of ischaemia and modulation by afterload

M.J. Amorim, M.S. Guerra, A.F. Leite-Moreira. *Faculty of Medicine, Physiology Dept., Porto, Portugal*

Experimental and clinical studies have shown significant diastolic intraventricular pressure gradients (IVPGs) in early as well as late diastole and their sensibility to changes in preload and ischemia. However, data about systolic IVPGs and their modulation by afterload and ischemia are lacking.

Simultaneous apical and outflow tract (OT) left ventricular pressures (LVP) were recorded in 5 anesthetized open-chest rabbits by 2 high-fidelity micromanometers. IVPGs (OT minus apical LVP) were analysed in control and progressively afterloaded heartbeats at baseline and after LAD coronary artery occlusion, along the cardiac cycle. Afterload was increased with beat-to-beat ascending aortic occlusions.

Mean IVPGs (mmHg) along the cardiac cycle in control beats, in afterloaded beats reaching 90% of peak isovolumetric LVP and during ischemia are shown in the table (IC: isovolumetric contraction; REj: rapid ejection; SEj: slow ejection; IR: isovolumetric relaxation; RFill: rapid filling; Di: diastase; AtrC: atrial contraction). During REj there was a negative IVPG in control conditions that was inverted by afterload and ischemia. IVPGs were positive during IC and SEj, absent during Di and negative during AtrC, and were not affected by afterload or ischemia. During IR the large negative IVPG was significantly blunted by afterload but not affected by ischemia. The positive gradient observed during RFill disappeared during ischemia but was not affected by afterload. DP/dtmin occurred 2.2±0.4 ms earlier and was 736±101 mmHg/s more negative in the OT in control conditions, but these differences disappeared with afterload elevation.

Mean IVPGs (mmHg)

	IC	REj	SEj	IR	RFill	Di	AtrC
Control	1.5±0.2	-0.6±0.1	0.8±0.1	-4.6±0.7	0.6±0.2	0.0±0.0	-0.5±0.1
Afterload	1.4±0.2	0.9±0.1*	0.9±0.1	-1.4±0.3*	0.6±0.2	0.0±0.0	-0.6±0.1
Ischemia	1.5±0.2	0.6±0.4*	1.0±0.3	-4.8±0.4	-0.2±0.5*	0.0±0.0	-0.5±0.2

*p<0.05 vs. control

The present study shows that IVPGs during ejection, in control conditions, parallel the aortic-ventricular pressure gradients and might favour ventricular emptying. Inversion of REj IVPGs during afterload elevations and ischemia might contribute to impaired ventricular ejection in these conditions. IVPGs during IR reflect earlier onset and faster relaxation in the OT in control conditions, which disappear with afterload elevations.

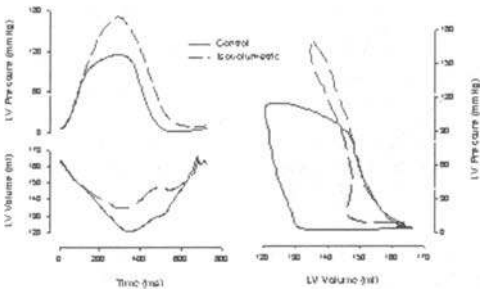
P563 Afterload-induced diastolic disfunction in the human heart and its exacerbation by systolic dysfunction and volume loading

A.F. Leite-Moreira[1], P. Pinho[2], J. Correia-Pinto[1], P.T. Bastos[2], M.R. Gomes[2]. *[1]Faculty of Medicine, Physiology Dept., Porto, Portugal; [2]Hospital de São João, Cardio-thoracic surgery, Porto, Portugal*

Pulmonary congestion in acute severe hypertension was recently attributed to diastolic dysfunction (NEJM, 2001). A potential mechanism underlying this phenomenon is afterload-induced diastolic dysfunction, previously described in animal models but not yet investigated in the human heart.

Twenty CABG patients (63±9 yrs) with variable degrees of systolic dysfunction (EF 25-75%) were studied prior to cardiopulmonary bypass with a pressure (n=17) or a pressure-volume (n=3) catheter. Afterload elevations were performed by clamping the ascending aorta to increase left ventricular pressure (LVP) from control up to isovolumetric. In 7 patients aortic clamping was repeated after 500cc of the priming solution.

Peak isovolumetric LVP (LVPiso) ranged from 113 to 261 (191±39)mmHg and dP/dtmax from 522 to 2399 (1208±452)mmHg/s, reflecting the variable degrees of systolic dysfunction. Afterload elevations induced diastolic dysfunction only in patients with impaired systolic function. Maximum LVP elevations (LVPiso) increased Tau 50±54% (from -37 to +160%) and EDP 3.5±2.3 (from 0 to 8) mmHg. Effects of afterload on diastolic function were inversely related with systolic function: Tau vs. LVPiso (r=-0.92, p<0.01), EDP vs. LVPiso (r=-0.96, p<0.01). Increased EDP in response to afterload elevations reflect an upward shift of the diastolic P-V relation (figure). After volume loading effects of afterload on EDP were exacerbated (7.9±3.7 vs. 3.0±1.5 mmHg) and became apparent even in patients with normal systolic function.



In conclusion, afterload-induced diastolic dysfunction is also observed in the human heart, being exacerbated by systolic dysfunction and volume loading. This mechanism might contribute to pulmonary congestion in acute afterload elevations such in severe hypertension.

P564 Analysis of dispersion of myocardial velocities by tissue Doppler echocardiography in the assessment of heart failure etiology

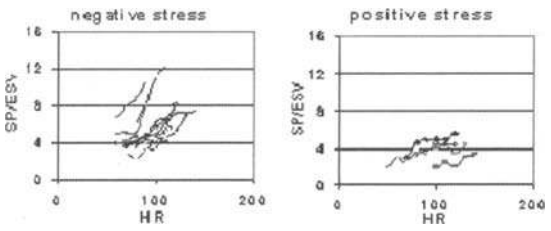
M. Plewka, J. Drozdz, M. Ciesielczyk, J Z. Peruga, B. Plewka, M. Krzeminska-Pakula, J D. Kasprzak. *Medical University of Lodz, Cardiology Dept., Lodz, Poland*

Differentiating between an ischemic and nonischemic cause has important clinical implication in patients with heart failure. Several noninvasive techniques have been proposed to distinguish the two forms of cardiomyopathy, but the results are controversial and optimal strategy remains unsettled.
The aim of the study was to compare the regional heterogeneity of myocardial velocities in patients with ischemic and non-ischemic cardiomyopathy using spectral tissue Doppler echocardiography (TDE).
Study group consisted of 120 individuals- 60 patients with heart failure incl. 30 pts after myocardial infarction-MI (aged 58±10 yrs; LVEF 28±7%) and 30 pts with dilated cardiomyopathy -DCM (aged 43±12 yrs, LVEF 25±8%). Etiology was detected by coronary angiography. Control group consisted of 60 healthy volunteers (aged 43±12yrs, LVEF 65±2%). Myocardial velocities (systolic- Sm, early diastolic-Em and late diastolic-Am) were recorded with pulsed wave TDE from 3 standard apical views in the middle of 6 basal segments/pts. (lateral, anterior, posterior, inferior, anterior septum and posterior septum). To measure the regional heterogenity we calculated an index of dispersion of myocardial velocities among 6 studied walls- (V=standard deviation/mean*100%).
Results: Systolic and diastolic velocities were significantly lower in patients with heart failure than in control subjects (Sm- 4,5±1,2 vs 11,1±1,5 cm/s; Em-6,1±2,4 vs 16,6±2,2 cm/s, Am-4,6±2,0 vs 11,8±1,2 cm/s; p<0,001), but there were no significant differences in systolic and late diastolic velocities between patients with MI and DCM. The dispersion of systolic, early and late diastolic velocities was significantly higher in patients after MI than in patients with DCM (respectively; VS 32±8% vs 13±4%; VE 26±10% vs 16±5%; VA 24±11% vs 16±6%; p<0,0001). Best predictor of ischemic etiology of cardiomyopathy was dispersion of systolic velocities greater than 20% - specificity 96,8% (95%CI: 83,3%- 99,9%), sensitivity 100,0% (95%CI: 88,1%- 100,0%), PPV 100,0% (95%CI: 88,4%- 100%), NPV 96,7% (95%CI: 82,8%- 99,9%), kappa 0,97.
Conclusion: Long axis TDE velocities of the left ventricle are significantly lower in patients with heart failure. Systolic velocity dispersion index over 20% is suggestive of ischemic left ventricle dysfunction etiology.

P565 Force-frequency relationship in the echo lab: a noninvasive assessment of "Bowditch-treppe"?

T. Bombardini[1], A. Ripoli[1], E. Pasanisi[1], C. Cicerone[2], E. Hoffmann[2], E. Picano[1]. [1]*Institute of Clinical Physiology, PISA, Italy;* [2]*Palermo Hospital, Cardiology Division, Palermo, Italy*

Background: Estimation of contractility of left ventricle is an important, and as yet elusive, goal with noninvasive techniques. Positive inotropic interventions are mirrored by smaller end-systolic volumes and higher end-systolic pressures. An increased heart rate progressively increases the force of ventricular contraction (Bowditch treppe or staircase phenomenon).
Aim: To assess the feasibility of a totally noninvasive estimation of force-frequency relation during stress in the echo lab.
Methods: Sixteen patients (11 males, 57±8 years) referred for exercise-echo were consecutively enrolled.Wall Motion Score Index (WMSI, 16 segment model, from 1=normal to 4=dyskinetic) was calculated. To build the force-frequency relationship, the force was determined at each step as the ratio of systolic pressure (SP, cuff sphygmomanometer)/end-systolic volume (ESV, biplane Simpson rule). The slope of the relationship was calculated with the linear best fit of the force-frequency relationship:



Results: By regional wall motion analysis, 2 groups of patients were identified: Group I (n=5) had a positive echo (WMSI baseline = 1.2 ± 0.27 vs peak stress = 1.41 ± 0.23); and group II (n = 11) had a negative echo (WMSI baseline = peak stress = 1.05 ± 0.15). The slope of the linear best fit of the force-frequency curve was lower in patients with compared to those without ischemia (Group I = 2.7 ± 1.7 x 10^{-2} vs Group II = 9.1 ± 6.3 x 10^{-2}; p=0.013): F
Conclusion: A noninvasive estimation of force-frequency relationship can be easily determined during stress echo and separates patients with and without ischemic response. This index of global contractility is theoretically appealing for identification of limited contractile reserve and latent global left ventricular dysfunction.

P566 Rate of segmental myocardial wall stress increase in dobutamine stress echocardiography – its relation with negative study and clinical symptoms

H. Custódio, J. Galvão, J. Monge, M.J. Bruno, I. Arroja, J. Fernandes, J. Azevedo, A. Aleixo. *Hospital São Francisco Xavier, Echocardiographic Laboratory, Lisbon, Portugal*

The use of pharmacological agents such as intravenous dobutamine during stress echocardiography (DSE) changes significantly the time course of several hemodynamic and functional parameters of the left ventricular (LV) global and regional performance. Myocardial wall stress (MWS) is considered a functional quantitative parameter of regional LV function that suffers a dynamic change during DSE, and which can be evaluated using new noninvasive methods. Objective: The aim of our study was to investigate the time course changes of several segmental MWS (Kdynes/cm^2 or KPa) LV functional parameters during DSE study.
Material and Methods: MWS was calculated during both systole (S) and diastole (D) according to the general mathematical formula PA.(D+d)/4h, where PA is the S or D blood pressure, D major and d minor LV cavity diameters (mm) and h the individual segmental LV myocardial wall thickness (mm). In a group of 60 patients (pts) with a negative DSE (DSE-), mean age 57±12 yrs (43-69 yrs), 64% (35/65) males, we calculated several segmental LV functional parameters according to the ASE LV model of 16 segments. To enhance LV endocardial resolution and improve quantitation, ultrasound contrast agent Levovist® (Schering AG, Germany) was injected from baseline to peak fose, 4 gr dose, 300 mg/ml concentration. We calculated the individual value of MWS (MWSi), the mean segmental MWS (MWSm), the absolute (Var-KPa) and % (%Var-%) MWS variations, and the rate of MWSi and MWSm increases (RMWSi and RMWSm-KPa) per DSE stage (RMWS=MWSn/1-MWsn) and its mean values (RMWS/n stages), both in S and D. Data was compared among negative DSE with and without chest pain (CP-; n=35 pts vs CP+; n=25 pts).
Results: RMWS registered higher values and increase in S (1.8±0.4 KPa) compared to D (1.0±0.4 KPa; p=0.01). The basal interventricular septum (2.5±0.6 KPa p<0.01) and lateral (2.3±0.4 KPa; p<0.01) walls registered the highest RMWS values when compared to all other LV segments speciallly during the S phase. CP+ revealed higher values (S-2.2±0.4 and D-1.2±0.2KPa; p=0.01 and <0.01) when compared to CP- (S-1.4±0.3 and D-0.4±0.2 KPa) during the DSE study.
Conclusions: The LV segmental RMWS registered higher values during both the systolic and diastolic phases, increased exponentially with DSE duration and was directly related with the occurrence of chest pain during DSE, a finding that was independent of the duration of each study. Our results reflect the rate of increase of LV myocardial wall stress not compensated by the blood flow redistribution mechanisms of the subendocardial coronary microcirculation.

P567 Left ventricular geometry influences left ventricular relaxation detected by color M-mode mitral inflow propagation velocity in patients with left ventricular dysfunction

C. Aggeli, S. Brili, M. Bonou, G. Roussakis, M. Vavuranakis, C. Pitsavos, C. Stefanadis, P. Toutouzas. *Athens, Greece*

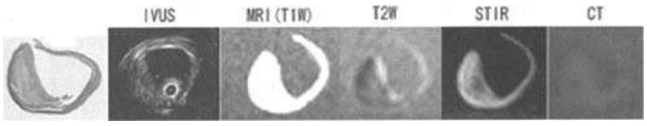
Background: The propagation velocity (vp) of left ventricular (LV) inflow using color M-mode Doppler has been proposed as a reliable determinant of LV relaxation. The aim of this study was to assess the effect of LV geometry on vp values in patients (pts) with comparable ventricular function and different geometry.
Methods: We studied 25 pts with coronary artery disease and left ventricular aneurysm (Group 1), as well as 25 pts with dilated cardiomyopathy (Group 2). Groups 1 and 2 did not differ regarding age (mean age 64±4 vs. 60±5 yrs), LV ejection fraction (LVEF) (28±4% vs. 31±5%) and LV end-diastolic pressure (LVEDP) (16±2 vs. 17±1.5 mmHg) (all NS). Digitization of the LV endocardial borders in diastole and systole in the apical 4 and 2 chamber views was used for the study of LV geometry. As far as the segmental kinetic is concerned, the wall motion score (WMS) (the sum of segmental scores), the wall motion score index (scores sum/number of segments) and the extension of dyssynergy (percentage of dyssynergic segments) were calculated. Vp was measured as the slope of the first aliazing velocity in early diastole. All pts underwent left ventricular catheterization immediately after the echocardiographic study and the LVEDP was measured.
Results: The pts of Group 1 had lower vp than Group 2 (17±3 vs. 25±4 cm/sec). The wall motion index of Group 1 was higher than Group 2 (2.8±0.3 vs. 1.8±0.2, p<0.001). The extension of dyssynergy had negative relation to flow propagation (r=-0.63, p=0.034). Multiple regression analysis showed that the LVEDP [p=0.01, OR (CI95%): 0.97 (0.92-0.99)] and the extension of dyssynergy [p=0.04, OR (CI95%) 0.9 (0.88-0.95)] were independent factors for vp values.
Conclusions: Left ventricular geometry affects mitral inflow propagation velocity. This means that pts with left ventricular aneurysm have worse relaxation than pts with dilated cardiomyopathy. Left ventricular geometry needs to be accounted when attempting to evaluate the left ventricular diastolic function.

PERIPHERAL CIRCULATION

P568 Diagnosis of atherosclerotic carotid plaque structure and fibrous cap in vitro by IVUS, CT and MRI

H. Kawakami, H. Matsuoka, Y. Koyama, T. Matsunaka, T. Ito. *Ehime Prefectural Imabari Hospital, Cardiology Dept., Imabari, Japan*

Vulnerable plaque was consisted of large lipid pool and thin fibrous cap. Using intravascular ultrasound (IVUS), we could observe plaque type and plaque distribution but lipid pool and fibrous cap could not clearly detect. The aim of this study is to investigate what is the best modality to detect atherosclerotic plaque structure and fibrous cap. We examined 4 pieces of atherosclerotic carotid arteries excised by endatherectomy. Cross sectional scanning was performed by IVUS (CVIS Insight System, Ultra Cross 20MHz; Boston Scientific Scimed, Inc) by auto-pull back method, CT (Proceed SA; GE Yokogawa Medical) by conventional method and MRI (MAGNETON (H-15) 1.5T; Siemens, Inc) by STIR imaging in addition to T1 and T2-weighted SE imaging. Each image compared with histology. Calcification of the plaque was clearly detected by IVUS but lipid pool and fibrous could not observe. MRI (T2-weighted SE imaging and STIR imaging) and conventional CT imaging could clearly detect lipid pool and fibrous cap. In terms of plaque calcification, although CT had a sensitive enough to detect plaque calcification, intraplaque structure became unclear by the effect of high CT value of the calcificaton. In comparison with these two modalities, as image quality, MRI could clearly detect intraplaque structure and thickness of fibrous cap rather than CT and as scanning time, CT was much shorter than MRI.



Atherosclerotic plaque.

In conclusion, MRI had the highest detectability of lipid pool and fibrous cap and CT was thought to have a high potential to detect plaque morphology.

P569 Impact of intravascular ultrasound, transoesophageal echocardiography and angiography guidance on aortic stent-graft placement

D.H. Koschyk[1], C.A. Nienaber[2], M. Knap[1], V. Skriabina[1], T. Hofmann[1], Y. V. Kodolitsch[1], W. Wolf[3], T. Meinertz[1]. *[1]University Hospital Hamburg-Eppendorf, Cardiology, Hamburg, Germany; [2]University Hospital Rostock, Cardiology, Rostock, Germany; [3]University Hospital Eppendorf, Dept. of Heart Surgery, Hamburg, Germany*

Background: Endovascular stent-graft placement is a new concept of treating aortic dissection and aneurysm but there are no overall accepted recommendations for the guidance of the intervention.
Method: We directly compared angiography (ANGIO), transesophageal echocardiography (TEE) and intravascular ultrasound (IVUS) before and after implantation of 39 stent-grafts of 33 patients (9 female, 60 ± 11years) for the capability to guide the intervention in the aorta. Twenty-five patients had aortic dissection type B and 8 patient's thoracic aortic aneurysm.
Results: ANGIO, TEE and IVUS were performed without any complications in all patients. Aortic dissection: IVUS and TEE are superior to ANGIO in the identification of multiple entry (44 and 36 versus 29; $p<0.005$ each), the diagnosis of slow blood-flow in the false lumen post stent-graft implantation (26 and 25 versus 18, $p<0.005$ each) and in the detection of incomplete stentapposition (14 and 13 versus 6; $p<0.005$ each). Remaining flow in the false lumen after stent-graft implantation was detected more frequently in TEE in comparison to ANGIO (13 versus 5, $p<0.05$). In 4 patients with abdominal extension of the dissection, only IVUS was able to accurately identify the false lumen over the entire length. Thoracic aortic aneurysm: The size of the aneurysm was calculated precisely with TEE and ANGIO, not with IVUS (11 versus 4; $p<0.05$). TEE was superior to IVUS in the detection of endoleaks (4 versus 0; $p<0.05$).
Conclusion: Based on our patient data we recommend to guide stent-graft implantation in aortic dissection type B with angiography and transesophageal echocardiography and the availability of intravascular ultrasound. In complex anatomy and abdominal extension of the dissection IVUS is recommended in addition. We believe that stent-graft implantation in thoracic aortic aneurysm can be guided with angiography and transesophageal echocardiography alone, without intravascular ultrasound.

P570 Conventional vascular echography versus contrast-enhanced Doppler ultrasound of renal artery stenosis: sensibility, specificity and accuracy

M. Liccese, M.M. Ciccone, P. Caputo, T. Parenzan, F. Morisco, M.C. Lanzilotti, N. De Carli, P. Rizzon. *Azienda Policlinico, Universitary Cardiology, Bari, Italy*

Doppler ultrasound (US) is one of many modalities that have been evaluted for the detection of renal artery stenosis. Recently the introduction of US contrast agents has substantially expanded the potential of color Doppler US. The use of echo-enhancer in combination with Doppler imaging has shown to significantly reduce the number of equivocal examinations.
The aim of the present paper has been to calculate sensibility, specificity and accuracy of conventional renal artery vascular echography (CRVE) vs renal artery contrast-enhanced Doppler Ultrasound (RCE)in blind angiographically detected arterial renal stenosis.
We have enrolled 40 pts (mean age 52 ± 8) with an angiographically detected renal artery stenosis. All the pts have been underwent in different times CRVE and RCE by using a 3,5 MHz electronic Probe (Hewlett Packard Sonos 1000). RCE have been realized giving 5-10 ml of watery suspension of Levovist as a slow bolus.
Results: see table. The valutation of renal artery stenosis has been possible in a bigger number of cases with RCE compared to CRVE (85% vs 60%). With RCE we have been obtained an increase (40% and 35% rispectivly) of Doppler signal and of color Doppler image.

n=40	feasibility	sensibility	specifisity	accuracy
RVCE	33/40	71%	78%	76%
RCE	38/40	87%	92%	89%

RVCE: conventional renal artery echography; RCE: contrast-enhanced renal artery ecography.

Conclusions: These results suggest the diagnostic effectiveness of RCE but because of major costs and prolonged duration of investigation we think that echo-enhancement is indicated when the CRVE presents a lacking quality or technical limitations

P571 The Allen and inverse Allen test, as a simple method for detecting ulnar or radial predominance. Sensitive but not specific

J. Gourassas[1], C. Papadopoulos[1], U. Albedd[1], T. Karoulas[1], A. Billi[2], G. Louridas[1]. *[1]AHEPA Hospital, Aristotle University, 1st Dept. of Cardiology, Thessaloniki, Greece; [2]AHEPA Hospital, Aristotle University, 1st Dpt of Internal Medicine, Thessaloniki, Greece*

Intoduction: Allen test is used broadly in order to assess ulnar artery patency during radial catheterisation procedures. The purpose of our study was to evaluate Allen and inverse Allen test sensitivity and specificity in detecting ulnar or radial upper extremity predominance, giving evidence for best and easier accessibility for cardiac interventions.
Methods: Routine coronary angiography was performed after informed consent in 49 patients, through the right femoral artery. After completion of the angiography, right brachial artery was catheterised, using the right Judkins catheter. The catheter was retrogradely inserted to the proximal end of the brachial artery, through the right subclavian artery. The right arm of the patient was in complete extension using a special supporter. Selective angiography of the upper extremity was performed, using the A-P projection. Cine films were interpreted and analyzed by two separate interventional Cardiologists and anatomic variables of both arteries were compared respectively. Radial and ulnar luminal diameter was measured at 25 mm proximal to the styloid process and pissiform bone respectively, using electronic calipers. Before catheterisation, Allen and inverse Allen test was performed in every patient and their mean time was recorded. The sensitivity, specificity, positive predictive value and negative predictive value of the Allen/Inverse Allen test for the diameter of radial artery at 25 mm compared to ulnar artery was calculated based on a 2x2 table of Allen>Inverse Allen x radial>ulnar diameter.
Results: The sensitivity of the test was estimated at the level of 90% and the specificity at the level of 50% respectively. Positive predictive value reached 73% and negative predictive value 77%.
Conclusions: Allen/inverse Allen test, an easy, cheap and no time consuming test, seem to be a quite sensitive method with a rather low specificity in detecting ulnar or radial predominance, reflecting easiest accessibility for cardiac catheterisation procedures. More elegant and costly methods are possibly needed for such decision making.

P572 Endothelial damage in atherosclerotic vascular disease by quantifying circulating endothelial cells: relationship with von Willebrand factor

A. Makin[1], S. Silverman[2], G. Lip[1]. [1]City Hospital NHS Trust, University Department of Medicine, BIRMINGHAM, United Kingdom; [2]City Hospital NHS Trust, Department of Vascular Surgery, BIRMINGHAM, United Kingdom

Introduction: Established atherosclerosis is associated with disturbances in endothelial function and a prothrombotic state. Furthermore severe peripheral vascular disease (PVD) manifesting as ischaemic rest pain (IRP) is related to significant morbidity and mortality. Plasma von Willebrand Factor (vWf) is an established index of endothelial damage/dysfunction. Circulating endothelial Cells (CECs) are a new index of endothelial damage, and previously been shown to be abnormal in patients with acute myocardial infarction (AMI) and unstable angina, but not in effort angina. We hypothesised that CECs would increased in patients suffering from IRP compared to healthy controls or patients with Intermittent Claudication (IC).
Methods: We studied 20 patients with IRP (15 males, age 68±10 years), 20 with IC (13 males, age 63±7 years), 20 patients within AMI <24hours (12 males, mean age 61±8 years), and 20 healthy controls (11 males, age 67±10 years). vWf was measured by ELISA. CECs were captured from EDTA/NaF whole blood using an immunomagnetic separating technique, and counted under a fluorescent microscope by an observer blinded to patient group.
Results: CECs were highest in patients with IRP and AMI, with no difference between IC and control groups (Kruskal-Wallis test, p<0.0005). The differences in vWf levels were of borderline significance between the 4 study groups (oneway ANOVA, p=0.06), with a significant difference in vWf levels between control and the IRP groups (p=0.013). There were no correlations between vWf and CECs in any of the groups.

	AMI	IC	IRP	Control	P Value
CECs (cells/ml)	4.9 (4.8-8.6)	1.1 (0.6-2.9)	3.5 (2.0-5.8)	1.0 (0.5-1.7)	<0.0005
vWf (IU/dl)	125±25	120±25	134±28	112±26	0.066

Values given as median (interquartile range) or mean ± standard deviation

Conclusion: This study demonstrates for the first time evidence of direct endothelial cell damage in severe PVD, resulting in the shedding of endothelial cells (raised CECs), perhaps indicative of tissue loss or insipient tissue loss. Such endothelial damage may contribute to the thrombotic complications of atherosclerotic vascular disease.

P573 Markers of the prothrombotic state are not increased with severity of atherosclerotic disease

A. Makin[1], N. Chung[1], S. Silverman[2], G. Lip[1]. [1]City Hospital NHS Trust, University Department of Medicine, BIRMINGHAM, United Kingdom; [2]City Hospital NHS Trust, Department of Vascular Surgery, BIRMINGHAM, United Kingdom

Background: Raised levels of von Willebrand Factor (vWf), a marker of endothelial dysfunction, soluble p-selectin (s-Psel), a marker of platelet activation and fibrinogen and increased plasma viscosity (PV) are known to contribute to the hypercoagulable state in atherosclerotic disease. Tissue factor (TF) is usually expressed in extravascular tissues and is part of the 'extrinsic pathway' of coagulation. Fibrinogen is also known to correlate with disease severity although vWf and s-Psel have not and little data is available on the role of plasma TF in atherosclerosis.
Methods and Results: We studied 234 patients with established atherosclerosis of the peripheral arteries defined as an ankle brachial pressure index (ABPI) of less than 0.8 (145 males, mean age 68±10 years). ABPI was taken as a marker of disease severity. Patients were split into two groups above and below the median ABPI (0.52). The vWf, TF and s-Psel were measured by ELISA, fibrinogen by CLAUSS and PV by viscometer. The table shows that other than for fibrinogen there is no difference between these markers above and below the median ABPI (unpaired t-test or Mann Whitney U test as appropriate).
Conclusion: Severity of disease does not affect the hypercoagulable state in patients with established atherosclerosis.

P574 Screening for abdominal aortic aneurysm during transthoracic echocardiography in hypertensive patients

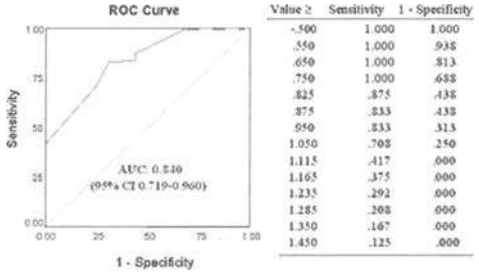
A. Navazio[1], E. Catellani[1], P. Montanari[2], A. Piazza[1], D. Giberti[2], A. Colli[1]. [1]Franchini Hospital, Dept. of Cardiology, Montecchio Emilia (RE), Italy; [2]Franchini Hospital, Dept of Internal Medicine, Montecchio Emilia (RE), Italy

Aim: this study was undertaken to determine the utility of transthoracic echocardiography as a screening test for occult abdominal aortic aneurysm in hypertensive patients subjected to transthoracic echocardiography older 50 years of age.
Methods: In hypertensive patients subjected to transthoracic echocardiography, longitudinal and transverse images of the abdominal aorta were obtained during the subcostal portion of the transthoracic echocardiography. Abdominal aortic aneurysm was defined as an abdominal aortic dimension (anteroposterior or lateral) ≥ 3 cm. Exclusion criteria included prior abdominal aortic aneurysm repair, know abdominal aortic aneurysm and inadeguate images of the abdominal aorta.
Results: 180 patients met the study inclusion criteria (97 men; 83 women, mean age 73 years, range 51-90 years). An occult abdominal aortic aneurysm was identified in 14 patients (7.7%). 10 patients were men (71.4%), with a mean age of 74 years and a mean duration of hypertension of 13 years, 11 patients (78.5%) had a history of tobacco use and 3 patients (21%) had a positive family history of abdominal aortic aneurysm. All aneurysms were infrarenal in location excpet 1 (7%); the mean diameter was 3.8 cm (range 3-5.1 cm). Laminated thrombus was present in 7 patients (50%). Imaging of the abdominal aorta during transthoracic echocardiography required an average of 7.1 minutes (range 5-11 minutes).
Conclusions: Abdominal aortic aneurysm is frequently asymptomatic and often occult on physical examination. Ultrasonography is highly accurate in the diagnosis of abdominal aortic aneurysm and screening for abdominal aortic aneurysm can be readily incorporated into the transthoracic echocardiography examination. Abdominal aorta can be accurately imaged in the majority of patients (94%) undergoing transthoracic echocardiography. The present study shows that incidence of occult abdominal aortic aneurysm detected by transthoracic echocardiography in hypertensive patients older 50 years of age is significant. Screening for an occult abdominal aortic aneurysm in this patient population should be a routine extension of transthoracic echocardiography.

P575 Differentiation between ischaemic and non-ischaemic dilated cardiomyopathy by ultrasonic scanning of carotid artery with high-frequency transducers

R. Moreno, J. Zamorano, A. D Ovidio, C. Almería, J.L. Rodrigo, D. Herrera, L. Alvarez, L. Sánchez-Harguindey. Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain

Aim of the study was to evaluate the usefulness of the non-invasive evaluation of carotid artery artery with high-frequency transducers in the differentiation between ischemic and non-ischemic dilated cardiomyopathy (DC).
Methods: 40 patients with DC undergoing cardiac cath were studied. Ultrasonic scanning of the carotid artery using high-frequency transducers (Agilent 5500 or Aloka SSD 870 machine) was performed. ROC curves were obtained in order to test the usefulness of intima-media carotid wall thickness in the differentiation between ischemic and non-ischemic DC. Also, the presence of visually detected carotid plaques was tested.
Results: Out of the 40 patients, 24 (60%) had ischemic, and 16 (40%) non-ischemic DC. Patients with ischemic DC had a significantly higher carotid artery intima thickness (1.14±0.23 vs. 0.84±0.20 mm, p<0.001). ROC curve showed a high diagnostic value of intima-media carotid artery thickness (area under the curve 0.840; see figure).



Sensitivity, specificity, and predictive values of the variables tested are shown on the table.

Diagnostic value

	Sensitivity	Specificity	Positive PV	Negative PV	Accuracy
Carotid plaques	79.2	75.0	82.6	70.6	77.5
Intima-media > 1mm	83.3	68.8	80.0	73.3	77.5
Any finding	91.7	62.5	78.6	83.3	80.0

Conclusion: Ultrasonic scanning of carotid artery with high-frequency transducers at the Echo Lab is a rapid and reliable method of differentiating ischemic and non-ischemic DC.
ROC curve

P576 Endoluminal stenting for obstructive lesions of the subclavian artery

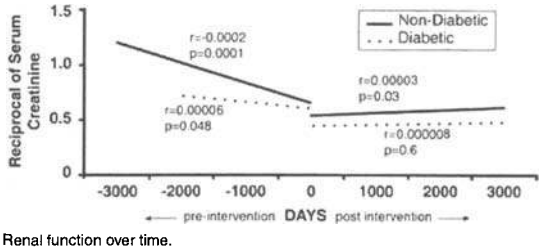
S. Nakamura[1], T. Miyauchi[1], J. Yokoyama[1], A. Kanazawa[1], K. Hozawa[2], S. Nakamura[2], J. Koyama[3], H. Ohira[4]. *[1]New Tokyo Hospital, Department of Cardiorogy, Matsudo-shi, Japan; [2]Kasori Hospital, Dept. of Cardiology, Chiba-shi, Japan; [3]Kobari General Hospital, Department of Cardiology, Noda-shi,Chiba, Japan; [4]Edogawa Hospital, Department of Cardiology, Edogawa-ku, Japan*

Background: Obstructive lesions of the subclavian artery can result in arm claudication, symptoms of subclavian steal. Surgical revascularization has been preferred method for treating these lesions. Aim: To evaluate the safety and efficacy of endovascular stenting for treating 61 obstructive lesions of subclavian artery.
Method: We performed 61 endoluminal stenting 61 patients (24males, 59±12 years). All procedures were performed with the Palmaz stents. Indications for stenting were arm claudication in 44 cases, subclavian steal syndrome in 12 cases and myocardial ischemia secondary to compromised flow through internal mammary graft in 5 cases.
Results: Procedural success (defined as abolition of pressure gradient across the aorta and subclavian artery and a residual diameter stenosis <20% without major complications (acute stent thrombosis, myocardial infarction, embolization, emergency surgery or death) was achieved in all 61 patients. All patients had symptomatic relief acutely. None of the patients had any major complications. Baseline diameter stenosis was reduced from 100% to 14.2±8.3%, mean systolic pressure difference between the upper extremities was 49.2±14.3mHg to 1.2±2.3mHg (p<0.01). In 59 of 61 patients, we performed follow-up (6 to 12 months later) angiography and these were no restenosis.
Conclusion: Endoluminal stenting of the subclavian artery is safe and effective with high technical success and excellent hemodynamic results. These were no cerebral or distal embolization.

P577 Beneficial effects of renal artery stenting on renal function in diabetic patients with chronic renal insufficiency

R. Subramanian, J.A. Silva, S.R. Ramee, T.J. Collins, S.J. Jenkins, C.J. White. *Ochsner Clinic Foundation, Cardiology, New Orleans, United States of America*

Background: Renal artery stenting has been shown to stabilize or improve renal function in a significant proportion of pts with atherosclerotic renovascular disease and impaired renal function. Whether diabetic (DM) pts obtain similar benefit as nondiabetic pts (NDM) is not known.
Methods: The renal function of 36 consecutive pts with bilateral renal artery stenoses (11 DM; 25 NDM) and renal insufficiency (serum creatinine ≥ 1.5 mg/dl) was analyzed by plotting the reciprocal of serum creatinine versus time in days before and after stenting.
Results: All pts had deterioration of renal function prior to intervention. At 47.4 ± 31.2 months post intervention renal function improved or did not change in 76% and worsened in 24% of NDM patients compared to 73% and 27% of DM pts respectively (p=NS).(fig)



Renal function over time.

Conclusion: Renal artery stenting is equally beneficial in DM and NDM pts with impaired renal function and atherosclerotic renal artery stenosis.

P578 Immediate and follow-up results of carotid artery stenting with cerebral protection: a single centre experience on 100 consecutive procedures

C. cernetti, B. Reimers, S. Saccà, G. Pasquetto, M. Napodano, A. Picciolo, P. Pascotto. *Mirano Hospital, Cardiology, Mirano, Italy*

Background: Purpose of this prospective study was to determine periprocedural complications and short- and medium-term outcomes in a cohort of patients treated with carotid stent implantation routinely using cerebral protection devices.
Methods and Results: Stent implantation was attempted in 96 consecutive patients (mean age 70,8±14 years; 77,1% males) presenting significant stenosis (>70%; mean 82,8±9%) in 100 lesions of the extracranial carotid artery. Forty lesions (40%) presented previous stroke or transient ischemic attacks related to the ipsilateral hemisphere. Cerebral protection was performed using filter devices in 93% of procedures and endoluminal clamping of the common and external carotid artery in 5% of procedures. In 2 procedures it was not possible to deploy a protection device. Selfexpandable stents (mesh-wire 60%; nitinol 40%) were successfully implanted in all lesions. Neurological complications during the procedure and in-hospital, occurred after 3 procedures (3%). These were 1 major stroke (1% amaurosis of ipsilateral eye) and 2 transient ischemic attacks (2%). During a follow-up of 9.3 ±3.5 months (mimum 3 months) further neurologic events did not occur. Ecocolor-Doppler at 6month after the procedure was available in 78 treated lesions and >50% in-stent restenosis was found in 2 lesions (2.5%). Major adverse cardiac events during follow-up occurred in 2 patients (2%), this were 1 fatal an 1 non-fatal myocardial infarction.
Conclusions: Incidence of procedural complication during carotid artery stenting with routine use of cerebral protection appeared low. During follow-up no further neurological events occurred and restenosis rate was low.

P579 Carotid artery stenting in patients at high clinical risk of carotid endarterectomy complications: immediate and long-term outcome

F. Liistro[1], A. Chieffo[1], G. Stankovic[2], C. Sarais[1], B. Reimers[3], C. Di Mario[2], N. Corvaia[2], A. Colombo[2]. *[1]Ospedale San Raffaele, Emodinamica, Milano, Italy; [2]Emo Centro Cuore Columbus, Emodinamica, Milan, Italy; [3]Ospedale di Mirano, Emodinamica, Mirano, Italy*

Background: Carotid endoarterectomy (CEA) has been shown to be superior to medical treatment in reducing the overall risk of stroke in patients with symptomatic (>50%) or asymptomatic (>60%) carotid artery stenosis compared to medical treatment. Nevertheless, in subgroups of patients at high risk of acute events, a high complication rate may limit the efficacy and safety of this approach. The aim of this study is to evaluate the efficacy and safety of the percutaneous approach to carotid artery stenosis in a subgroup of patients at higher risk of CEA complications.
Methods: Between May 1998 and January 2002 161 patients (164 lesions) with elective indication and a Mayo Clinic Risk Score > 2 underwent percutaneous carotid revascularization at our institutions. Transient Ischemic Attack (TIA), minor stroke and major stroke were classified accordingly to The National Institutes of Health Stroke Scale (NIHSS). The incidence of death, acute neurological events and myocardial infarction was assessed in-hospital and during follow-up.
Results: 88% of patients were in Mayo clinic risk stratification grade III, 5% in grade IV, 7% in grade VI. Angiographic success was 97.5%; four lesions could not be treated due to severe vessel tortuosity. Procedural success was obtained in 96.2% of patients. Mean residual diameter stenosis was 4.7±5.2 mm. Distal protection device was used in 79.5% of the lesions and stenting was performed in all the treated lesions except for three (in-stent restenosis). Debris was founded in 40% of the protection devices. In-hospital events consisted of 10 (6.2%) TIAs, 1(0.6%) category 1 minor stroke and 1(0.6%) major stroke. At follow-up (mean time:10±5.6 months) death occurred in 9(5.6%) patients; in two of them (1.2%) it was related to acute neurological events, in the remaining 7 (4.4%) it was related to cardiac events (4 patients) and other causes (3 patients). Severe restenosis occurred in 3 (1.8%) lesions.
Conclusions: Carotid artery stenting is feasible and can be performed with extremely low rate of acute events in patients at high clinical risk of CEA complications. The positive results are maintained on long-term outcome with a low incidence of neurological acute events and a low rate of restenosis.

P580 Arterial stiffness is associated with atherosclerotic plaques but not with intima-media thickness in healthy middle-aged subjects

V. Bongard[1], J.B. Ruidavets[1], J. Amar[2], B. Chamontin[2], H. Boccalon[3], J. Ferrières[1]. [1]*INSERM U558, Department of Epidemiology, Toulouse, France;* [2]*CHU Purpan, Médecine Interne et HTA, Toulouse, France;* [3]*Rangueil Hospital, Department of Angiology, Toulouse, France*

The relationship of arterial stiffness with atherosclerosis is controversial and has been scarcely studied in large population-based samples, particularly in youngest subjects. In a sample of middle-aged apparently healthy subjects, we studied the relationships of carotid-femoral pulse wave velocity (PWV) with the presence of atherosclerotic plaques on the one hand and with common carotid intima-media thickness (IMT) on the other hand.

Methods: A sample of 905 southwestern French men and women (35 to 64 years), taking part in the Third French MONICA cross-sectional Survey on cardiovascular risk factors (1994-1996) was analyzed. Each participant filled in extensive questionnaires focused on their cardiovascular risk factors and a blood sample was drawn for biological measurements. Heart rate, arterial blood pressure and carotid-femoral PWV were measured in supine position. PWV measurements were performed with a semi-automatic device (Complior). B-mode ultrasonography was used to measure common carotid IMT and to assess the presence of atherosclerotic plaques in common, internal and external carotid and femoral arteries.

Results: Mean values of PWV and IMT were 9.0 m/s (standard error: 0.06) and 0.59 mm (0.003) respectively and the proportion of subjects with at least one plaque was 50.4%. There was a significant increase in PWV values according to the number of plaques in the artery explored sites: mean PWV equaled 8.6 (0.06), 9.3 (0.11), 10.4 (0.19) and 11.4 (0.45) m/s respectively in subjects with 0 to 1; 2 to 3; 4 to 5; and 6 plaques or more ($p<0.0001$). A similar trend was observed with common carotid IMT quartiles: mean PWV values were 8.3 (0.11), 8.8 (0.11), 9.1 (0.11) and 9.6 (0.11) m/s respectively in the first, second, third and fourth quartiles ($p<0.0001$). After adjustment for sex, age, tobacco consumption, body mass index, resting heart rate, systolic blood pressure, total and HDL-cholesterol and glycaemia, PWV remained significantly associated with the presence of plaques: adjusted means were 8.8 (0.06), 9.0 (0.10), 9.5 (0.17) and 10.0 (0.40) m/s in subjects with 0 to 1; 2 to 3; 4 to 5; and 6 plaques or more (p for trend: $p<0.001$). However, after adjustment, the relationship between mean values of PWV and IMT quartiles disappeared (adjusted p value for trend: $p=0.42$).

Conclusion: In this sample, PWV was independently associated with atherosclerotic plaques but not with common carotid IMT, perhaps because of the relatively low values of IMT observed in this sample of middle-aged subjects.

P581 Folic acid enhances endothelial function and reduces blood pressure in smokers: a randomised controlled trial

A.A. Mangoni[1], R.A. Sherwood[2], C.G. Swift[1], S.H.D. Jackson[1]. [1]*King's College London, Health Care of the Elderly, London, United Kingdom;* [2]*King's College Hospital, Clinical Biochemistry, London, United Kingdom*

Objective: Chronic cigarette smoking is associated with increased plasma homocysteine concentrations, endothelial dysfunction, and arterial stiffening. Homocysteine per se induces endothelial dysfunction and arterial stiffening and might account, at least partly, for the vascular abnormalities observed in smokers. The aim of the study was to determine whether folic acid supplementation, by reducing plasma homocysteine concentrations, enhanced endothelial function and reduced arterial stiffness in smokers.

Methods: Twenty-four healthy cigarette smokers (age 37.8±2.5 years, mean±SEM) were randomly assigned to 4-week folic acid 5 mg/d or placebo. The following were measured before and after treatment: 1) peripheral vasoreactivity (forearm arterial blood flow, FABF) during intra-arterial administration of endothelium-dependent (acethylcholine 1.5, 4.5, and 15 μg/100ml/min) and endothelium-independent (sodium nitroprusside 1, 2, and 4 μg/100ml/min) vasodilators; 2) carotid-femoral pulse-wave velocity (PWV); 3) blood pressure (BP).

Results: Folic acid reduced homocysteine concentrations (10.8±0.6 vs. 8.2±0.5 μmol/L, $p<0.001$) and enhanced endothelium-dependent vasodilatation during each acetylcholine infusion rate (FABF ratio between the infused and control arm at baseline 1.09±0.03 vs. 1.41±0.09 after treatment, $p<0.01$; 1.39±0.07 vs. 1.83±0.12, $p<0.01$; 1.65±0.16 vs. 2.72±0.36, $p<0.05$) whilst endothelium-independent vasodilatation was unaffected. A significant fall in BP was also observed (mean BP 88±2 vs. 83±1 mmHg, $p<0.01$). By contrast, PWV did not change (8.4±0.3 vs. 7.8±0.4 m/s). No changes in homocysteine concentrations, FABF, BP, and PWV were observed in the placebo group.

Conclusions: Short-term folic acid supplementation significantly enhanced endothelial function and reduced blood pressure in young chronic smokers. Thus, a simple, non-toxic, and relatively inexpensive vitamin intervention might be a useful primary cardiovascular prevention tool in this high-risk group.

P582 Predictive value of intima-media thickening and asymptomatic carotid plaque for cardiovascular events in the follow-up

S. Novo[1], R. Tantillo[1], G. Evola[2], S. Evola[2], I. Muratori[1], A. Strano[3], S. Mansueto[4], M. Affronti[4]. [1]*Università di Palermo, Chair of Cardiovascular diseases, Palermo, Italy;* [2]*University, Cardiovascular diseases, Palermo, Italy;* [3]*University Tor Vergata, Arteriosclerosi and Dismetabolic Dis., Roma, Italy;* [4]*Università, Internal Medicine and Emerging Path., Palermo, Italy*

During the years 1998-1993, on behalf of the research project CIFTI 4-GESCO-MUTST, we examined 755 subjects of both gender, aged between 18 and 85 years, without or with risk factors, to evaluate the prevalence of asymptomatic carotid lesions (IMT= intima-media thickening and ACP= asymptomatic carotid plaque). In this study we demonstrated that these lesions are more frequent in the male gender, increase with aging and are significantly related with the presence of single RF (arterial hypertension, diabetes mellitus, hypercholesterolemia, smoking) as well as with multiple and associated RF. The follow-up of these subjects continued and in this moment we have available data of 5 years follow-up concerning 123 patients, 42 normal, with mean age of 56.84± 13.96 years, 39 with IMT and mean age of 63.18± 13.21 and 42 with ACP and mean age of 69.62± 6.98 years, at first examination. The mean number of RF was 1.36± 1.18, 1.77± 1.20 and 1.76± 1.3 respectively in the three groups. In the group of normal subjects 38.09% remained normal, 21.42% showed an evolution versus IMT and 28.57% versus ACP, while 11.9% died. In the group with IMT, 7.69% showed a regression, 48.71% were unchanged, 20.51% died and only 2.56% had non-fatal events. In the group with ACP only 2% showed a partial regression of lesions, 40.7% remained unchanged, 45.23% died, while 11.90% had non-fatal evens. Distinguishing between cardiovascular and non cardiovascular death, the frequency was respectively 0.47 and 1.9% for year in normals, 2.56% and 1.53% for year in patients with IMT and 3.33% and 4.76% for year in subjects with ACP was. 7 fatal AMI were registered in the group with ACP and 1 in the group of normals, 3 non fatal AMI in the group with ACP, 5 fatal stroke in the group with ACP, 2 non fatal stroke in the group with ACP and 1 in the group with IMT.

The preliminary results of our study referring to a 5 years follow-up of 123 subjects, shows that the most part of patients with asymptomatic carotid lesions have a progression of lesions as well as an important increase of both total mortality and cerebrovascular and cardiac, fatal and non fatal evens.

So, our study suggests that asymptomatic carotid lesions have to be considered an important risk factor for cardiovascular morbidity and mortality.

P583 Coronary ectasia and varicose veins; is there any relationship?

A.E. Androulakis, A.A. Katsaros, A.A. Pantazis, E.G. Triadafyllidi, P.N. Stougiannos, I.M. Pylarinos, A.N. Kartalis, I.E. Kallikazaros. *Hippokration Hospital, State cardiac department, Athens, Greece*

Coronary artery ectasia (CAE) represents abnormal coronary arterial dilatation, the diameter of which exceeds by 1.5 times the adjacent normal segment. It is estimated that CAE affects about 2% of the general population and it is found in 1.4-4.9% of coronary arteriograms. The aetiology of CAE remains unknown and its origin is not clear whether it is a pure wall defect, a pure endothelium defect or a mixture of these. The same helds true in varicose veins (VV), a common clinical situation, with a prevalence of 15-30% in all populations. Though CAE and VV refer to the pathology of different vessels, the underlying histologic changes of the arterial wall between the two entities show some interesting similarities. We sought to assess the prevalence of VV in patients with CAE. From previous studies performed in our geographical area, the prenalence of VV in the general population was found to be about 23%.

Methods: During the last two years, all pts undergoing coronary arteriography in whom CAE was present, were immediately checked clinically for the presence of VV. Another 165 subjects without profound disease were also examined for the presence of VV during the same time period.

Results: A total of 6768 pts underwent coronary arteriography at our institution within 2 years. CAE was present in 147 of them (2.17%). Fifty-nine pts with CAE were found to suffer from VV (40.13%), and were significantly more than the 41 of the 165 control subjects (24.85%) in whom VV were present, $p<0.001$ (table).

	Varicose Veins (VV)	Lack of VV
Coronary Artery Ectasia (N=147)	59 (40.13%)	88 (59.87%) °
General Population (N=165)	41 (24.84%)	124 (75.16%) °

° $P<0.001$

Conclusions: It seems that there is a relationship between CAE and VV, as VV are more common in pts with CAE. While there are important difficulties in studying the pathology of both CAE and VV in the same patient at the same time, an underlying generalized defect of the vessel wall might be responsible for such an observation and merits further study.

P584 Long-term follow-up of critical limb ischaemia (CLI) treated by spinal cord stimulation

E. Melillo[1], D. giannini[1], F. Buttitta[1], A. Menegato[1], M. Nuti[1], M. Ferrari[2], R. Berchiolli[2], A. Balbarini[1]. [1]*Ospedale Cisanello, Cardiac and thoracic Department-Univ., PISA, Italy;* [2]*Cisanello Hospital, Vascula Surgery Unit, Pisa, Italy*

Introduction: Although Spinal Cord Stimulation (SCS) has been effectively used for unrecontructable CLI, during the past 10 years, in controlled studies, for some clinical investigators (TASC 2000) SCS "on current evidence cannot be recommended in the treatment of CLI".
Aim of the study: A. Evaluation of the clinical response to SCS treatment in long-term follow-up. B.Evaluation of the transcutaneous oxygen and carbon dioxide pressures -TCpO2 and TCpCO2-, LaserDoppler Flowmetry -LDF- to define local microcirculatory variations and the predicting capacity in limb salvage. **Subjects and methods:** 11 consecutive CLI patients, 3 in stage III, 8 in stage IV (M/F: 7/4, mean age 71.8,5 diabetics), with unrecontructable CLI, were treated for a minimum of 15 days with a temporary SCS and then with a permanent spinal pacemaker. The patients were subject to clinical (analgesic therapy, trophic lesions and walking capacity) and instrumental evaluation by means of the measurement of cardiac frequency (CF) and arterial pressure (AP), Winsor index (WI), TcpO2 and TCpCO2, LDF: these evaluations were made both prior to SCS treatment and in the SCS follow-up of 15, 90, 180, 360, 730 days. RESULTS: the overall mortality rate was 27% and the overall amputation rate was 9%. At the clinical level 73% of cases were Responders (n=8)vs 27% Non-responder (n=3;1 amputation within 6 months). No significant variations in CF, AP and WI were registered. However, TCpO2 of the symptomatic foot of the Responders showed notable mean pressure improvement ($p<0.03$) from zero to 30 mmHg after 15 days and to 40 mmHg after one year of stimulation. In non-Responders the TCpO2 remained consistently below 5 mmHg for the entire duration of the treatment. SCS did not affect the high TcpCO2 basal median in the Non Responders, while in the Responders the TcpCO2 (m: 49mmHg) values normalised within a maximum of three months (<40 mmHg). In the Non Responders, the LDF confirmed low levels of perfusion, lack of an increase in the LDF signal after maximal heating, and marked alteration in the postural venous-arterial reflex (VAR) both at the hallux and at the first inter-metatarsus, while the Doppler laser signal indicated more favourable results in the Responders.
Conclusions: This study confirms the indication of SCS in patients in CLI who are no longer susceptive to medical therapy and/or surgery. The instrumental evaluation is more accurate than clinical evaluation.TcpO2 and TcpCO2 continue to be the most useful predicatibility index in patients subject to the permanent implant of a medullary pacemaker.

P585 Significant association between markers of systemic inflammation and the extent of atherosclerosis in the arterial vessel tree

C. Espinola-Klein, H-J. Rupprecht, S. Blankenberg, C. Bickel, M. Ries, J. Meyer. *University Clinic Mainz, 2nd department of internal medicine, Mainz, Germany*

Inflammation in the arterial vessel wall has been considered to play an important role in the pathogenesis of atherosclerosis. Recent prospective studies have shown that cytocines like interleukin-6 (IL-6) or tumor necrosis factor a (TNF a) as well as acute phase proteins like sensitive C reactive protein (CRP) or fibrinogen are associated with atherosclerosis. Therefore we evaluated the correlation between different markers of inflammation and the extent of atherosclerosis including coronary, carotid and peripheral arteries.
Methods: In a prospective study we included 825 patients (70% men, mean age 63 years) preceding heart catheterization. The extent of atherosclerosis was determined by coronary angiography (stenosis >30%), carotid duplex sonography (stenosis >50%) and by evaluation of the ankle-arm index (= ankle/arm blood pressure, pathologic <0.9). Patients were divided into 3 groups with regard to the extent of atherosclerosis to: control (=no atherosclerosis, N=91), limited disease (=atherosclerosis in 1 vascular region, N=394) and advanced disease (=atherosclerosis in 2 or 3 vascular regions, N=340). Blood samples were taken by all patients and values of IL-6, TNF a, CRP and fibrinogen were evaluated. Regression test was used for statistical evaluation.
Results: Median (25th-75th percentile) inflammatory parameters in the 3 patient groups are shown in the table.

Inflammation and atherosclerosis

	Control	Limited disease	Advanced disease	
IL-6 (ng/ml)	8.2 (4-13)	11.0 (5-23)	11.9 (6-24)	P<0.002
TNF a (pg/ml)	22.2 (16-27)	22.9 (16-29)	24.3 (17-32)	P<0.02
CRP (mg/L)	2.6 (1-7)	4.3 (2-11)	5.0 (2-15)	P<0.0001
Fibrinogen (mg/dl)	294.0 (257-330)	328.5 (279-397)	354.0 (290-434)	P<0.0001

Association between inflammatory parameters and extent of atherosclerosis.

Conclusion: There was a significant correlation between all evaluated markers of systemic inflammation and the extent of atherosclerosis including coronary, carotid and peripheral vessels.

P586 Nebivolol restores vasomotion and vasodilator capacity of microcirculatory bed in hypertensive patients with altered microvascular function

C. Morizzo[1], F. Vittone[2], A. Colantuoni[3], M. Kozàkovà[2], A. Magagna[2], M.A. Morales[1], A. L'Abbate[1], C. Palombo[2]. [1]*Clinical Physiology Institute, CNR, Pisa;* [2]*University of Pisa, Dept. of Internal Medicine, Pisa;* [3]*University of Naples "Federico II", Dept. of Neuroscience, Naples, Italy*

Nebivolol is a beta1-adrenergic blocker suggested to improve NO-dependent vasorelaxation in the forearm model in human hypertension. The so-called low frequency flowmotion waves (LF) of peripheral microcirculation, i.e. the low frequency components (0.05- 0.1 Hz) of the oscillatory Laser Doppler perfusion monitoring (LDPM) signals, are related to spontaneous arterial vasomotion and depend at least partially on endothelial functional integrity. These frequency components usually disappear in presence of severe systemic vascular disease.
Aim of the study was to assess the effects of Nebivolol therapy on peripheral microcirculation in patients (pts) with essential hypertension (HBP). Methods: in 22 HBP pts (mean age 52±10, 14 males, SBP/DBP 151±9/98±7 mmHg) and 20 age and gender matched NT(SBP/DBP 118±12/72±9 mmHg), forearm skin blood flow was assessed by LDPM at rest and after stepwise doses of Acetylcholine (ACh) and Sodium Nitroprusside (SNP) administered simultaneously by iontophoresis at the two forearms. Oscillatory components of LDPM were assessed by time-dependent power spectrum analysis of the resting signals. In HBP the study was repeated after Nebivolol therapy (21 days, at 5 mg/die).
Results: In HBP pts, peak response to ACh was comparable to NT (peak ACh: 50±29 vs 63±24 PU p=ns) while peak response to SNP was significantly lower (peak SNP: 34±24 vs 54±35 PU, $p<0.05$). However, comparing pre-treatment dose-response curves to ACh and SNP in HBP pts to the average of NT, we could distinguish two subgroups: A) with a depressed response (flow max<1sd below the average peak flow in NT, n=9) and B) with a preserved response (flow max>1sd below the average peak flow in NT, n= 13). Before therapy, LF were detected in 8/22 pts (3 A and 5 B) and in all NT. After therapy, BP significantly decreased in all pts (average 134±12/81±10 mmHg, $p<0.001$ vs baseline). Flow response to both vasoactive agents did not significantly change compared to pretreatment value in the overall population (maximal response to ACh: 51±15 PU, and SNP: 46±30 PU, p=ns vs pretreatment). However, the response to ACh and SNP significantly improved ($p<0.05$) in those pts with a corresponding basally impaired response. In LDPM signals, LF were detected in 9 more pts (4 A and 5B) as compared to pretreatment recordings ($p<0.05$).
Conclusions: in HBP, Nebivolol treatment improves both arteriolar vasomotion and vasodilator capacity at peripheral microcirculatory level. The enhancement of the vasodilator response to ACh and SNP appears to be selective in those pts with basally impaired vascular function.

P587 Effects of gender on large artery elasticity. A study in male to female transsexuals

C. Tsioufis, P. Papageorgaki, K. Tzioumis, M. Toutouza, M. Vitalis, C. Stefanadis, I. Kallikazaros, P. Toutouzas. *Hippokration, University of Athens, Department of Cardiology, Melissia, Greece*

It is not well determined whether the gender differences on cardiovascular disease may be explained, at least partially, by differences on large artery elasticity. Also, limited information exists regarding vascular function in male to female transsexuals.
Methods: Towards this end, we evaluated aortic elastic properties in 13 male to female transsexuals (age 44±9 years, 18±11 years after surgery) and we compared these findings with those observed in 10 premenopausal women (age 42±5 years) and in 10 men (age 43±5 years). Aortic compliance was evaluated non-invasively on the basis of Doppler ultrasound measurements of pulse wave velocity (PWV) from the carotid to femoral artery by the foot-to-foot method. All included subjects had a negative glucose intolerance test.
Results: The three groups of men, women and male to female transsexuals were matched for age (44 vs 42 vs 43 years, respectively) body mass index (25 vs 23 vs 24 Kgr/m^2, respectively), smoking status (current smokers 45% vs 42% vs 48%, respectively), total cholesterol plasma levels (232 vs 229 vs 218 mg/dl, respectively) and office blood pressure (115/75 vs 110/75 vs 115/73 mmHg, respectively) (p=NS for all the above cases). Also, these three groups did not differ regarding the left ventricular echocardiographic data of left ventricular mass (171 vs 142 vs 158 gr, respectively), and relative wall thickness (0.41 vs 0.42 vs 0.41, respectively)(p=NS for all measurements). In contrast, the aortic PWV was significantly higher in men compared to transsexuals and women (217±30 vs 204±21 vs 201±20 cm/sec, respectively) while the PWV did not differ between transsexuals and women (p=NS). In the entire population aortic PWV had a positive correlation with age ($r=0.30$, $p<0.05$), systolic BP ($r=0.44$, $p<0.005$)
Conclusion: These results suggest that vascular adaptations in male to female transsexuals are more closely related to those observed in premenopausal women than those in age-matched men.

P588 Agonistic antibodies against the angiotensin-1 receptor from preeclamptic patients stimulate the NADPH oxidase

R. Dechend[1], C. Viedt[2], D.N. Muller[1], R. Dietz[1], J. Kreuzer[2], F.C. Luft[1]. *[1]Franz Volhard Clinic, Cardiology, Berlin, Germany; [2]University of Heidelberg, Cardiology, Heidelberg, Germany*

We recently identified agonistic autoantibodies directed against the angiotensin AT1 receptor (AT1-AA) in the plasma of preeclamptic women. To elucidate whether or not AT1-AA could account for some of the clinical findings, we studied the effects of AT1-AA on reactive oxygen species (ROS) production, NADPH oxidase expression, and NF-kB activation in vascular smooth muscle cells (VSMC) and human primary trophoblasts. Antisense against p22 phox reduced AT1-AA induced ROS activation. Ang II and AT1-AA increased ROS production, as well as the expression of the NADPH oxidase components, p22, p47, and p67 phox, in western blot. We next tested whether or not AT1-AA could lead to nuclear factor-kB activation in VSMC and trophoblasts. We used electrophoretic mobility shift assays and found that AT1-AA activated NF-kB. IkBalpha expression was reduced in response to AT1-AA. VSMC from p47 Knockout mice showed reduced NF-kB activation in response to AT1-AA. Furthermore, p22, p47, and p67 phox expression in the placentas from preeclamptic patients was increased, compared to normal placentas. Increased ROS production was observed in preeclamptic placentas in situ. Correspondingly, we observed that NF-kB was activated and IkBalpha reduced in placentas from preeclamptic women, compared to normal placentas. Thus, NADPH oxidase is potentially an important source of ROS and upregulates NF-kB in preeclampsia. We suggest that AT1-AA via activation of the NADPH oxidase could account for the well-established production of ROS and chronic inflammatory responses in preeclampsia.

P589 Dialytic membrane biocompatibility on the development of atherosclerosis in haemodialysis: the role of chronic infections

T. Parenzan[1], M.M. Ciccone[1], M.C. Lanzilotti[1], M. Liccese[1], A. Teutonico[2], G. Pertosa[2], F.P. Schena[2], P. Rizzon[1]. *[1]Azienda Policlinico, Universitary Cardiology, Bari, Italy; [2]Nephrology, University of Bari, Bari, Italy*

Haemodialytic treatment is often associated with an increased cardiovascular mortality and morbidity due to a complex inflammatory process that accelerates atherosclerosis.Chronic low-grade infections with Chlamydia pneumoniae (CP) or Helicobacter pylori (HP) may play a pathogenic role in the development of atherosclerosis (ATS). The aim of this study was to investigate the relationship between different types of dialytic membranes, seropositivity to CP or HP and early markers of ATS. The study was carried out in 68 patients (M 39 F 29; mean age 54, range 18-70 years; mean time on dialysis 50 months) on renal replacement therapy for over 6 months with cellulosic (C) (32) or synthetic (S) (36) membranes. In this patients we evaluated anti-CP and anti-HP IgG titres, C reactive protein (CRP) levels, serum albumin, PTH, chol and plasma C5b-9 concentrations,intima-media thickness (IMT) and number of ATS plaques in carotid arteries (PL) obtained by high resolution vascular echography. The concentrations of CRP were directly and significantly correlated with the IMT ($r2=0.56$, $p<0.001$). No correlation could be observed between these parameters and serum PTH and chol concentrations, but instead, was interesting to observe that patients treated with C membranes as compared to patients treated with S membranes presented higher CRP (C 0.66±0.6, S 0.24±0.2 mg/dl) and C5b-9 (C 187±82, S 136±33 ng/ml) levels and an increased IMT (C 1.08±0.3, S 1.01±0.2 mm). On the other hand, patients with an anti-CP IgG titre higher than 1:8 presented a significantly higher IMT, number of PL, and presented an higher CRP concentration(table). No differences were observed in either IMT or number of PL in patients with (titre higher than 1:4) or without anti-HP IgG.

	IMT	PL	CRP
anti-CP > 1:8	1.03 ± 0.26	0.55 ± 0.3	0.53 ± 0.51
anti-CP < 1:8	0.86 ± 0.13	0.12 ± 0.2	0.20 ± 0.15
p	< 0.005	< 0.002	< 0.05

anti-CP: antibodies anti C. pneumoniae (titre); IMT: intima-media thickness carotid arteries (mm); PL: atherosclerotic plaques >40% (n°); CRP: serum levels of C reactive protein (mg/dl)

In conclusion, our data would suggest that persistent CP, but not HP; infection as well as the use of cellulosic membranes may play a key role in the development of ATS lesions

P590 Decreased endothelial eNOS expression in varicose veins is associated with increased smooth muscle cell apoptosis

H. Lass[1], D. Bonderman[2], C. Adlbrecht[2], J.C. Huber[1], I.M. Lang[2]. *[1]Obst. and Gynaecology, [2]Cardiology Dept., Univ. of Vienna, Vienna, Austria*

Introduction: The pathogenesis of varicose veins (VV) is poorly understood. VV are characterized by thinning of the medial layer through loss of medial smooth muscle cells. We previously identified the loss of VV-endothelial eNOS expression and function as a key feature of the pathology of VV. Because inhibition of NO synthesis increases apoptotic cell death, those segments of saphenous veins that had been investigated for their NOS expression status, were subjected to TUNEL analysis. Furthermore, genomic DNA from those same patients were analyzed for a candidate eNOS polymorphism to understand whether the observation was a primary genetic defect, or a secondary, observational finding.

Material and Methods: We studied specimens from 33 patients (19f/14m) undergoing VV excisions and from 28 (13f/15m) controls. NOS activity was measured in saphenous veins endothelial scrapings by the conversion of L-[14C]arginine to L-[14C]citrulline in pmol/min/g. In situ labeling of DNA fragments by TUNEL was performed with the ApopTag in situ apoptosis detection kit. Apoptotic indices were determined by dividing the number of TUNEL-positive cell nuclei by the total number of cell nuclei/100. Finally, genomic DNA was amplified using oligonucleotide primers specific for intron 4 of eNOS.

Results: In accord with the immunohistochemical finding of a dramatically reduced endothelial eNOS expression, endothelial eNOS activity was significantly lower in VV compared with controls (p=0,03, table). In addition, intimal and medial apoptotic indices were significantly increased in VV (p=0,028 and 0,0006, respectively). Genetic analysis revealed that the allelic frequency of NOS3 T-788C was not different from a reference population.

	INTIMA		MEDIA	
	Healthy vein	Varicose vein	Healthy vein	Varicose vein
Apoptotic Index	0.14±0.06	0.23±0.12	0.15±0.1	0.28±0.1
eNOS-activity	968.2±1025	138.3±109	not applicable	not applicable

Discussion: This study suggests that the lack of eNOS expression in VV endothelium is associated with enhanced smooth muscle cell apoptosis, thus contributing to progressive intimal and medial fibrosis. However, the NOS3 T-788C polymorphism is not a key mutation underlying eNOS loss from VV endothelium.

P591 Invasive and non-invasive evaluation of spontaneous arteriogenesis in a novel porcine model for peripheral arterial obstructive disease

I.R. Buschmann[1], M. Voskuil[2], N. Van Royen[2], B. Guth[3], R. Seidler[3], W. Schaper[4], C. Bode[1], J.J. Piek[2]. *[1]University of Freiburg, Cardiology and Angiology, Freiburg, Germany; [2]Academic Medical Center, Cardiology, Amsterdam, Netherlands; [3]Boehringer Ingelheim, Pharmacology, Biberach, Germany; [4]Max-Planck Institute, Experimental Cardiology, Bad Nauheim, Germany*

Introduction: Most experimental arteriogenesis data are based on studies using small animals such as mice or rabbits, which only partially reflect the situation in humans with peripheral artery obstructive disease (PAOD), because of the relatively small tissue mass necessary for the morphogenesis of new arteries in mice versus man. The objective of this study was to evaluate a pig hindlimb ligation model for PAOD.

Methods: 12 farm pigs (FP) and 13 Göttinger minipigs (MP) underwent a ligation of the A. Femoralis Superficialis, distal to the bifurcation of the A. Femoralis Profunda. The animals were examined either directly after ligation (FP; n=7 and MP; n=4) or after two weeks of intra-arterial PBS infusion (FP; n=5 and MP; n=9). In the terminal experiment, inflow to the legs was assessed using ultrasonic flow probes placed on the A. Iliaca. Distal arterial pressures in the legs as well as perfusion pressure in the abdominal aorta were measured using fluid-filled catheters before and after installation of an extracorporal system in the abdominal aorta. Using this pump driven extracorporal circulation, leg perfusion pressures could be controlled. At different perfusion pressure levels and under maximal vasodilatation using papaverin, inflow to the legs and distal pressures were assessed and vascular conductance was calculated. X-ray & MR angiographies and histology were performed in some animals to visualize collateral arteries.

Results: Peripheral arterial pressures and flow in the A. Iliaca dropped markedly after acute ligation in both farm pigs (from 94±9 to 25±9 mmHg and 189±29 to 101±24 ml/min) and minipigs (from 71±18 to 34±7 mmHg and 91±30 to 29±17 ml/min). Pressure and flow recovered partially after two weeks in FP and MP (61±9 and 55±12 mmHg and 158±25 and 64±36 ml/min, respectively). Conductance increased from 4% and 9% of the normal leg in MP and FP after acute ligation, respectively, to 9% in minipigs compared to 22% in farm pigs after two weeks ($p<0.05$). MR and X-ray angiography showed collateral artery formation from the A. Femoralis Profunda.

Conclusions: This is the first pig model for hemodynamic assessment of growth of collateral arteries in the peripheral circulation, that is suitable for evaluation of arteriogenic effects of growth factors or genes. Age and animal strain may have an impact on this collateral vascular development.

P592 Is there a scientific rationale for routine greater saphenous vein stripping?

R. Molino Lova[1], M. Cappelli[2], A. Conti[1], C. Macchi[1], S. Ermini[2], B. Miniati[1], G.F. Gensini[3], L. Ferrucci[4]. [1]*Fondazione Don Gnocchi, Cardiology, Pozzolatico, Italy;* [2]*Phlebologic Surgery, Florence, Italy;* [3]*University of Florence, Internal Medicine and Cardiology, Florence, Italy;* [4]*INRCA, Laboratory of Clinical Epidemiology, Florence, Italy*

Background: The stripping of the entire Greater Saphenous Vein (GSV) is currently the most used surgical procedure performed in patients with varicose veins, based on the assumption that, in these patients, all superficial veins, including the entire GSVs, are heavily affected by the varicose disease. Using recently validated well defined echographic criteria, we assessed, in a large series of patients, the extent of varicose involvement of the entire GSV.
Methods: We performed echo-Doppler examination in 350 lower limbs with primary varicose veins in the territory of the GSV due to incompetence of the sapheno-femoral junction, belonging to 300 consecutive patients. Patient population consisted of 71 males and 229 females, age-ranging 21 to 84 years. A varicose vein was defined as a diffusely swollen and elongated vein with bends, and a segmental swelling was defined as a length-limited venous dilatations less than 2.5 cm long. Valve incompetence was diagnosed by detecting a retrograde flowusing both compression/release test and the Valsalva maneuver.
Results: By the above mentioned criteria, only 1 GSV out of 350 was varicose, and 82 GSVs out of 350 showed segmental swellings. Fifty-two percent of the examined GSVs were competent for at least half of their total length and only 7% were completely incompetent.
Conclusions: Our findings show that the GSV is largely spared by the varicose disease in the majority of cases. Accordingly, there appears to be no scientific rationale for routine Greater Saphenous Vein stripping.

P593 Late acute thrombotic occlusion after endovascular brachytherapy and stenting of femoro-popliteal arteries

A. Gallino[1], R. Bonvini[1], I. Baumgartner[2], D. Dai Do[2], M. Alerci[1], P. Tutta[1], K. Jäger[3], F. Mahler[2]. [1]*Ospedale San Giovanni, Cardiologia, Bellinzona, Switzerland;* [2]*Inselspital, Angiology, Bern, Switzerland;* [3]*University Hospital, Angiology, Basel, Switzerland*

Introduction: Endovascular brachytherapy (EVBT) has been proposed as a promising treatment modality to reduce restenosis after angioplasty. However, the phenomenon of late acute thrombotic occlusion (LATO) in patients receiving EVBT after stenting is of major concern. Aim of this article is to underline the importance of this complication after EVBT and intravascular stenting of the femoro-popliteal arteries occurring in a running randomized trial.
Methods and results: A total of 294 patients have been randomized so far in a running prospective multicenter trial of patients undergoing EVBT (Ir 192; 14 Gy in 5mm) after percutaneous recanalisation of femoro-popliteal obstructions. Ninety-four patients out of 204 patients, who completed the 6-month follow-up, were randomized to EVBT.
LATO occurred exclusively in 6/22 patients (27%) receiving EVBT after intravascular stenting and in concomitance with reduction of antithrombotic drug prevention (Clopidogrel). Conversely, none of the 72 patients undergoing EVBT after balloon angioplasty without stenting ($p<0,01$), and none of the 110 patients without EVBT presented LATO ($p<0,05$).
Conclusion: Late thrombotic occlusion occurs not only in patients undergoing EVBT after percutaneous coronary recanalisation but also after stenting of the femoro-popliteal arteries and may challenge the benefits of endovascular radiation. The fact that all our cases with LATO occurred in concomitance with stopping Clopidogrel may indicate a possible rebound mechanism. An intensive and prolonged antithrombotic prevention is probably indicated in these patients.

P594 Aortic atherosclerotic disease as a risk factor for cerebrovascular accidents in patients without prior cerebrovascular events

M. Imazio, M. Tidu, E. Cecchi, F. Pomari, L. Coda, R. Trinchero. *Maria Vittoria Hospital, Cardiology Dept., Turin, Italy*

Background: Atherosclerotic disease of the ascending aorta and the aortic arch (detected by transesophageal echocardiography) is known as a significant predictor of recurrent brain infarction and other vascular events in patients with prior cerebrovascular accidents. After a literature review we found little evidence about aortic atherosclerosis as a cerebrovascular risk factor for patients without a prior cerebrovascular event.
Aim: To evaluate the frequence and prognostic value of aortic atheromas detected by transesophageal echocardiography in these patients.
Methods: We studied 414 consecutive patients who performed a transesophageal echocardiography between January 1999 and July 2001. Baseline clinical characteristics (including coronary risk factors, presence of atrial fibrillation, carotid stenosis and peripheral arterial disease) were recorded. At transesophageal echocardiography we studied atherosclerotic aortic plaques morphology giving a grading from I to V (grade I. minimal intimal thickening, grade II: extensive intimal thickening, grade III: sessile atheroma, grade IV: protruding atheroma, grade V: mobile atheroma).
Results: We found aortic atheromas in 77 cases (19,3%, mean age 66,0 ± 9,6 years, male/femal ratio= 46/31). Aortic atheromas were found in ascending aorta in 22 cases (28,6%), in the aortic arch in 37 cases (48,1%) and in the descending aorta in 18 cases (23,3%). Aortic plaque grading was: grade I in 17 cases (22,0%), grade II in 28 cases (36,4%), grade III in 11 cases (14,3%), grade IV in 14 cases (18,2%) and grade V in 7 cases (9,1%). After a mean follow-up of 29,2 months (range 6-48 months) we observed 33 vascular events (42,9% of all case: 24 cerebral infarction, 6 transient ischemic attacks, 3 myocardial infarction). A higher number of vascular events were recorded in patients with aortic plaques grade III vs grade I-II (respectively 81,2% vs 11,1%, $p<0,001$) and grade IV-V vs grade I-II (respectively 90,5 vs 11,1%, $p<0,001$). After adjustment for the presence of carotid stenosis, atrial fibrillation, peripheral arterial disease and coronary risk factors we found that only grade IV-V (OR 5,12 CI 95% 1,78 to 8,4) was an independent predictor of cerebrovascular events.
Conclusions: Asymptomatic atherosclerotic aortic disease can be a frequent occasional finding at transesophageal echocardiography. Presence of high risk plaques by grading I to V is a significant predictor of cerebrovascular events also in asymptomatic patients without prior cerebrovascular events.

P595 Predictive value of atherosclerotic risk factors, chest X-ray, haemostatic and inflammatory parameters for aortic arch atheromatosis

P. Ehlermann[1], W. Mirau[1], J. Jahn[2], A. Remppis[1], A. Sheikhzadeh[3]. [1]*Universitaetsklinikum Luebeck, Medizinische Klinik II, Luebeck, Germany;* [2]*Medizinische Klinik, Borromäus-Hospital, Leer, Germany;* [3]*Herzzentrum, Segeberger Kliniken, Bad Segeberg, Germany*

Aortic arch atheromatosis (AAA) is a common cause of cerebral and peripheral embolisations. Transesophageal echocardiography (TEE) is the diagnostic method of choice showing not only the extension and consistency of aortic atherosclerotic plaques but also the mobility of superimposed thrombi. In most cases AAA is only detected when the first embolic event has already occurred. This study was therefore designed to identify predictive factors for AAA.
112 consecutive patients on routine TEE entered the study. Exclusion criteria were warfarin therapy, recent surgery, any sign of infectious, immunological or malignant disease. Among classic atherosclerotic risk factors diabetes mellitus was accompanied with the highest risk for AAA Grade IIIa and IIIb (odds ratio 3.0), followed by hyperlipidemia (2.5) and arterial hypertension (2.3). Age above 70 years was accompanied by a 1.8-fold increased risk. Patients with calcifications of the aortic shadow on standard chest x-ray had a 4.6-fold higher prevalence of AAA. Patients with AAA grade IIIb had significantly higher levels of C-reactive protein (19.9 vs. 7.9 mg/l), prothrombin fragments F1+2 (1.21±0.70 vs. 0.90±0.65 nmol/l), PAP (727±298 vs. 440±212 µg/l) and D-dimers (968±656 vs. 452±310 µg/l), but lower ATIII (92.0±18.0 vs. 99.6±20.1%). Patients with echolucent plaques in contrast to other plaque morphologies were older (70.3±7.8 vs. 65.4±9.5) and showed significantly higher leves of von Willebrand factor antigen (148.0±46.0 vs. 126.4±32.1%), D-dimers (920±569 vs. 406±312 µg/l) and PAP (623±288 vs. 454±237 µg/l). AAA is accompanied by an elevation of inflammatory and hemostatic parameters, while patients with classic cardiovascular risk factors display a higher prevalence of this disease. Further prospective studies will have to establish a risc score that identifies patients that might profit from a TEE screening.

P596 Evolution of intramural haematoma to aortic aneurysm

A. Evangelista Masip[1], G. Avegliano[1], C. Elorz[1], M.C. Sebastiá[2], M.T. González-Alujas[1], H. García del Castillo[1], R. Domínguez[2], J. Soler-Soler[1]. [1]Vall d'Hebron Hospital, Dept. of Cardiology, Barcelona, Spain; [2]Hospital Vall d'Hebron, Institut de diagnòstic per la imatge, Barcelona, Spain

Aortic intramural haematoma (IMH) evolves in the short-term to dissection, rupture or reabsorption. Long-term evolution of IMH remains relatively unknown. From January 1991 to December 2000, 68 patients with acute aortic syndrome were diagnosed of IMH. Of these, 48 (67±8 y) were treated medically and followed on an out-patient basis (5-261 months; 57±53). TEE, CT and MRI were performed at 3 and 6 months and annually thereafter. 3 patients underwent endovascular treatment and two surgery (>24 months).
In the mid-term (6 months), IMH was almost totally reabsorbed in 15 (33%), had evolved to classical dissection in 5 (11%) or localized dissection in 15 (33%).
In the long-term, normal aorta (without dilation) was observed in 15 (33%), classical dissection in 5 (11%), and saccular or fusiforme aneurysm in 16 (35%) and 10 (22%), respectively.
Predictive variables of IMH reabsortion were basal aortic diameter at the IMH site (46±1.2 vs 39±1.1 mm, $p<0.001$) and IMH thickening (14±0.7 vs 12±1 mm, $p<0.04$).
12 of 16 (75%) saccular aneurysms had evolved in short-mid-term with localized dissection ($p<0.001$). Aneurysms formation had greater diameters in acute phase and IMH thickening than the remaining patients (47±1.4 vs 40±1.2 mm, $p<0.001$) and (14±0.7 vs 11±0.9 mm, $p<0.01$), respectively.
Conclusion: Most IMH evolved to normalcy or aneurysm formation after 6 months of follow-up. Aortic diameter, IMH thickening and localized dissection in the short term have prognostic value for posterior aneurysm formation.

P597 Weight loss after bariatric surgery normalizes aortic distensibility and left ventricular mass in morbidly obese subjects. Six months follow-up

I. Ikonomidis[1], A. Mazarakis[2], N. Patsouras[2], J. Chiladakis[2], F. Kalfarentzos[3], A. Manolis[2]. [1]Alexandra Hospital, Univ. of Athens, Dep. of Clinical Therapeutics, Athens, Greece; [2]University of Patras, Cardiology Dept., Patras, Greece; [3]Univ. of Patras, Surgery Dept., Patras, Greece

Mordid obesity has been associated with a high incidence of heart failure. Aortic distensibility (AoD) is an important determinant of left ventricular (LV) function. We investigated whether: a) increased body mass index (BMI) is related with impaired AoD and LV mass b) weight loss after bariartic surgery (gastric bypass) is related with changes in lipids, glucose serum levels and resting blood pressure in parallel to improvement of AoD and LV mass in morbidly obese subjects.
Methods: We studied 60 subjects (mean age 37±12 years) with morbid obesity (BMI>40 kg/m^2) by 2D, and Doppler Echocardiography 1 week before, 3 and 6 months after surgery. AoD was calculated using the formula 2 x (pulsatile change in aortic diameter)/[diastolic aortic diameter x (aortic pulse pressure)]. Aortic diameters were measured 3 cm above the aortic valve by 2D guided M-mode echocardiography and aortic pulse pressure [systolic (SBP)-diastolic blood (DBP)pressure (mmHg)] was obtained simultaneously by cuff sphygmomanometry. Samples were obtained for measurement (mg/dl) of total cholesterol (TCH), low density lipoprotein (LDL), triglycerides (TG) and glucose (GLUC).
Results: All patients had normal systolic function before and after surgery. Aortic distensibility [normal range:2.4-4.4 cm^2 dyn(-1) 10^{-6} was impaired before surgery (Table). Increased BMI was related to decreased AoD ($r=0.43, p<0.01$) before surgery. Increased LV mass was independently related to increased BMI ($r=0.47$ $p<0.01$) and reduced AoD ($r=0.40$ $p<0.01$) before surgery. Three and 6 months after surgery, BMI, LV mass (gr), TCH, LDL,TG,GLUC and SBP were all reduced, whereas AoD was increased (table, $p<0.01$). Changes in LV mass were related to changes of SBP 3 and 6 months after surgery($r=0.46$ and $r=0.47$ $p<0.01$).

Surgery	BMI	AoD	LVmass	TCH	LDL	TG	GLUC	SBP	DBP
Before (1week)	49±7	1.6±1	335±83	212±38	144±32	134±55	99±21	125±13	80±15
After (3months)	38±9	3.4±1.1	252±48	153±32	99±29	104±28	85±18	119±18	78±11
Follow up (6months)	30±7	3.8±1.1	195±48	130±30	89±20	94±21	80±15	110±10	75±11
p	<0.01	<0.01	<0.01	<0.01	<0.01	<0.01	<0.01	<0.01	ns

Conclusion: Morbid obesity is related with impaired aortic distensibility and increased LV mass. Weight reduction after bariatric surgery, reduces serum lipids, lowers blood pressure and thus, normalizes aortic distensibility and LV mass[2]

P598 Influence of major depression on regional cerebral blood flow in elderly patients with heart failure

T.C.T.F. Alves[1], J. Rays[2], M. Wajngarten[3], R. Fraguas[1], C.C. Robilotta[4], J.C. Meneghetti[5], C.A. Buschpigel[6], G.F. Bussato[6]. [1]Faculty of Medicine, Dept. of Psychiatry, Sao Paulo; [2]Sao Paulo; [3]Heart Institute (InCor), Geriatric Cardiology, Sao Paulo; [4]Heart Institute (InCor, Technology Dept., Sao Paulo; [5]Heart Institute (InCor), Nuclear Medicine, São Paulo; [6]Fac. of Medicine, Dept. of Radiology, São Paulo, Brazil

Introduction: In patients with heart failure (HF) major depression (D) has a high prevalence and a prognostic impact. Changes in cerebral perfusion have been related to D and could have a physiopathological role. However, regional cerebral blood flow (RCBF) in patients with D and HF has not been studied.
Objectives: To investigate the Regional Cerebral Blood Flow in patients with D and HF.
Methods: 20 elderly patients with HF class II and III (NYHA), and D (DSM-IV criteria and Hamilton score > 18), free of psychotropic drugs were evaluated as well as 18 non depressed elderly patients with ejection fraction of 36.5%±7.6 and 38.6% ± 8.1 respectively and matched for HF functional class (NYHA). Both groups were compared to 19 controls 71.1 ± 4.8 years old, matched for age, sex, cerebral dominance and social level. Brain perfusion was evaluated with a double-headed SPECT system (Sophy-DST), after 99mTc-HMPAO injection. Group differences were investigated using Statistical Parametric Mapping program that compares differences in RCBF voxel-to-voxel, with a $p<0.001$ with a statistical significance.
Results: Significant RCBF reductions were seen in HF relative to C in the right lateral temporal lobe, cuneus and precuneus, as well as in a small area of the medial prefrontal cortex. In HF patients with D, significant cortical RCBF reductions relative to C were seen in similar locations but more extensively. In addition, they had RCBF reductions in limbic and subcortical areas, including the right parahypocampal gyrus, posterior cingulate, thalamus and caudate at the border of the lateral ventricle, and bilaterally in the posterior insula.
Conclusions: HF leads to significant RCBF reduction, however patients with D + HF associated seem to have further reductions in RCBF, especially in limbic and subcortical areas, what could have a physiopathological role due to the relation of the limbic areas with emotional functions. Further studies are necessary to evaluate the treatment of D and HF in RCBF.

MYOCARDIAL INFARCTION – PROGNOSIS ASSESSMENT

P599 Management and outcomes of cardiogenic shock patients in a Canadian province. ICONS data

I. Bata, S. Sharma, J. Cox, B. O'Neill, D. Johnstone. *Dalhousie University, Department of Medicine (Cardiology), Halifax, Canada*

Introduction: Cardiogenic shock following acute myocardial infarction carries a poor prognosis and a high early mortality rate. Overall mortality benefit from early revascularization of affected patients has not been convincingly demonstrated in controlled trials, especially in the short term phase. Practice patterns and outcomes of cardiogenic shock patients on a population wide level are not known.
Methods: We accessed the population-based registry of the Improving Cardiovascular Outcomes in Nova Scotia (ICONS) that collects detailed clinical data on all patients hospitalized with acute coronary syndromes among other conditions in the province of Nova Scotia, Canada. Individuals admitted between October 1997 and June 2001 with chest pain and an increase in cardiac enzymes, as well as blood pressure below 90 systole and pulmonary congestion were identified as having cardiogenic shock and were used as subjects for this analysis. Patients had to have these features either at admission or develop shock during their hospital stay. Group 1 patients were those admitted directly to the sole tertiary care center in the province with intervention facilities and those subsequently transferred there from other sites. Group 2 patients were those managed at non-tertiary facilities. Five patients from Group 2 came for cardiac catheterization/PCI and were returned back to the non-tertiary center.
Results: On the basis of the diagnostic criteria used to define cardiogenic shock patients, a total of 354 patients were identified. Shock on admission was present in 151(42.7%) and shock developed subsequently during the hospital stay in 203 (57.3%). Respective characteristics for Group 1 (n=204) versus Group 2 (n=150) were: mean age 69.9 years Vs 74.4 years, cardiac catheterization rates 57.4% Vs 2%; PCI 21.6% Vs 1.3%; CABG 36.3% Vs 0%; In-hospital mortality 50% Vs 64%. All these differences were statistically significant. No differences were seen in history of previous MI, previous PCI, previous CABG or previous renal failure. There was no difference in the use of thrombolytic therapy between the two groups.
Conclusion: Mortality of cardiogenic shock patients even in the tertiary care center was high, although comparatively lower than patients treated at non-tertiary centers and the difference may relate to revascularization procedures. Further study into factors impeding referral of patients with cardiogenic shock to centers with interventional facilities is required.

P600 Differences in characteristics, management and outcome of patients with acute coronary syndromes hospitalized in cardiology versus medicine departments

N. Ben-Dov[1], A. Porath[1], H. Gilutz[1], I. Zelinger[1], R. Ilia[1], I. Mats[1], A. Battler[1], J. Leor[2]. [1]*Soroka Medical Center, Cardiology, Beer Sheva, Israel;* [2]*Neufeld Cardiac Research Institute, Sheba Medical Center, Tel-Hashomer, Israel*

Background: The incidence of acute coronary syndrome without persistent ST elevation (ACS) has increased over the last decade. The mortality of patients with ACS, however, remained constant. Doctor specialty, internist vs. cardiologist, may affect the quality of care and outcome of patients with ACS. We sought to determine the effect of specialty, cardiologist vs. internist, on management and outcome of patients with ACS.

Methods and Results: From June to Sept 1999, we prospectively collected data on a cohort of 187 consecutive patients with ACS admitted to the Cardiology Department vs. 3 of 6 Internal Medicine Departments in the Soroka Medical Center. The patients were followed through the hospitalization period and over 32 months from discharge. Patients treated by cardiologists were younger (65+10 vs.61.6+11 years, p=0.03) and had high % of ischemic indexes on admission (ST elevation>1 mm: 42% vs. 7%p<0.0001; anterior ischemia: 60% vs. 26%, p<0.0001 or non Q MI 10% vs. 3%; p=0.06).

Patients treated by internists were less likely to receive aspirin (94% vs. 78%, p=0.004) or lipid lowering drugs (25% vs. 39%; p=0.02) during hospital stay. Patients treated by cardiologists were less likely to refer to early exercise test (0% vs. 5%, p<0.0001) but significantly more likely to undergo coronary angiography (63% vs. 12%, p<0.0001) and PTCA (28% vs. 5%, p<0.0001) than patients treated by internists.

By multivariate analysis, cardiologist management was associated with reduced risk for the combined primary endpoint of death, re-MI, or readmission at one year (OR=0.48; 95% CI 0.26-0.88) and 32 months (OR=0.26; 95% CI0.13-0.53).

Mortality rate at 30 days after admission was similar (0% vs.1%, p=1). However, mortality at 32 months was significantly lower in cardiology-treated patients (7% vs. 20%, p<0.0001). After multivariate adjustment, mortality after 2 years was independently associated with age (OR=1.07; 95% CI 1.02-1.12), TIPI risk index (OR=0.03; 95% CI 0.002-0.06) or in-hospital coronary angiography (OR=0.3; 95% CI 0.84-1.08).

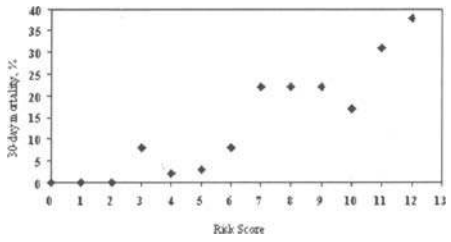
Conclusions: We observed significant variations in patient characteristics, care and outcome of patients with ACS admitted to Cardiology vs. Medicine departments. Although most of the patients were treated in Medicine departments, high-risk patients were more likely to be treated by Cardiologists. Cardiologists used more frequently evidence-based-medicine and interventional procedures. Our findings support the use of coronary angiography in high-risk ACS patients.

P601 A prognostic risk score for 30-day mortality after acute myocardial infarction in a community-based population

B.A. Williams[1], R.S. Wright[2], I.P. Clements[1], E. Brilakis[1], P.A. Smars[1], J.G. Murphy[1], G.S. Reeder[1], A.S. Jaffe[1]. [1]*Mayo Clinic, Rochester, United States of America;* [2]*Mayo Clinic, Rochester, United States of America*

Background: Risk scoring (RS) systems to define mortality risk after acute myocardial infarction (AMI) have been developed from clinical trial data. However, trials often enroll patients who do not reflect the spectrum of risk seen in AMI, cannot track trends over time and often require information not readily available on presentation. Accordingly, we developed and validated a RS system from a large clinical database of consecutive patients evaluated over a 12-year period. Parameters included only ones available during the initial clinical evaluation.

Methods: Our cohort included 1212 consecutive Olmsted County, MN patients with AMI from January 1988 to July 2000. A RS was developed to predict 30-day mortality. The RS (0-18) was calculated as the sum of points for the following factors: age >80 (2), female gender (3), SBP ≤ 140 (3), creatinine > 1.4 (1), ST segment depression 1-2 mV (1), ST segment depression > 2 mV (3), QRS duration ≥ 100 msec (1), Killip class > I (3), and anterior location (1). The sample was split into a training set from before January 1, 1997, and a test set from after that date for development, validation and to allow evaluation of accuracy over time.



30-Day mortality by risk score.

Results: The RS predicted 30-day mortality when viewed as a continuous variable (Figure) or when divided into low (RS < 6, 3.4%), intermediate (RS 7-10, 21.4%) or high risk groups (RS > 11, 35.3%), p<0.01. Predictive ability was high in the training set (c=0.78, see Figure) and increased over time (c=0.74, 0.73, 0.82, and 0.89 for years 1997-2000, respectively).

Conclusion: Short-term survival for the entire spectrum of AMI patients can be predicted based on clinical data available on presentation. Our RS is statistically robust and should aid clinical-decision making.

P602 Geographic differences in clinical characteristics and long-term clinical outcome in the TARGET study

M. Bertrand[1], D.J. Moliterno[2], F.J. Neumann[3], D. Ardissimo[4], P. DiBattiste[5], E.J. Topol[6]. [1]*Lille, France;* [2]*Cleveland Clinic Foundation, Cleveland, United States of America;* [3]*Heart Center, Bad Krozingen, Germany;* [4]*Ospedale Maggiore, Parma, Italy;* [5]*Princeton, United States of America;* [6]*Cleveland Clinic Foundation, Cleveland, United States of America*

Background: Gp IIb/IIIa inhibitors have consistently reduced adverse cardiac events in acute coronary syndromes and in coronary intervention (PCI). However, outcomes have varied widely by geography. TARGET compared outcomes with tirofiban (T) vs. abciximab (A) in 4809 patients (pts) undergoing PCI/stent. The primary endpoint (death, myocardial infarction (MI) or urgent revascularization at 30 days) occurred in 7.6% of T pts vs. 6.0% of A pts. Event rates were substantially different in the US compared with Non-US (7.2% US vs. 4.9% Non-US, p = <0.05) 6-month TVR was also different: US=9.0% vs. 5.4% Non -US. At 1-year FU the mortality rate was 1.9% in US group and 1.3% in non-US group.

Methods: We examined demographic, clinical, and procedural characteristics of TARGET pts by country.

Results: Mean ages were higher in US vs ex-US and a higher percentage of US pts were >75 years old. Women comprised a higher percentage of US pts. US pts weighed more, and had a higher prevalence of diabetes. A greater percentage of US pts underwent PCI for ACS. US pts had a shorter pre-procedure hospital stay. Rotational atherectomy (RA) was used more often in US. Peak ACT was lower in the US.

Geographic differences in TARGET

	US (n=3910)	Non-US (n=899)	p
Age	62.5±11.1	61.6 ± 10.1	0.023
> 75y.o.	16.3%	9.6%	0.001
Women	27.1%	23.7%	0.034
Weight (kg)	87.6	79.5	0.001
Diabetes	24.5%	17.6%	0.001
ACS	65.0%	54.0%	0.001
Admission to PCI (d)	0.57	2.24	<0.001
RA	6.5%	0.7%	<0.001

Conclusions: Despite identical inclusion criteria, significant differences in patient characteristics were identified between US and ex-US cohorts. Multivariate modeling is being performed to assess the impact of these variables on outcome.

P603 Analysis of case-fatality following coronary artery bypass grafting using an administrative database

S.Z. Abildström, S. Rasmussen. *National Institute of Public Health, Copenhagen, Denmark*

Background: The aim of the present study was to evaluate the case-fatality after Coronary Artery Bypass Grafting (CABG) using data from a national administrative database. All hospitalisations in Denmark where a CABG was performed at one of the five public invasive centres were studied.
Method: By linkage of the National Hospitalisation Register and the Danish Civil Registration System we were able to describe the course of 12466 CABGs from 1997 to 2000. From the Hospitalisation register we had individual data concerning date of procedure, concomitant procedures, centre, age, gender, in-hospital mortality and whether the admission was acute or elective. Information regarding mortality up to 30 days after the procedure was acquired from the Danish Civil Registration System. The outcome was total mortality in-hospital and within 30 days. Differences in case-fatality were analysed in logistic regression. The national average was used as reference.
Results: Female gender was associated with a significant increased risk of 30-day mortality independently of age, odds ratio 1.5, $p<0.0001$. An increase of age of 10 years increased the risk by 1.7, $p<0.0001$, independently of gender. After adjustment for age and gender there was no significant difference between the five centres in the case-fatality after isolated CABG when surgery was planned. The crude 30-day mortality ranged from 1.5% to 2.3%. For acute isolated CABG there was a significant difference in case-fatality between centres. The crude mortality ranged from 3.7% to 11.6%. The odds ratios estimated were 0.6, 0.7, 1.2, 1.3, and 1.9, $p<0.01$. The analyses were also performed using only in-hospital mortality as out-come. These data showed more pronounced differences between centres attributable to early transfer to other department or hospital or fast track surgery.
Conclusion: For planned CABG adjustment for age and gender explained the variation in institutional performance. For acute CABG the variation was significant after adjustment for age and gender. The odds ratios ranged from 0.6 to 1.9. We find that the administrative database has limited information to adjust for the differences in patients undergoing acute CABG. Patients undergoing planned CABG were more comparable with regard to prognosis. These patients are more comparable with regard to the pre-operative status, since there is consensus on the indication and selection of candidates for CABG. A fixed period of follow-up should be used (e.g. 30-day mortality), since in-hospital mortality is biased by transfers and early discharge.

P604 Clinical characteristics, dobutamine stress echo, and beta-blocker therapy to optimize long-term cardiac management after major vascular surgery

M.D. Kertai, E. Boersma, J.J. Bax, E. Vourvouri, F. Sozzi, M. Bountioukos, J.R.T.C. Roelandt, D. Poldermans. *Erasmus Medical Centre, Cardiology, Rotterdam, Netherlands*

Aims: Patients after major vascular surgery are at increased risk of continuing cardiac complications. We examined the relationship of clinical characteristics, dobutamine stress echocardiography (DSE) results, beta-blocker therapy (BBL), and long-term cardiac events in patients undergoing major vascular surgery.
Methods: A total of 1351 patients scheduled for major vascular surgery were screened for cardiac risk factors, including age> 70 years, prior myocardial infarction (MI), angina, diabetes mellitus, stroke, renal failure, and heart failure. DSE was performed in 1097 patients (81%) with at least one risk factor or a reduced exercise capacity. Stress induced ischemia was present in 199 patients (18%). BBLs were administrated in 360 patients (27%). A total of 1294 patients (96%) survived surgery for at least 30 days. Mean outcome measures were cardiac death or non-fatal MI during long-term follow-up, compared by clinical characteristics, DSE results and BBL use.
Results: Mean follow-up duration was 23 months (range 14-33 months); 13 patients (1%) were lost to follow-up. There were 7 (1.9%) cardiac events in 373 patients without risk factors, 33 (4.4%) events in 745 patients with 1-2 risk factors, and 33 (19%) in 176 patients with 3 or more risk factors. In patients without risk factors, BBL use reduced the risk of cardiac event (1.8% vs 0%), and DSE had no additional prognostic value. In patients with 1-2 risk factors the presence of ischemia during DSE increased cardiac events from 3.7% to 8.9%. However, if patients with ischemia were treated with BBL the risk decreased to 4.1%, comparable to patients without ischemia. In patients, with 3 or more risk factors DSE and BBL stratified patients into intermediate and high risk. In patients without ischemia BBL use reduced cardiac rate from 14% to 10%. However, in patients with 3 or more risk factors and ischemia BBL use was not protective: event rate as high as 22%.
Conclusion: BBL effectively reduces long-term cardiac events. DSE provides no additional prognostic information in patients with 0-2 risk factors, provided BBL are applied. In patients with 3 or more risk factors DSE stratifies patients into intermediate and high-risk groups.

P605 In-hospital mortality of acute myocardial infarction in relation to polymorphisms of the renin-angiotensin system genes

G. Andrikopoulos[1], D. Richter[2], E.W. Needham[3], N. Exadactylos[4], C. Stefanadis[5], J. Gialafos[5], P. Toutouzas[5], R. Mattu[3] on behalf of The GEMIG study investigators. *[1]Athens, Greece; [2]Euroclinic, Cardiac Dpt, Athens, Greece; [3]Walsgrave Hospital, Cardiac Department, Coventry, United Kingdom; [4]Evaggelismos Hospital, 1st Cardiac Department, Athens, Greece; [5]Hippokration Hosp., Athens University, Cardiac Department, Athens, Greece*

Aims: The Insertion/Deletion polymorphism of the Angiotensin-Converting Enzyme (ACE) gene and the A1166C single nucleotide polymorphism of the angiotensin II AT1 receptor (ATR1) have been associated with left ventricular remodelling and prognosis after acute myocardial infarction (AMI). We investigated whether these genetic variants associate with increased risk for in-hospital mortality after AMI and whether their possible effects are mediated by their relation to the modulation of the left ventricular systolic function during hospitalization for AMI.
Methods: We studied 1629 consecutive, AMI patients (mean age 62±13 years, 79% males), enrolled in the GEMIG study (Genetic predisposition and Epidemiology of acute Myocardial Infarction in the Greek population). All patients were recruited on admission from 9 Cardiac Departments located in three cities and were genotyped for the ACE I/D and ATR1 A1166C polymorphisms utilizing polymerase chain reaction amplification techniques.
Results: The in-hospital mortality was 7.1%. Deceased patients were older (71±13 vs 62±12 years, $P<0.001$) and had lower left ventricular ejection fraction (LVEF) estimated by echocardiography (45±9 vs 33±12%, $P<0.001$). In univariate analysis the LVEF did not differ among patients with or without the DD (44.4±9.7 vs 44.4±9.6%, P=NS) or the CC genotype (44.3±9.7 vs 45.8±9.8%, P=NS). In multivariate analysis with only clinical variables included as covariates, age (RR=1.047, 95%CI=1.007-1.088, P=0.001), prior AMI (RR=2.976, 95%CI=1.158-7.647, P=0.024) and LVEF<45% (RR=6.4 95%CI=1.5-27.7,P=0.013) were significant and independent predictors of in-hospital mortality. Inclusion of the DD and/or the CC genotype in the multivariate model did not effect the results of multivariate analysis. The studied genetic variables were associated neither with in-hospital mortality nor with LVEF after AMI.
Conclusions: In this multicenter, prospective study, the I/D polymorphism of the ACE gene and the A1166C polymorphism of the ATR1 gene were not associated with short-term prognosis after AMI. In symphony with previous studies the LVEF was an independent predictor of poor short-term outcome. However, its relation with in-hospital mortality was not influenced by the studied genetic variables. Our data, derived from a large-scale specifically designed study question the role of the studied genotypes in the pathogenesis of AMI, and in contrast to previous reports in the field, do not support the hypothesis that the studied genotypes influence prognosis after AMI.

P606 Atypical presentation of acute coronary syndromes independently predicts myocardial infarction and increased in-hospital mortality: insights from the GRACE registry

D. Brieger[1], K.A. Eagle[2], S.G. Goodman[3], J. López-Sendón[4], P.H.G. Steg[5], A. Budaj[6], K. White[7], G. Montalescot[8] on behalf of the GRACE investigators. *[1]Concord Hospital, Coronary Care Unit, Concord, Australia; [2]University of Michigan Health System, Cardiology Division, Ann Arbor, United States of America; [3]St. Michael Hospital, Department of Cardiology, Toronto, Canada; [4]Hospital Universitario Gregorio Marañó, Cardiology Department, Madrid, Spain; [5]Hôpital Bichat, Service de Cardiologie, Paris, France; [6]Grochowski Hospital, Cardiology, Warsaw, Poland; [7]UMASS Medical School, Center for Outcomes Research, Worcester, United States of America; [8]Pitié-Salpétrière Hospital, Service de Cardiologie, Paris, France*

Background: Patients with acute coronary syndromes(ACS) may not experience retrosternal chest pain (atypical presentation). We interrogated a contemporary multinational registry of patients with acute coronary syndromes(GRACE) to determine clinical characteristics and prognostic significance of atypical presentations in patients with ACS.
Methods: 16,026 patients with unstable angina (UA), non-ST-segment elevation (NSTEMI) and ST-segment-elevation myocardial infarction (STEMI) from 95 hospitals in 14 countries were included in this analysis. Patients were grouped according to the presenting symptoms (atypical vs typical) and baseline characteristics and in-hospital outcomes compared.
Results: 1,324 (8.3%) of patients with ACS presented without chest pain. The most common atypical presentations were dyspnea (46.2%), diaphoresis (25.3%), nausea/vomiting (24.7%), syncope/pre-syncope (22.3%). Atypical presentation occurred in 5.5% UA, in 12.1% NSTEMI and in 8.0% of STEMI patients. When compared to patients with chest pain, those with atypical presentations were older (72.2y vs 65.7y), more likely to be female (39.7% vs 32.5%), diabetic (31.2% vs 23.5%), have a history of heart failure (22.5% vs 9.7%), to have an MI (75.2% vs 61.7%) and were less likely to be revascularised in hospital (26.5% vs 35.9%; all $p < 0.0001$). Atypical presentations were more common in the US than in Europe (14.6% vs 6.1%), and carried an adverse prognosis: in hospital death 14.2% vs 4.5%, $p < .0001$). Multivariate analysis adjusting for age, sex, diabetes, medical history and type of ACS (mortality only), revealed that an atypical presentation was independently predictive of both a diagnosis of MI and in-hospital mortality (Table).

Outcome	Adjusted OR (95% CI)
Death	2.4 (2.0-2.9)
MI	2.0 (1.7-2.3)

In-Hospital Outcomes for Atypical Presentation (vs Typical)

Conclusions: Atypical presentation of ACS is independently associated with an adverse outcome. These high risk patients merit close in-hospital monitoring and where appropriate, early aggressive management directed toward improving their outcomes.

P607 Low-risk patients with chest pain and without evidence of myocardial infarction may be safely discharged from emergency department

H. Koukkunen[1], K. Pyörälä[2], M. Halinen[3]. *[1]Kuopio University Hospital, Department of Medicine, Kuopio, Finland; [2]University of Kuopio, Department of Medicine, Kuopio, Finland; [3]Kuopio University Hospital, Accident and Emergency Department, Kuopio, Finland*

Introduction: In previous studies, 2 - 8% of patients with myocardial infarction (MI) have been inappropriately discharged from emergency departments due to missed diagnoses of MI. Usually, these patients have had adverse prognosis. The purpose of this study was to investigate the prognosis of patients with chest pain attack, in whom MI was ruled out and in whom there was no evidence of high-risk acute coronary syndrome on the basis of history, clinical examination, electrocardiogram (ECG) and biochemical markers of myocardial injury, and who were discharged from emergency room (ER) or adjacent chest pain observation unit (CPU).
Methods: This study is a part of a clinical audit of the management of 3718 consecutive patients admitted to the emergency department of the Kuopio University Hospital due to chest pain or cardiac arrest during the period from 1 January 1997 until 31 December 1999. MI was ruled out in 2636 (71%) patients, and 1317 (50%) of them were discharged to home from the ER or CPU within 24 hours from admission. The patients were retrospectively identified from the outpatient clinic register and hospital discharge register. One-week, 4-week, 3-month, and 6-month mortality data were received from the national Causes-of-Death Register.
Results: After observation, of the 1317 patients (672 men and 645 women; mean age 58 years) 855 (65%) were discharged from the ER and 462 (35%) from the CPU. The patients discharged from the ER were younger than those discharged from the CPU (mean age 54 vs 64 years; $p < 0.001$). One-week mortality after the discharge from the ER was 0% and from the CPU 0%. Four-week mortality was 0.2% and 0.6%, 3-month mortality 1.3% and 1.9%, and 6-month mortality 1.8% and 3.2%, respectively.
Conclusions: Patients admitted to the ER or the CPU with chest pain may be safely discharged within 24 hours from admission, if there is no evidence of MI or high-risk acute coronary syndrome on the basis of history, clinical examination, ECG, and biochemical markers.

P608 Is coronary angiography performed in the appropriate patients after myocardial infarction? A study in 2493 patients (the PRIMA study)

F. Delahaye[1], M. Rabilloud[1], R. Ecochard[1], E. MacFadden[1], L. Meunier[1], E. Cheneau[1], H. Milon[2], G. de Gevigney[1] on behalf of the PRIMA group. *[1]Hôpital Cardiologique, Lyon, France; [2]HOPITAL DE LA CROIX-ROUSSE, LYON, France*

Objective: Rates of coronary angiography after myocardial infarction vary widely between institutions. Furthermore, the indications for coronary angiography are often in conflict with recognized guidelines. The present study sought to determine the characteristics and the one-year mortality in patients with myocardial infarction, regardless of age and hospital facilities, according to the use of coronary angiography after myocardial infarction.
Methods: Data were prospectively collected in all patients with myocardial infarction admitted to all hospitals in three departments in the Rhône-Alpes region.
Results: Among 2,493 patients, 1,117 (45%) underwent coronary angiography within 3 months after myocardial infarction (median delay: 10 days). Coronary angiography was performed in 89% of the patients * 45 years old, 65% of the patients 45-70 years old and 18% of the patients * 70 years old ($p < 0.0001$). In multivariate analysis, coronary angiography rate was lower with older age (odds ratio [OR]: 0.40 for 10 years), female gender (OR: 0.54), in patients with comorbidity (OR: 0.62) or heart failure (at admission: OR: 0.68; worsening of heart failure during the first 5 days: OR: 0.71). It was higher in patients with non-Q wave myocardial infarction (OR: 1.93) and in patients who had thrombolysis (OR: 1.49). Coronary angiography was performed in 49% of patients admitted to hospitals with on-site coronary angiography vs 32% in hospitals without on-site coronary angiography (OR: 3.54, after adjustment for patients' characteristics). One-year mortality rate was 6.5% for the coronary angiography group and 36.9% for the no-coronary angiography group. In multivariate analysis, age, history of angina pectoris, presence of Q waves, Killip class at admission II, III, or IV and CPK ratio * 9 were significant predictors of a higher one-year mortality, but performance of coronary angiography did not significantly influence it: RR: 0.79 (95% CI 0.58 to 1.07).
Conclusions: Among patients with myocardial infarction in a large unselected cohort in a French region, the one-year mortality was significantly lower in those referred for angiography. However, after correction for the confounding effects of simple baseline clinical indicators of risk, this apparent benefit reflected the fact that angiography was performed in those at lowest risk.

P609 Influence of known arterial hypertension on hospital mortality of acute ST-segment elevation myocardial infarction: results of MITRA and MIR

A K. Gitt[1], B. Klein[1], H. Wienbergen[1], T. Heer[1], C. Meisenzahl[1], R. Schiele[1], M G. Gottwik[2], J. Senges[1] on behalf of the MITRA- and MIR Study Groups. [1]*Herzzentrum Ludwigshafen, Cardiology, Ludwigshafen/Rhein, Germany;* [2]*Cardiology, Klinikum Nürnberg Süd, Nürnberg, Germany*

Background: Arterial hypertension (HT) is a main risk factor for the development of cardiovascular disease. The influence of previously known HT on prognosis of acute ST-elevation myocardial infarction (STEMI) has been discussed very controversially.
Methods: The German Registries MITRA and MIR included 21441 consecutive patients with STEMI between 1994 and 2000. The hospital and long-term mortality (18 months, MITRA) of STEMI-patients with and without previously known HT were compared.
Results: Out of 21441 consecutive STEMI-patients 8485 had a previously known HT (40%). STEMI-patients with known HT were older (69 vs 67 years, $p<0.001$), more often had prior STEMI (19.3 vs 14.7%, $p<0.001$), diabetes mellitus (35.0 vs 16.4%, $p<0.001$) and a 35 min longer prehospital delay ($p<0.001$). Patients with known HT received acute reperfusion for STEMI significantly less often (45.6 vs 52.3%, $p<0.001$). Despite this worse risk profile, patients with known HT had a significantly lower hospital mortality as compared to STEMI patients without history of HT (13.2 vs 16.3%, $p<0.001$). Within a follow-up of 18 months after acute STEMI, patients with history of HT more often had myocardial reinfarctions (3.0 vs 2.3%, $p<0.01$). Long-term-mortality in patients with known HT was 28% higher than in patients without previously known HT. After correction for age, differences in baseline characteristics and acute therapy using a logistic regression model, hospital mortality was lower in patients with known HT whereas long-term mortality was not different in both groups (table).

Influence of HT on outcome of STEMI

Parameter	Odds Ratio	CI 95%
Hospital Mortality	0,86	0,78-0,96
18-months Mortality	0,99	0,79-1,25

Conclusion: STEMI-patients with previously known HT had a 14% lower hospital mortality as compared to patients without known HT. Long-term mortality within 18 months after the index STEMI was similar in patients with and without known HT.

P610 Early missed diagnosis of acute myocardial infarction: patients at risk and in-hospital mortality

D. Jenni[1], M. Pfisterer[2]. [1]*Cardiology, Basel, Switzerland;* [2]*University Hospitals, Cardiology, Basel, Switzerland*

Background: Acute myocardial infarction (AMI) may present with atypical or no chest pain and/or with unspecific ECG changes and may therefore be missed initially. To assess which patients are at risk for such "early missed diagnosis" and what their inhospital outcome is, we performed a retrospective chart analysis.
Methods: Charts of 247 consecutive patients (pts) with the discharge diagnosis of AMI between 7/2000 and 6/2001 were retrospectively analysed. The initial ECG was reanalysed and compared to initial and final diagnoses. All relevant data regarding coronary artery disease and hospitalisation were collected and compared between pts with and without the initial diagnosis of AMI.
Results: Of the 247 pts, 120 (49%) were 75 years or older (elderly: 81 ± 7 years versus 65 ± 10 years in pts under 75 years), 98 (40%) were women. The initial diagnosis was other than acute coronary syndrome in 25% of elderly versus 7% of younger pts ($p<0.0001$) and 22% in women versus 11% in men ($p<0.05$). The missed AMI diagnosis in the initial ECG was higher in elderly pts (29% versus 8%, $p<0.001$) whereas there was no significant influence of gender. Comorbidity was higher in the elderly pts (74% versus 30%, $p<0.0001$) and also non-cardiac disease with a presumed life-span < 1 year (19% versus 5%, $p<0.001$). At entry 31% of the elderly and 16% of the younger were without anginal pain ($p<0.01$), but the strongest predictor for presenting without chest pain was female gender (36% versus 15%, $p<0.001$). Most of the pts without pain had only dyspnea (46%) or general weakness (18%). An other predictor of no pain at presentation was mental disorder in elderly pts (14% versus 0%, $p<0.005$). Inhospital mortality was higher in pts with early missed versus correct diagnosis (33% versus 13%, $p<0.005$), but no difference was found in outcome between age groups.
Conclusion: AMI may present without chest pain particularly in elderly pts, women and pts with mental disorders. In addition, early ECG changes are unspecific in almost 1/3 of elderly pts. Still, pts with such a missed early diagnosis of AMI have a three times higher in-hospital mortality than pts with correct diagnosis. Therefore, early diagnosis of AMI has to be actively sought for, particularly in elderly women presenting with dyspnea.

P611 Angiotensin-converting enzyme inhibitor use predicts increased risk of death and recurrent myocardial infarction among patients receiving aspirin after myocardial infarction

B.H. Trichon[1], M.E. McIvor[2], A.S. Hellkamp[3], P.T. O'Gara[4], A. Langer[5], R.N. Daly[6], C.M. O'Connor[3], R.A. Harrington[3]. [1]*Duke University Medical Center, Durham, United States of America;* [2]*The St. Petersburg Heart Center, St. Petersburg, United States of America;* [3]*Duke Clinical Research Institute, Durham, United States of America;* [4]*Brigham & Women's Hospital, Boston, United States of America;* [5]*Toronto, Canada;* [6]*Dupont Pharma, Wilmington, United States of America*

Background: Both aspirin (ASA) and Angiotensin converting enzyme inhibitors (ACE-I) have established benefit in reducing ischemic events after myocardial infarction (MI). Some evidence suggests that ASA may attenuate the beneficial effects of ACE-I among patients with CAD or left-ventricular dysfunction. There is controversy regarding their concurrent use and the appropriate dose of ASA among patients receiving ACE-I.
Methods: We examined the relationship between the combined use of ACE-I and ASA and clinical outcomes among patients after MI randomized to three different anticoagulant/ASA regimens in the Coumadin Aspirin Reinfarction Study. On presentation, patients were randomized to one of three treatments: 160mg ASA, 80mg ASA + 1mg warfarin, 80mg ASA + 3mg warfarin. The groups receiving the 80mg ASA dose were combined for this analysis.
Baseline characteristics and the percentage of patients taking ACE-I at study entry were defined. A Cox proportional hazards model was utilized to assess the association between ACE-I use, ASA dose and the end-point of death or recurrent MI.
Results: Data from 8796 patients were analyzed (99% of study population). Median duration of follow-up was 14 months. 2310 (26.2%) patients were receiving ACE-I at enrollment. Patients receiving ACE-I tended to be older (61 vs. 58, $p<0.001$), have diabetes mellitus (28% vs. 16%, $p<0.001$), and have heart failure (23% vs. 6%, $p<0.001$). Ejection fraction was lower among patients receiving ACE-I (45% vs. 55%, $p<0.001$).
After adjusting for important co-variates, patients receiving an ACE-I with ASA had a higher rate of death or recurrent MI compared to those receiving ASA alone (HR=1.22, 95% CI=1.04-1.43, p=0.013). There was no significant interaction between ASA dose and the effect of ACE-I use on the above endpoint (p=0.69).
Conclusions: Patients receiving ASA and ACE-I after MI have higher rates of death and recurrent MI compared to those receiving ASA alone, this difference persists after adjusting for important prognostic factors. The higher rate of adverse outcomes with this combination is present even in those receiving "low-dose" (80mg) ASA. Prospective studies are needed to clarify the interaction(s) between these agents.

P612 Cardiovascular mortality and morbidity in chronic haemodialysis patients: CORDIAL, a 3-year follow-up cohort study

F. Zannad[1], F. Alla[1], M. Echemann[1], G. Hacquard[2], B. Risse[1], M. Kessler[3]. *[1]INSERM-CHU, Centre d'investigation clinique (CIC), Nancy, France; [2]CHU, Cardiology Dept., Nancy, France; [3]CHU, Nephrology, Nancy, France*

Introduction: Chronic hemodialysis (HD) patients are at high risk of cardiovascular (CV) events and death. No therapeutic intervention aimed to prevent CV outcome has been tested in prospective randomised clinical trials in such patients. Assessing the rate and the determinants of CV events in HD patients is critical for the design of future clinical trials and therapeutic strategies in patients with this condition. This was the aim of CORDIAL (Cardiac Outcome Registry in DIALysis), a prospective observational cohort study with a 3 year follow up period.

Methods and results: Among a total of 685 patients registered in 11 HD centres in the east of France during year 1996, a cohort of 378 patients aged 50 years to 80 years, on dialysis for more than 3 months was identified. They were aged 66±7 years, 59% were male, 46% had a history of CV disease (17% heart failure, 10% MI, 20% angina, 6% stroke), 18% had diabetes. At baseline blood pressure was 139/74 +24/14 mmHg, hemoglobin 10.5±1.8 g/dL, Kt/V 1.48±0.35. Echocardiography was available in 304 patients and showed a LV mass index at 155±51 g/m^2 and LVEF at 64±13% (30% pts had LVEF<45%). Total mortality was 15% at 1 year and 41% at 3 years (9% and 24% respectively were related to a CV cause). One year mortality was 8 fold (and CV death 13 fold) superior to that observed in age and gender matched general population in eastern France. Combined death and CV non fatal event rate was 39% at one year and 70% at 3 years. In multivariate analysis, the following factors were shown to be independently associated to total mortality: diabetes (RR=2.0[95%CI=1.3-2.9]), CV disease history (2.1[1.5-3.1]), age>70 (1.6[1.1-2.3]), LV mass index>median (1.9[1.2-2.8]) and duration of dialysis>10yrs (2.1[1.4-3.2]). Only CV disease history was independently associated to CV mortality (2.3[1.4-3.8]). Male gender (2.0[1.2-3.3]), history of CV disease (2.1[1.3-3.3]), and age>70 (1.8[1.1-2.8]) were associated to CV fatal and non fatal events.

Conclusion: Chronic hemodialysis patients aged 50 to 80 are at excessive risk of CV death and CV events. LV hypertrophy is very prevalent and is a predictor of total mortality. The CORDIAL cohort provides epidemiological observational community based prospective data which may be useful for sample size calculation and design of much needed CV prevention clinical trials in hemodialysis patients.

P613 Do differences in characteristics or in management account for the poorer outcome after myocardial infarction in diabetics? The PRIMA study

F. Delahaye[1], M. Rabilloud[1], E. McFadden[1], R. Ecochard[1], D. Cao[1], F. Chorfa[1], H. Milon[2], G. de Gevigney[1] on behalf of the PRIMA group. *[1]Hôpital Cardiologique, Lyon; [2]Hôpital de la Croix-Rousse, Lyon, France*

Background: There is an excess mortality after myocardial infarction in diabetics, but also documented significant differences in the characteristics of myocardial infarction and in management between diabetics and non-diabetics. The aim of this prospective study in a large unselected patient cohort in a single French region was to determine if baseline characteristics, management, or in-hospital and one-year mortality differed in diabetic and non-diabetic patients with myocardial infarction.

Methods: Data were prospectively collected in consecutive patients with myocardial infarction admitted to all hospitals in 3 departments in the Rhône-Alpes region between 09/01/1993 and 01/31/1995.

Results: Among the 2,297 patients, 410 patients (17.8%) were diabetic. The proportion of diabetics was almost 4 times greater in the PRIMA population than the expected rate in a cohort of the overall French population with a comparable age distribution. Although diabetics were older than non-diabetics (70.3 vs 67.8 years; p < 0.0004), and less likely to receive thrombolysis (31% vs 36%; p = 0.043), in-hospital mortality was not significantly higher (17.3% vs 14.7%) than in non-diabetics. Coronary angiography was performed significantly less frequently in diabetics than in non-diabetics (39% vs 46%; p = 0.015). Left anterior descending artery disease was more frequent in diabetics than in non-diabetics (67% vs 58%). Reinfarction and use of CABG or of PTCA did not differ significantly between diabetics and non-diabetics. One-year mortality rate was significantly higher in diabetics (31% vs 22%; p = 0.001) than in non-diabetics. In multivariate analysis, diabetes was a significant predictor of one-year mortality (relative risk: 1.41; 95% CI = 1.10 - 1.79; p = 0.0063) but not of in-hospital mortality (relative risk: 1.2; 95% CI = 0.9 - 1.7; p = 0.25). Multivariate predictors of in-hospital and one-year mortality in diabetics were age and Killip class at admission.

Conclusions: In this large unselected French cohort, diabetes mellitus was a significant predictor of one-year but not of in-hospital mortality after myocardial infarction in a French region. This pejorative effect of diabetes on mortality was not related to differences in baseline characteristics, or in initial or post-discharge management between diabetics and non-diabetics.

P614 Coronary angioplasty in acute coronary syndromes – impact of stents and Gp-IIb/IIIa blockers beyond randomized trials

J. Woehrle, O. Grebe, E. Al-Khayer, T. Nusser, M. Kochs, M. Höher. *University of Ulm, Cardiology, Ulm, Germany*

Randomized clinical trials have shown that the use of stents or Gp-IIb/IIIa receptor blockers in patients with an acute coronary syndrome receiving coronary interventions improves clinical and angiographic outcome. Whether these results can be transferred to a real world collective has not been settled. We analyzed the influence of stents and Gp-IIb/IIIa blockers on the clinical and angiographic outcome in a consecutive series of 1103 emergency angioplasties in patients presenting with an acute coronary syndrome.

Patients suffered from unstable angina (UA) in 51% and acute myocardial infarction (MI) in 49%. Rates of stenting increased from 10% before 1997 to 65% in 2001. Angiographical success rates (TIMI 3 flow and <50% residual stenosis) and minimal lumen diameter post angioplasty were significantly higher after stenting (98.5%, MLD 2.63±0.54 mm) compared with balloon dilation alone (84.1%, MLD 1.81±0.78 mm; p<0.001). In-hospital mortality was significantly higher in patients suffering from MI (9.8%) compared with UA (3.0%, p<0.01), but did not differ in patients with (6.6%) and without (6.1%) stenting. Patients with TIMI-3 flow after angioplasty had received more often Gp-IIb/IIIa blockers compared with patients having TIMI 0-2 flow (ns). In-hospital mortality was strongly correlated to the success of the intervention and was 4.9% in patients with TIMI-3 and 16.9% in patients with TIMI 0-2.

Out of 1034 patients discharged from the hospital, 92% received clinical and 48% angiographic follow-up after median 228 days. Free of angina were 68% of the MI and 58% of the UA patients (p<0.02), with no difference in patients with and without stents. Occurrence of myocardial infarctions during follow-up was more frequent in MI patients (4.7%) as compared with UA patients (1.4%, p<0.01). Patients with stent implantation had significantly less major adverse cardiac events (death, MI, re-PTCA, CABG) than patients with PTCA alone (30% vs 37%, p<0.04). Angiographic subgroup analysis revealed, that restenosis rate was significantly lower (33% vs 46%, p<0.01) and MLD at follow-up was significantly higher in stented compared with non-stented lesions (1.70±0.91 mm vs 1.30±0.89 mm, p<0.001). Occurrence of restenosis did not differ between patients with MI and patients with UA.

The beneficial results of stents and Gp-IIa/IIIa blockers are preserved in daily practice. Stenting in acute coronary syndromes does not reduce the in-hospital mortality, but improves the clinical long-term result and lowers the angiographic restenosis rate.

P615 Relative role of troponin I and acute-phase reactants to predict outcome in patients with non-ST-segment elevation acute coronary syndrome

V. Bodí, J. Sanchis, A. Llácer, L. Fácila, J. Núñez, L. Insa, F.J. Chorro. *Hospital Clínic i Universitari, Servei de Cardiología, València, Spain*

Background: Myocardial damage markers and acute-phase reactants have been related to long-term outcome of non-ST-segment elevation acute coronary syndromes (NST). We analysed the adjusted predictive power of these variables to establish the in-hospital prognosis of patients admitted for NST.

Method: The study group was composed by 518 consecutive patients admitted in our institution with a diagnosis of NST. A conservative strategy was applied. Clinical and electrocardiographic (ECG) data, Troponin I (TnI), high-sensitivity C-reactive protein (CRP) and Fibrinogen (Fb) were prospectively recorded. Only major events (death and myocardial infarction) were considered. The cut-off values of biochemical data were determined by means of their ROC curves to predict major events.

Results: During admission 19 exitus (3,7%), 16 infarctions (3,1%) and 35 major events (6,8%) were registered. In the univariate analysis major events were more frequent in patients with CRP> 14 mg/l (13,7% vs 2% p<0,01), Fb> 5 g/l (10,9% vs 2,8% p<0,01) and TnI> 3 ng/ml (11,3% vs 3,2% p<0,01); in the multivariate analysis (including clinical risk factors, heart failure at presentation, ECG changes and biochemical data) only age (OR 1,07 [1,02-1,12] per year; p<0,01) and CRP> 14 mg/l (OR 5,2 [1,8-14,8] p<0,01) were independent predictors; by quartiles of CRP: 1%; 4%; 5%; 16,3% (p<0,01). The only independent predictor of myocardial infarction was Fb (OR 1,4 [1,07-1,9] per 1 g/l increase; p=0,02). In the multivariate analysis, in-hospital cardiac death was related to age (OR 1,1 [1,03-1,2] per year; p<0,01), insulin-dependent diabetes (OR 3,9 [1-16,1] p=0,05) and CRP> 14 mg/l (OR 15,6 [1,9-127,4] p=0,01). Troponin I was associated with major events (p<0,01) and death (p=0,01) in the univariate analysis but it was not an independent predictor in any case.

Conclusions: The acute-phase reactants C-reactive protein and Fibrinogen add independent information to clinical variables in the short-term risk stratification of patients admitted for a NST-ACS. The in-hospital predictive power of Troponin I decreases when corrected by these variables.

P616 Prognostic value of D-dimer assay in patients with non-ST-segment elevation acute coronary syndromes

C. Aguiar[1], J. Ferreira[1], I. Freire[2], F. Crespo[2], R. Seabra-Gomes[1]. [1]*Hospital Santa Cruz, Cardiology Dept., Carnaxide, Portugal;* [2]*Hospital Santa Cruz, Clinical Pathology Dept., Carnaxide, Portugal*

In patients (pts) presenting symptoms consistent with an acute coronary syndrome, risk stratification plays a pivotal role in management decisions and improving outcomes. An earlier marker of plaque rupture could provide an important advantage over markers such as the cardiac-specific troponins (cTn), which later identify myocardial cell injury, the downstream effect of a plaque rupture event. D-dimer (DD) is the end product of the ongoing process of thrombus formation and fragmentation at the site of active plaques.

Aim: To evaluate the prognostic value of DD levels on admission in pts with non-ST-elevation acute coronary syndromes.

Methods: We prospectively studied 105 pts without co-morbid conditions known to increase DD levels. DD was measured on admission using a quantitative fibrin-specific ELISA. CTn I was measured on admission and every 6 hrs during 24 hrs. Primary endpoint was time to death or nonfatal myocardial infarction (MI) during the first 30 days after admission. Additionally, overall mortality was assessed at 1-year follow-up. For endpoint analyses, we dichotomized DD levels into their top (>470ng/ml) and lower 2 risk tertiles and used the max cTn I level (normal<0.1ng/ml).

Results: CTn I was elevated in 55 pts. At 30 days follow-up, death or nonfatal MI had occurred in 20.0% pts with DD>470ng/ml (vs 5.7% in remaining pts, log rank p=0.02) and in 16.4% pts with elevated cTn I (vs 4.0% in remaining pts, log rank p=0.04). Pts with both markers positive (n=22) were at highest risk (31.8% endpoint rate, p=0.001 vs remaining pts). After adjusting for baseline clinical characteristics, ECG findings and max cTn I level (Cox regression analysis), DD>470ng/ml was an independent predictor of 30-day outcome (hazard ratio 3.7; 95%CI 1.1-12.6; p=0.038). At 1-year follow-up, pts with DD>470ng/ml showed increased mortality (17.1% vs 4.3% in remaining pts, log rank p=0.023).

Conclusion: The DD level is a powerful independent predictor of outcome in pts with non-ST-elevation acute coronary syndromes. Future prospective trials are needed to evaluate if higher DD levels identify a subset of pts who may benefit from more aggressive antithrombotic strategies during hospitalization and more aggressive management during long-term follow-up.

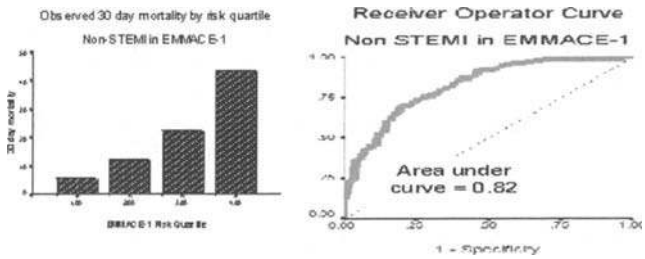
P617 Application of a validated simple risk model to a non-STEMI population

R. Das[1], R. Lawrance[1], M.F. Dorsch[1], R.J. Sapsford[2], B.M. Jackson[1], C. Morrell[1], M.B. Robinson[3], A.S. Hall[1] on behalf of the EMMACE investigators. [1]*Leeds General Infirmary, Institute for Cardiovascular Research, Leeds;* [2]*St James's University Hospital, Department of Cardiology, Leeds;* [3]*Nuffield Institute for Health, Leeds, United Kingdom*

Background: Recently, in an unselected AMI population, we have developed a simple risk model to predict 30-day mortality, based on three admission characteristics: systolic blood pressure, age and heart rate. We examined the utility of this model in a non-STEMI cohort of patients.

Methods: From coronary care registers, biochemistry record and hospital management systems, 2,153 consecutive patients with confirmed acute myocardial infarction were identified, of which, 899 had a non-STEMI event. Stratification was performed on the basis of admission ECG and included patients presenting with a normal ECG, with ST depression or with isolated T wave changes. Patients with ST elevation, bundle branch block or a cardiac arrhythmia were excluded. The three variable risk model to predict 30-day mortality (P30 = 1/(1+exp(-L30) and L30= -5.624 +(0.085 x age) + (0.014 x heart rate) – (0.022 x systolic blood pressure)) was assessed within our non-STEMI population.

Results: Using multivariable logistic regression the area under a receiver operating characteristic curve was 0.82 (CI 0.78-0.86), as compared to 0.77 (0.75-0.80) for the ROC value obtained from the whole AMI population.



Conclusion: This model, derived and validated from an unselected AMI population, and based on characteristics easily available at the time of initial triage, represents a simple clinical tool to allow appropriate risk stratification of non-STEMI patients. Its performance appears at least as robust at predicting 30-day mortality as other more complicated published risk tools.

P618 Predictors of 6-month mortality in high-risk patients undergoing percutaneous coronary intervention

C. Staniloae[1], P. Theroux[1], R. Gallo[1], A. Jessel[2]. [1]*Montreal Heart Institute, Research Center, Montreal, Canada;* [2]*Aventis Inc, Bridgewater, NJ, United States of America*

Introduction: Percutaneous coronary interventions are widely applied in high-risk patients and are associated with increasing success. In this study, we looked at the determinants of the 6-month mortality in 4447 high-risk patients who underwent PCI in the GUARDIAN trial.

Materials and Methods: The clinical and angiographic characteristics and procedure related events prospectively collected in the database were reviewed. The indication for PCI was non-ST segment elevation acute coronary syndrome in 1656 patients (37.3%) and an elective procedure for a complex lesion (2 type B or 1 type C characteristic) in 2791 patients (62.7%). Odds ratios (OR) and p values were calculated for a number of variables and independent predictors of mortality at 6 months assessed by multiple logistic regression models.

Results: Death at 6 months occurred in 159 patients (3.6%). A stent was implanted in 72% of patients By multivariate logistic regression analysis, the independent predictors of mortality at 6 months were: history of CHF (OR 2.96), procedure-related complications (OR 2.52), prior CABG (OR 1.90), urgent intervention (OR 1.85), use of lipid lowering agents (OR 0.54), age<65 (OR 1.84), type C lesion (OR 1.63), history of vascular disease (OR 1.56), use of thienopyridines (0R 0.66), PCI for unstable angina (OR 1.48) and diabetes (OR 1.36); all p values were < 0.05.

Conclusions: Despite progress in stent technology and pharmacology, 6-month mortality following high-risk PCI remains elevated. Most predictors of mortality identified in the study are amenable to corrective measures.

P619 Comparison of current risk classifications in non-ST-segment elevation acute coronary syndromes. Preliminary results of RESCUER registry

S. Stec[1], A. Budaj[2], E. Pogorzelska[3], A. Kuklinska[4], P. Podoba[5], M. Sienicki[3], W. Musial[4], A. Kleinrok[5] on behalf of RESCUER Investigators. [1]*Dept. of Cardiology, Grochowski Hosp., Postgraduate Medical School, Warsaw, Poland;* [2]*Postgraduate Medical School, Dept. of Cardiology, Grochowski Hosp., Warsaw, Poland;* [3]*SPZOZ, Dept. of Cardiology, Rzeszow, Poland;* [4]*Medical Academy of Bialystok, Dept. of Cardiology, Bialystok, Poland;* [5]*WS Zamosc, Dept. of Cardiology, Zamosc, Poland*

Background: Early risk stratification in patients with non-ST segment elevation acute coronary syndromes (NSTE ACS) indicates the strategy of management. Current guidelines identify high risk patients who warrant early aggressive therapy. However, there are limited data on prospective evaluation of this group of patients and on a direct comparison of various risk classifications, such as ACC/AHA, ESC, TIMI Risk Score (TRS) and simplified TIMI Risk Score (sTRS). We investigated a direct, prospective comparison of the above risk classifications for identifying high-risk group in an unselected population of NSTE ACS.

Methods: RESCUER is a prospective, multicenter, web-based registry of patients with NSTE ACS from 10 centres in Poland. Consecutive patients with symptoms of unstable angina within 24 hours were classified according to ACC/AHA, ESC and TIMI risk classification. Cardiac troponin I and CK-MB were routinely measured by on-site quantitative analysis of the Dade Behring's assays. Patients were monitored during hospitalisation and followed for 6 months. All data were collected by electronic CRFs into a web-based database.

Results: Patients admitted to participating hospitals were stratified on admission according to each classification. Data of the first 225 patients (mean age: 65±12, 55% males) were available for the analysis. High risk group characteristics and in-hospital follow-up are shown in the table.

High Risk Profile	ACC/AHA	ESC	TRS > 4	sTRS=3
n (% total group)	150 (66)	145 (64)	39 (17)	42 (18)
% in-hospital MACE*	9	11	8	17
% MI diagnosed < 24 h	56	62	70	83

*MACE: death, MI > 24h, urgent revascularisation

Significantly higher number of patients was classified into high risk group by ACC/AHA and ESC as compared to TIMI classifications (p<0.0001). 47% of NSTE ACS patients were classified consistently by ACC/AHA and ESC classifications as a high risk group, but only 9% by all tested classifications.

Conclusions: There are substantial differences between currently used risk classifications.

P620 White blood cell count and long-term mortality after non-ST-segment elevation acute coronary syndrome treated with a very early revascularization

C. Mueller[1], H.J. Buettner[2], S. Marsch[1], P. Hunziker[1], A.P. Perruchoud[1], F.J. Neumann[2], H. Roskamm[2]. [1]University hospital Basel, Medical Intensive Care Unit, Basel, Switzerland; [2]Herz-Zentrum, Cardiology Dept., Bad Krozingen, Germany

Background This study sought to evaluate the predictive value of white blood cell count (WBC) on short and long-term mortality in patients with non-ST-elevation acute coronary syndromes (NSTACS) treated with an very early invasive strategy.
Methods We conducted a prospective cohort study in 1391 consecutive patients with NSTACS undergoing coronary angiography and subsequent coronary stenting of the culprit lesion as the primary revascularization strategy within 24 hours. Patients were stratified according to quartiles of WBC determined on admission. The patients were followed for a mean of 20 months.
Results Kaplan-Meier survival analysis demonstrated a cumulative 3-year survival of 93.8% in the first quartile of WBC (<6.8 nL-1), 94.4% in the second quartile (6.8-8.0 nL-1), 95.1% in the third quartile (8.0-10.0 nL-1), and 82.4% in the fourth quartile (>10.0 nL-1) at 36 months ($p<0.001$ by log-rank). Relative to patients in the three lower WBC quartiles, patients in the highest quartile were three times more likely to die during the hospitalization (hazard ratio 3.2, 95% confidence interval 1.5 to 7.1; p=0.003) and during long-term follow-up (hazard ratio 3.4, 95% confidence interval 2.2 to 5.3; $p<0.001$). By multivariate Cox regression analysis including baseline demographic, clinical and angiographic covariables, WBC in the highest quartile remained a strong independent predictor of mortality (hazard ratio 3.3, 95% confidence interval 1.9 to 5.6; $p<0.001$).
Conclusion WBC count is a strong independent predictor of short and long-term mortality after NSTACS treated with very early revascularization.

P621 Aggressive time management strategies in acute myocardial infarction reduce duration of hospitalisation and mortality. Results of 346 consecutive patients

S. Rux, K. Lenßen, S. Sonntag, T. Thieme, F.X. Kleber. *ukb, Internal medicine/cardiology, Berlin, Germany*

Treatment of acute myocardial infarction (AMI) has undergone dramatic changes due to new interventional techniques and improved thrombolytic agents. Recent studies have pointed to favourable results with either a combination of GPIIb/IIIa-Inhibitors and reduced dose of thrombolytic agents or primary PCI under protection of GPIIb/IIIa-Inhibitors.
By January 1st 1999 we started a new AMI treatment program using either GPIIb/IIIa-Inhibitors and reduced dose of thrombolytic agents, if possible prehospital, or primary PCI. Decision in each case was based on the intention to minimise any time delay to reopening of the infarct related artery. For an optimal decision-process we installed a hot-line between emergency team and cardiologist.
By January 2002 132/346 patients were treated with GPIIb/IIIa-Inhibitors and half dose of a thrombolytic agent (55/132 prehospital), 214/346 underwent primary PCI. Overall median age was 61 years, 23% of the patients were women and anterior and posterior MI were equally distributed. Median time between onset of symptoms and beginning of thrombolytic therapy or PCI amounted to 4:00 hours. Maximum level of creatinekinase reached a median of 27.9 µkat/l, median left ventricular ejection fraction was 52%. The median length of hospital stay was 6.1 days. 146/346 patients (42%) did not require ICU treatment. Despite time between onset of symptoms and therapy was 4:00 hours, overall inhospital mortality was 3.7% (13 patients), mortality excluding cardiogenic shock was 0.3%. In Addition non-fatal major adverse cardiac events occurred in 4.0%.
We conclude that our new, time optimising concept is safe and effective. Inhospital mortality and overall inhospital stay can be reduced significantly.

P622 Association between the PIA platelet glycoprotein GP IIIa polymorphism and survived myocardial infarction and extent of CAD in 397 males

D. Ciecwierz[1], M. Gruchala[2], K. Ochman[3], R. Targonski[2], W. Dubaniewicz[2], W. Sobiczewski[2], M. Minikowski[2], A. Rynkiewicz[2]. [1]Medical University of Gdansk, Dept. Invasive Cardiology, Gdansk, Poland; [2]Medical University of Gdansk, First Department of Cardiology, Gdansk, Poland; [3]Medical University of Gdansk, Dept. Biology and Genetics, Gdansk, Poland

Background: Several reports since 1996 have suggested the PlA2 allele of the PlA GPIIIa polymorphism of the gene encoding for GPIIIa subunit of the platelet membrane receptor glycoprotein (GP) IIb/IIIa as a significant risk factor for thrombotic complications of coronary artery disease (CAD). The objective of the current investigation was to examine the potential association between the PlA GPIIIa polymorphic variants and survived myocardial infarction and the extent of angiographically confirmed CAD.
Methods: The study was performed in 397 male Caucasian patients from the north region of Poland with significant coronary artery stenosis confirmed by elective coronary angiography. Screening for the PlA GPIIIa genotypes was performed by polymerase chain reaction of genomic DNA, followed by NciI digestion and agarose gel electrophoresis.
Results: The genotype distribution of the PlA GPIIIa polymorphism in our study group was; PlA1/A1- 75%, PlA1/A2-24% and PlA2/A2-1% with PlA1 and PlA2 allele frequencies 0.87 and 0.13, respectively. We found no evidence of association between the PlA2 allele and survived myocardial infarction OR 1.12 (95%CI 0.70-1.79), p=0.63 in the whole study group. In addition there was no association between the PlA GPIIIa polymorphic variants and survived myocardial infarction either in patients below 60 years of age (n= 236) OR 0.95 (95%CI 0.52-1.75, p=0.86) or low risk subgroup (BMI<26 kg/m^2 and total cholesterol <250 mg%) (n= 103) OR 1.30 (95%CI 0.52-3.29, p=0.57). The prevalence of the homozygous PlA1/A1 genotype among subjects with multiple-vessel CAD (two or three >50% stenosed vessels) was significantly higher than in patients with single-vessel disease; the odds ratio of PlA2/A2 or PlA1/A2 patients for having multiple-vessel CAD was 0.46 (95%CI 0.27-0.77), $p<0.003$. Also, the mean CAD score for PlA1/A1 patients was significantly lower in comparison to PlA2/A2 and PlA1/A2 patients; 7.58+2.20 and 6.98+2.37 ($p<0.03$), respectively.
Conclusions: Our results from this relatively large sample of Caucasian male patients with significant coronary artery stenosis suggest that the PlA GPIIIa gene polymorphism is not associated with survived myocardial infarction but the PlA1/A1 genotype may be associated with more severe CAD.

P623 Less acute treatment and exsessive hospital mortality of STEMI in female diabetics: results of the MITRA- and MIR-registries

A K. Gitt, H. Wienbergen, R. Schiele, T. Heer, C. Meisenzahl, M G. Gottwik, J. Senges on behalf of the MITRA- and MIR-Study-Groups. *Herzzentrum Ludwigshafen, Cardiology, Ludwigshafen/Rhein, Germany*

Background: Patients (pts) with known diabetes and acute STEMI are on increased risk of hospital mortality. Recent studies have shown an increased risk of female as compared to male STEMI pts. It is unknown if the female gender does have an additional impact on the hospital course in the subgroup of diabetic STEMI pts.
Methods: We analysed the prospective data of 6502/28401 (23%) unselected STEMI-pts with known diabetes mellitus of two German STEMI-registies MITRA (Maximal Individual Therapy of AMI Registry) and MIR (Myocardial Infarction Registry) to identify the impact of female gender on acute treatment and on hospital outcome.
Results: Out of the 6502 diabetic pts with STEMI 3043 (23%) were female. Female diabetics were older and had more often prior myocardial infarction and concommittant diseases as compared to male diabetics.
After adjusting for these differences in baseline characteristics, female gender was an independent determinant against acute reperfusion therapy (OR 0. 72, 0.65-0.81) and against β-blocker therapy (OR 0.83, 0.74-0.93) of STEMI in diabetics. Associated with the lower frequency of acute therapy of STEMI, female diabetics had a significantly increased hospital mortality as compared to male diabetics (OR 1.27, 1.09-1.49).

Gender differences in diabetics

	Female diabetics	Male diabetics
Age (years)	75	68
Prior STEMI	25,7%	20,2%
Hypertension	63,5%	57,4%
Acute Reperfusion	34,2%	47,5%
β-blockers	47,9%	57,8%
ACE-inhibitors	62,8%	63,7%
Aspirin	89,2%	92,1%

$p<0,05$ for all parameters

Conclusion: Female diabetic STEMI pts were less likely to receive acute reperfusion therapy than diabetic men. Within the diabetic STEMI pts with already significantly increased risk of hospital mortality compared to non diabetics, female diabetics had an additional 27% increased risk of hospital mortality after STEMI as compared to male diabetics.

P624 Type of disease onset and hospital survival in patients with myocardial infarction

D. Platonov, A. Brandt, L. Zhukhorov, N. Kurochkin, D. Kileinikov, V. Volkov, S. Sergeeva. *Tver, Russian Federation*

Goal. To study an association between type of myocardial infarction (MI) onset and risk of in-hospital death within the first three weeks of disease.
Methods: A retrospective analysis of 420 randomly selected hospital medical records of patients with acute and subsequent MI was done. Two binary variables related to MI onset were considered: the presence of typical pain (TP) syndrome (in keeping with WHO-MONICA criteria), and the presence of unstable angina (UA) syndrome preceding MI development. The following factors were selected as potential confounders: sex; age; acute or subsequent MI; Q-wave or non-Q-wave MI; anterior, inferior or other MI location. The association between presence of TP and UA and potential confounders was assessed by chi-square test for contingency tables with calculation of odds ratios (OR). The relative risk (RR) of death within 21 days of hospitalization was studied in Cox regression models with above mentioned variables as independent covariates. All analysis was done in SPSS 9.0 for Windows.
Results: Overall, TP was present in 60.0% and absent in 32.9% of cases; pre-MI UA was recorded in 33.3% and was not in 59.5%; in 7.1% of records a retrospective judgement on both variables could not be made. There was an inverse relation between presence of TP and UA (OR 0.50; 95% CI 0.27-0.92). Univariate analysis showed no association of TP or UA with sex, age and MI location; meanwhile TP was more frequent in Q-wave than in non-Q-wave MI (OR 2.9; 95% CI 1.5-5.4), and UA - in subsequent than in acute MI (OR 1.8; 95% CI 1.1-3.0). Cox regression model with only TP and UA as covariates showed an increased risk of death with TP presence (RR 2.2; 95% CI 1.5-3.2) and decreased - with UA history (RR 0.65; 95% CI 0.45-0.93). No evidence of interaction between TP and UA, as well as of their time-dependency, was found. Introduction of potential confounders into regression models provided no significant impact on the above associations: RR for history of UA remained unchanged (0.65; 95% CI 0.42-0.97), while RR for TP syndrome was somewhat reduced (1.8; 95% CI 1.2-2.7).
Conclusion: The presence of TP at MI onset is associated with 80% higher risk of hospital death within first three weeks; the association is independent of patients' sex and age, of MI location, of whether MI is acute or subsequent, and, probably, is partially mediated by MI type (Q-wave or non-Q-wave). The history of pre-MI UA confers 35% lower risk of hospital death independently of patients' sex and age, MI type, location, and acute or subsequent nature.

P625 Beneficial effects of direct call to emergency medical services on time delays and management of patients with acute myocardial infarction

J.C. Beer[1], G. Dentan[2], L. Janin-Magnificat[3], M. Zeller[1], Y. Laurent[4], J. Ravisy[2], Y. Cottin[1], J.E. Wolf[1]. [1]*CHU-Dijon, Cardiology Dept., Dijon, France;* [2]*Clinique de Fontaine, Cardiology, Fontaine les Dijon, France;* [3]*CH, Cardiology, Beaune, France;* [4]*CH, Cardiology, Semur en Auxois, France*

Background: Delayed access to medical care in patients with acute myocardial infarction (AMI) increases myocardial damage. Only few studies have analysed the influence of direct call to emergency medical services (EMS) in patients with AMI. From the regional observatory of MI (RICO) data base, we report the acute management in patients calling either EMS or other medical contact (OMC) as first medical seek after symptoms onset of MI.
Methods: Data were prospectively collected from January to October 2001, in the 6 medical units in charge of MI in the region of Côte-d'Or. Among the 322 patients included, only 57 (18%) directly called EMS after symptoms onset (group EMS) and 265 (82%) called another medical contact (group OMC).
Results: The baseline characteristics including age and risk factors were similar among the 2 groups of patients. Moreover, cardiovascular history was the same between the two groups, except for history of MI (21% in EMS group vs 11% in OMC group, $p<0.05$). The median times from symptoms onset to first medical intervention (48 vs 105 min, $p<0.02$) and from first medical intervention to hospital admission (60 vs 103 min, $p<0.02$) were markedly shorter in EMS group. We also observed a significant increase in reperfusion therapy at the acute phase in EMS group compared to OMC group (respectively 70% vs 48%, $p<0.003$), mainly due to a higher rate of primary angioplasty (respectively 33% vs 20%, $p<0.04$).
Conclusion: Our study in real world collecting data from a French regional population demonstrated that only a small rate of patients use the direct call to EMS at symptoms onset of MI. This study also documents the beneficial effect of a direct call to EMS by reducing the pre-hospital delays and by increasing the rate of early revascularisation.

P626 Sex differences in the treatment and outcome of acute myocardial infarction in an unselected population: data from the AMI-Florence registry

G.M. Santoro[1], E. Buiatti[2], D. Balzi[3], N. Carrabba[1], M.C. Landini[3], M. Filice[3], L. Scarti[3], R. Vergassola[3]. [1]*Careggi Hospital, Florence, Italy;* [2]*Tuscany Health Agency, Florence, Italy;* [3]*Health Unit, Florence, Italy*

Background: A higher mortality for women vs men with acute myocardial infarction (AMI) was reported in previous studies. However, scanty data exists about differences between males (M) and females (F) in the treatment strategy and outcome of AMI in an unselected population.
Methods: Data are derived from the AMI – Florence Registry, a prospective observational registry including all the Florence area residents who experienced ST-segment elevation AMI from March 1, 2000 to February 28, 2001 and were admitted to hospital within 24 h from symptom onset.
Results: Out of 806 pts included, 557 (69%) were M and 249 (31%) F. Mean age was 67±13 in M and 76±11 in F ($p<.000$). F had a higher prevalence of hypertension (62% vs 45%, $p<.000$), a less frequent habit of smoking (16% vs 35%, $p<.000$), a lower rate of previous revascularization (2.4 vs 8.4%, $p<.001$) and a higher rate of Killip class >1 at admission (36.9% vs 11.5%, $p=.001$). Median time from symptom onset to hospital admission was 135 min in M and 159 min in F(p=ns). Reperfusion treatment (RT) was used in 63% of M (primary percutaneous transluminal coronary angioplasty (P-PTCA) in 93%) and in 55% of F (P-PTCA in 93%) (p=ns). Median door-to-balloon time was not different between M (40 min) and F (45 min). Similar rates of stenting were observed in M (96%) and F (96%) while abciximab use was higher in M (66% vs 50%, $p=.001$). LV dysfunction (EF <50%) was observed at discharge in 77% of M and 81% of F (p=ns). While in-hospital mortality was significantly higher in F (12.9% vs 8.1%, $p=.04$), 6-month mortality was not (16.5% vs 14.2%, P=ns). At multivariate analysis, after adjustment for age, hypertension, diabetes, history of angina or heart failure or ictus, Killip class, infarct location, use of RT, F showed a lower risk of 6-month mortality (OR 0.61, 95%CI 0.37-1.00).
Conclusion: Despite their more advanced age and higher risk profile, women with AMI show a similar outcome as men when P-PTCA is the preferred reperfusion strategy.

P627 Early revascularization improves 1-year survival in 14-day survivors of acute myocardial Infarction

U. Stenestrand[1], L. Wallentin[2] on behalf of the RIKS-HIA Group. [1]*Heart Center, Department of Cardiology, Linköping, Sweden;* [2]*University Hospital, Department of Cardiology, Uppsala, Sweden*

Background: Studies on the effect of early revascularization in acute coronary syndromes have conflicting results whether it improves survival or not. We investigated the association between revascularization performed within 14 days after an acute myocardial infarction (AMI) and 1-year mortality.
Methods: Prospective cohort study using data from the Register of Information and Knowledge about Swedish Heart Intensive care Admissions (RIKS-HIA) on patients admitted to the coronary care units of 61 Swedish hospitals 1995-1998. Patients with first registry-recorded AMI who were younger than 80 years and who were alive at day 14, including 2375 who were revascularized within 14 days, and 17862 who were not. One-year mortality data were obtained from the Swedish National Cause of Death Register.
Results: At 1 year unadjusted mortality was 8.9% (1598 deaths) in the conservative group and 3.3% (78 deaths) in the early revascularization group. In Cox regression analysis adjusting for 43 confounding factors and propensity score for revascularization, early revascularization was associated with reduction in 1-year mortality (relative risk, 0.48; 95% confidence interval 0.35-0.66; $P<0.001$) in 14-days survivors of AMI. This reduction of mortality was similar among all subgroups based on age, sex, baseline characteristics, previous disease manifestations, and medications.
Conclusions: In daily clinical practise early revascularization in AMI patients is associated with substantially reduced 1-year mortality. Our study supports an early invasive strategy in AMI patients.

P628 Standard versus early discharge with transtelephonic electrocardiogram transmission after acute myocardial infarction: a prospective randomized study

H. Eltchaninoff, L. Sebagh, S. Dupuy, C. Tron, A. Cribier. *Charles Nicolle, Cardiology Dept., Rouen, France*

The duration of hospital stay after acute myocardial infarction (MI) has decreased over the last years. The aim of our prospective, randomized ongoing study was to compare 2 discharge strategies in acute MI: standard at day 10 (STAND) vs early discharge at day 5 (EARLY). In the EARLY group, Pts were followed by transtelephonic ECG (TT-ECG) transmission (Card Guard, Israël) from day 5 through day 10. Endpoints were: mortality, cardiac complications (reocclusion, arrythmias, cardiac failure) at day 10, 1 month and 1 year. Pts were randomized at day 3 after admission. Exclusion criteria were: severe cardiac complication within 3 days and/or comorbidity requiring prolonged hospitalization. In the EARLY group, Pts had systematic EKG transmission at day 6, 8 and 10. Non invasive ischemic tests and coronary interventions were left at the discretion of the physician and were not mandatory for inclusion. Results. During the study period (march 2000- december 2001), 444 Pts admitted for acute MI were screened, and 90 Pts (20%) were randomized. Reasons for non-inclusion were: severe cardiac complication (141 Pts), comorbidity (59 Pts), refusal (43 Pts), participation to an other protocol (52 Pts), follow-up impossible (59 Pts). Baseline characteristics were comparable between the 2 groups except for age (57±11 vs 64±14 years) and female gender (7% vs 22%) in the EARLY and STAND groups respectively. Use of fibrinolytics (26% vs 23%), rates of primary PTCA (40% vs 28%) were comparable in the EARLY and STAND group respectively. There were 3 complications between day 5 and day 10, both in the EARLY group (unstable angina, transient stroke, pulmonary edema). Diagnostic was confirmed by phone contact and EKG transmission. Hospital stay was reduced by 3.5 ± 1.4 days in the EARLY group. At one-month, there were 2 deaths in the EARLY group: suicide in one, septal defect in one detected on the planed discharged day and 2 Pts (one in each group) had recurrent MI. In the EARLY group, a satisfaction questionnaire showed that all Pts were satisfied by early discharge and reassured by TT-ECG facilities. Early discharge was associated with subsequent cost reduction at one month (1500 euros).
Conclusion: In selected Pts with uncomplicated acute MI and no severe comorbidity, early discharge is safe and cost/effective. The use of TT-EKG-transmission gives adjunct security to the early discharge.

P629 Treatment and outcome of women and men with acute myocardial infarction: results from the Berlin myocardial infarction registry

H. Theres[1], R. Matteucci-Gothe[2], C. Graf-Bothe[3], A. Chorianopoulos[4] on behalf of Berlin Myocardial Infarction Registry. *[1]Charité, Medical Clinic, Cardiology, Berlin, Germany; [2]Technical University, Berlin, Germany; [3]DRK Klinikum Westend, Berlin, Germany; [4]Humboldt Krankenhaus, Berlin, Germany*

Introduction: Major Studies suggest, that women with acute myocardial infarction are treated less invasiv resulting in a reduced survival rate. The goal of our study was to evaluate gender specific differences in treatment and outcome of women and men with acute myocardial infarction in Berlin, Germany.
Methods and results: In the years 1999 and 2000 in 25 Berlin hospitals data from 3436 patients (35,7% f, 64,3% m) suffering from acute myocardial infarction was prospectivly collected. Mean age was 72,0 (f, ± 12,3) and 61,6 (m, ± 12,2) years. Time between myocardial infarction and hospital admission (median values) were 2.75h (f) and 2.25h (m) ($p<0,05$, U-test). Thrombolysis without catheter intervention was performed in 252 women (22,4%) and 523 men (26,15%). Acute catheter intervention without thrombolysis was performed in 218 women (19,3%) and 586 men (29,3%). A combined treatment (thormbolysis and acute PTCA) was performed in 55 women (4,9%) and 193 men (9,7%). After adjusting for the covariables (age, diabetes mellitus, arterial hypertension, former myocardial infarction, heart failure, localisation (anterior wall)) no significant difference was found between women and men regrading the frequency of PTCA and thrombolysis. No attempt to open the infarct related artery was performed in 602 women (53%) and 698 men (35%). In hospital 225 women (19%) and 187 men (8.8%) died. After adjusting for the fomer mentioned covariables this difference was non significant (OR=1,2; 95%CI 0,9-1,6).
Conclusion: After adjusting for the covariables women and men suffering from acute myocardial infarction (Berlin, Germany; years 1999 and 2000) don't show a difference regarding frequency of thrombolysis/PTCA and in hospital death ($p>0,05$).

P630 The prognosis after acute myocardial infarction continues to improve in the city of Göteborg, Sweden

B. Karlson[1], M. Dellborg[2], T. Karlsson[1], J. Herlitz[1]. *[1]Sahlgrenska University Hospital, Division of Cardiology, Göteborg, Sweden; [2]Ostra Hospital, Medical Department, Goteborg, Sweden*

Background and aim of study: New knowledge has formed new treatment strategies for patients with acute myocardial infarction (AMI). We wanted to study how this has affected the short and long term prognosis for infarct patients, and discribe the development of coronary heart disease (CHD) mortality in our community.
Methods: Patients aged below 75 years hospitalized in Goteborg for AMI during 1990-91 (period I) and 1995-96 (period II) were compared in terms of previous history, treatment for AMI and outcome during hospitalisation and three years of follow-up. Information on CHD mortality in the community was gathered from the National Registry of Deaths.
Results: The number of patients were 921 in period I and 861 in period II, corresponding to an incidence of 200 and 183 per 100 000 inhabitants, respectively. During period II there was an increase in the use of PTCA, coronary by pass surgery, ACE inhibitors, heparins and intravenous nitroglycerine. On the other hand there was a decrease in the use of thrombolysis, diuretics, digitalis, longacting nitrates, calcium blockers and lidocaine. The inhospital mortality declined from 9.4% in period I to 6.0% in period II ($p=0.01$), risk ratio 0.65 (95% CI 0.45-0.94). The mortality over three years was 26.5% for period I patients and 17.8% for period II patients ($p<0.0001$), risk ratio 0.67 (95% CI 0.54-0.82). The CHD mortality in Goteborg declined from 1990 to 1995 in the age interval 30-74 years: age adjusted odds ratio 0.79 (95% CI 0.68-0.92).
Conclusion: The prognosis of AMI patients in Goteborg improved from 1990 to 1995, both during hospitalisation and during three years of follow-up. During the same time period the CHD mortality declined in the community of Goteborg.

P631 Prognostic value of consecutive abnormal signal-averaged electrocardiograms in patients after acute myocardial infarction

G. Kazianis, A. Economou. *7th Hosp. Social Insurance Institution, Cardiology, Kallithea-Athens, Greece*

Objectives: To assess the prognostic ability of consecutive abnormal signal-averaged electrocardiograms (SAECGs) during hospitalization after an acute myocardial infarction (AMI).
Methods: Seven hundred and five pts (525 men), aged 63±0.4 (SE) years in sinus rythm were studied prospectively post AMI. All pts underwent 1) Estimation of functional Killip class on admission, 2) SAECG obtained at the 1st, 3rd and 7th days after admission. Abnormal SAECG was defined if fQRS>114 ms plus either LAS>38 msec or RMS<20 μV for a standard QRS duration <120 msec or fQRS>155 msec, LAS>55 msec or RMS<17 μV for a standard QRS>120 msec. 3) Measurement of ejection fraction (EF) by 2D-echo on 1st day. 4) 24-hour Holter ECG recording with arrhythmias analysis based on Lown's classifications. 5) 12-lead ECG estimation of infarct size by QRS score based on Q and R wave duration and R/S and R/Q ratio before hospital discharge. Thrombolysis was given in 58% of pts. A cohort of 60 pts had consecutive abnormal SAECG.
Results: During a follow-up period of 39±0.9 months 178 (25%) pts died of cardiac causes (including sudden cardiac death). The presence of the 3 consecutive abnormal SAECGs was correlated with age ($p=0.00$), EF ($p=0.00$), old MI ($p=0.05$), anterior AMI (0.00), QRS score (0.00) and Killip class>II ($p=0.00$). In multivariate analysis (logistic regression) only age ($p=0.001$), EF ($p=0.002$) and abnormal consecutive SECGs ($p=0.00$) were independent predictors of cardiac mortality. The presence of 3 consecutive abnormal SAECG had higher specificity and higher positive predictive value (96% and 65%) than the separate abnormal SAECG (89% and 52% for the 1st, 90% and 42% for the 3rd or 87% and 32% for the 7th day respectively).
Conclusion: The presence of consecutive abnormal SAECGs improved the independent prognostic value of the SAECG for cardiac mortality.

P632 The influence of preinfarction angina on intrahospital mortality in patients with acute myocardial infarction

T. Heer[1], A.K. Gitt[2], H. Wienbergen[2], C. Meisenzahl[2], M. Gottwik[3], U. Gieseler[4], M. Weber[5], R. Schiele[2] on behalf of the MITRA and MIR Study Group. [1]*Herzzentrum Ludwigshafen, Cardiology, Ludwigshafen, Germany;* [2]*Herzzentrum Ludwigshafen, Cardiology Dept., Ludwigshafen, Germany;* [3]*Klinikum Nürnberg, Cardiology, Nürnberg, Germany;* [4]*Krankenhaus Diakoniezentrum, Cardiology, Speyer, Germany;* [5]*Krankenhaus Dachau, Cardiology, Dachau, Germany*

In randomized trials it was found that patients (pt) with acute myocardial infarction (AMI) who had preinfarction angina (preAP) had a lower mortality compared to pt without preAP. This has not yet been shown in clinical practice.
Methods: From 5/96 to 01/01 we enrolled 20037 consecutive pt (age median 68 years; 34,5% female) with AMI in the German multicenter registries MIR-1, MIR-2 and MITRA-2 in whom in 18926 preAP was registered. We examined the influence of preAP on intrahospital mortality. PreAP was defined as instable angina pectoris which occurred up to 4 weeks before an AMI.
Results: (see table comparison of pt with and without preAP)
Prehospital delay in pt with preAP was 75 min longer compared to pt without preAP. Pt with preAP were 40% less often resuscitated and had about 30% less often a cardiogenic shock compared to pt without preAP. Hospital mortality in pt with preAP was significantly lower compared to pt without preAP.

Comparison of pt with and without preAP

	Pt with preAP (n=11483; 61%)	Pt without preAP (n=7443; 39%)	P value
Prehospital delay (min)	225	150	<0.001
Resuscitation	550 (4.8%)	602 (8.1%)	<0.001
Cardiogenic shock	470 (4.1%)	452 (6.1%)	<0.001
Hospital mortality	1563 (13.6%)	1096 (14.7%)	0.03

Conclusion: Almost 2/3 of all pt with AMI had preAP. Pt with preAP had a longer prehospital delay ($p<0.001$), they were less often resuscitated ($p<0.001$) and had less often a cardiogenic shock ($p<0.001$). In clinical practice hospital mortality in pt with preAP is little lower compared to pt without preAP ($p=0.03$).

P633 In-hospital and one-year outcomes of older high-risk patients with acute myocardial infarction treated with or without reperfusion therapy: data from the MISTRAL study

S. Baldasseroni, G. Steffenino, D. Ardissino, P. Maras, C. Auguadro, G. Materazzo, D. Lucci, A.P. Maggioni on behalf of the MISTRAL Investigators. *ANMCO Research Center, Florence, Italy*

Background: In spite of reduction of mortality for coronary heart disease in the last few years, the prognosis of older patients (pts) with acute myocardial infarction (AMI) still remains significantly unfavourable. Aim of this study was to assess the outcomes of older patients with high risk AMI in a large unselected Italian cohort of patients treated with or without reperfusion therapy (RT). Methods and results: 2227 HR-pts with ST-elevation AMI <12h were recruited at 17 centres with, and 30 without, feasibility of performing primary PCI (classified at HR having ≥1 of the following characteristics: female >70 y, diabetic >70 y, Killip class >1, SBP <100 mmHg and HR >100 b/m, >4 leads with ST deviation, previous Q-wave MI, contraindication to TT [10.2%]). 1747 pts (78.4%) were aged ≤75 years and 480 pts (21.6%) were older; older pts were more frequent females, presented a higher percentage of previous AMI, angina and history of heart failure and stroke, cardiac shock and acute heart failure at the entry and during hospital stay; they usually arrived later in hospital. Older patients were undertreated with RT (primary-PCI and thrombolysis) respect to younger ones (38.5% vs 13.2%, $p<0.0001$) and with life-saving therapy such as beta-blockers and ACE-inhibitors in hospital and during follow-up. In hospital mortality and combined end-point (death+reinfarction+stroke) rates were higher in older pts with respect to younger ones (26.2% vs 5.8%, $p<0.0001$; 28.1% vs 7.8%, $p<0.0001$, respectively). At 1-year we found that older pts still maintained a significant poor prognosis (death: 42.6% vs 10.6%, $p<0.0001$; death+reinfarction+heart failure+angina: 55.2% vs 29.8%, $p<0.0001$). Adjusting for clinical and haemodynamic parameters, older pts presented a higher mortality and combined end-point at 1-year rates (OR 4.21, 95%CI 3.15-5.62; OR 2.03 95%CI 1.60-2.58 respectively).
Conclusion: Advanced age is an independent predictor of prognosis independently of clinical and haemodynamic profile of high risk patient with AMI. Older patients seem to be excluded by aggressive therapy of AMI. To reduce their elevated mortality new methods for increasing the use of reperfusion therapy in this subgroup of patients should be planned.

P634 Prognostic importance of rest electrocardiogram for a large population of coronary care unit-patients (CCU): a one year follow-up

D. Westin[1], U. Stenestrand[2], L. Wallentin[3], E. Swahn[2]. [1]*Dept. of Cardiology, Linköping;* [2]*Univ. Hospital, Dept. of Cardiology, Heart Center, Linköping;* [3]*Cardiothoracic Center, Univ. Hospital, Dept. of Cardiology, Uppsala, Sweden*

Background: The aim of this study was to investigate the prognostic importance of an admission-ECG, on in-hospital and 1-year mortality.
Methods: The Swedish Register of Cardiac Intensive Care (RIKS-HIA) contains data collected on case record forms including 100 variables for each patient. A total of 167302 patients with chest pain as the cause of CCU-admission were divided, from an admission standard ECG taken at rest, into eight ECG-groups; normal ECG, ST-depression (STD), ST-elevation (STE), new Q-wave, left bundle branch block (LBBB), T-inversion, old Q-wave and other pathology. Study end points, in-hospital and 1-year-mortality, were studied by merging the RIKS-HIA database with The National Cause of Death-register. Multiple covariate Cox-regression analysis was used to identify any variable with a significant influence on mortality.
Results: Patients with abnormal ECG findings were older and risk factors were more common compared to the normal ECG-group ($p<.001$). The proportion of previous heart disease was significantly higher in the abnormal ECG-groups compared to normal ECG, with some exceptions for STE and new Q-wave groups. The normal ECG-group had the lowest in-hospital and 1-year mortality (0.7 and 3.5%). New Q-wave and STE had the highest incidence of in-hospital mortality (12.2 and 8.5% respectively), though all abnormal ECG-groups showed significantly ($p<.001$) higher mortality than normal ECG. 1-year mortality was high for new Q-wave (19.9%) and STE (15.6%) but compared to in-hospital mortality the incidence was increasing more for LBBB (6.6 to 22.0%), STD (4.5 to 15.7%) and other pathology (5.1 to 14.7%). Relative ratios for 1-year mortality using multiple covariate Cox-regression were for normal ECG 1.0, T-inversions 1.47, old Q-wave 1.58, other pathology 2.22, STD 2.25, LBBB 2.53, STE 2.97 and new Q-wave 3.32.
Conclusion: A first rest-ECG in patients with chest pain can be used as a prognostic instrument for 1-year mortality. A normal ECG is predictive of a good prognosis whereas LBBB, new Q-wave, STE and STD had the highest mortality during follow-up.

PLATELET FUNCTION AND BIOCHEMISTRY

P635 Platelet expression of GP IIb/IIIa and P-selectin and its relation to platelet aggregation early after percuteneous coronary intervention (PCI)

E. Bernardo[1], A. Fernandez-Ortiz[2], D.J. Angiolillo[1], M.E. Viveros[1], C.F. Barrera[1], S. Vazquez[1], F. Alfonso[3], C. Macaya[3]. [1]*Cardiovascular Research Laboratory,* [2]*Coronary Care Unit,* [3] *Invasive Cardiology Unit, Hospital Clinico San Carlos, Madrid, Spain*

Background: Platelets are key elements in early thrombotic events following PCI. Besides platelet-platelet aggregation, signalling transduction in activated platelets lead to expression of adhesion molecules on its surface and release of coagulation factors from platelet granules. Herein, we souhgt to determine the relation between fibrinogen binding to activated GPIIb/IIIa and P-selectin surface expression and platelet aggregation following PCI.
Methods: Blood samples from 32 consecutive pts were obtained before and at 1, 4, and 24 hours after coronary stenting. Platelet activation was assessed by measuring GPIIb/IIIa (anti-human fibrinogen FTIC) fibrinogen binding and P-selectin (CD62-PE) surface expression in stimulated platelets (2μM ADP) using whole blood cytometry. Platelet aggregation was measured using light transmittance aggregometry with 6 μM ADP as agonist. Pts were divided into 2 groups according to GPIIb/IIIa receptor fibrinogen binding. Pts having a percentage of fibrinogen positive platelets in 3 or more samples (baseline, 1, 4, 24h) above or below the median were considered as having high (group H, n=15 pts; 12 males, age 64 ±9y) or low (group L, n=17 pts; 16 males, age 61±11y) platelet activation. All pts were on aspirin treatment (100mg/day) and received 300 mg clopidogrel loading-dose at procedure time. Pts receiving GPIIb/IIIa inhibitors were excluded.
Results (mean±SD): Platelet aggregation was significantly higher in group H than L, at 1 hour (58±14% vs 46±18%; p=0.04) and 4 hours after PCI (46±17% vs 33±16%; p=0.04). P-selectin expression was higher in group H at 4 hours (29±11% vs 17±7%; p= 0.003) but not at 1hour (38±16% vs 29±13%; p= 0.1) following PCI. After 24hours, a trend towards higher P-selectin expression (31±15% vs 18±12%; p=0.2) and less platelet inhibition (40±24% vs 26±16%; p=0.07) was found in group H compared to group L. No difference in platelet count was observed between the two groups.
Conclusions: Pts having an increased GPIIb/IIIa activation following PCI have, in addition to less inhibition of platelet aggregation, an enhanced platelet surface P-selectin expression. These data suggest that antiplatelet therapy other than GP IIb/IIIa receptor antagonist may be necessary to improve clinical outcome following coronary interventions.

P636 Prevalence of HPA-2 and VNTR platelet glycoprotein Ib a polymorphisms in patients with angiographically documented coronary artery disease

V. Matos[1], T. Fidalgo[2], P. Martinho[2], H. Oliveira[3], A.M Leitão Marques[3], G. Tamagnini[2], A. Gonsalves[3]. *[1]Centro Hospitalar de Coimbra, Cardiology, COIMBRA, Portugal; [2]Centro Hospitalar Coimbra, Hematology, Coimbra, Portugal; [3]Centro Hospitalar Coimbra, Cardiology, Coimbra, Portugal*

Platelet GP Ib-IX-V complex receptors play a key role in primary haemostasis and in the development and progression of obstructive coronary artery disease (CAD). Two polymorphisms of GP Iba are hypothesised to facilitate platelet adhesion and therefore increasing thrombotic risk. Our objective was to investigate their prevalence in a case-control study in patients with angiographic documentation of CAD.We studied 690 patients(pts) referred to the Catheterization Laboratory for coronary angiography (mean age 61 ± 10 years, 67,5% males). Diagnoses: heart valve disease in 15,5%, acute coronary syndromes in 26,2% and stable angina in 58,3% of pts. HPA-2 and VNTR genotype were identified by polymerase chain reaction (PCR)/enzymatic restriction and PCR/direct electrophoresis. Statistical analysis was performed with SPSS software. Discrete variables were compared with x2 test and continuous variables were compared with Student t test. Odds ratios and confidence intervals (CI) were calculated. Cases were 386 pts (55,9%) with coronary artery disease (CAD +) and controls were 304 pts (44,1%) without coronary artery disease (CAD -). Pts with CAD were older (62 ± 10 vs. 60 ± 10 years; p= 0,03) and more frequently male (79% vs. 21%, p=0,0001). The frequencies of HPA, VNTR genotypes and prothrombotic alleles (b of HPA-2 and B of VNTR) were not statistically different between cases and controls (table).

	HPA-2			VNTR					
	a/a	a/b	b/b	B/C	C/C	C/D	D/D	B/D	B/B
CAD+	75,6	23,3	1	20,5	63,5	10,6	2,3	2,1	1
CAD-	79,6	19,7	0,7	18,1	67,4	10,5	1	2	1
p value		0,4					0,7		
alleles(%)	a	b		No B	B				
CAD+	75,6	24,4		76,4	23,6				
CAD-	79,6	20,4		78,9	21,1				
p value	0,2			0,4					
Odds Ratio(95%CI)	0,79(0,55-1,14)			0,86(0,6-1,24)					

Genotype and allele frequencies of HPA-2 and VNTR polymorphisms

These results were similar in patients younger and older than 60 years. We concluded that the presence of HPA-2 or VNTR polymorphisms did not increased the risk of angiographically documented coronary disease in this population.

P637 Platelet GP IIb/IIIa and non-receptor tyrosine kinases pp60 c-src and pp125FAK in patients with advanced pulmonary hypertension

N Y. Maeda[1], S.P. Bydlowski[2], A.A.B. Lopes[3]. *[1]Pró-Sangue Foundation, Lab. of Vaso-occlusive Disease, São Paulo, Brazil; [2]Pró-Sangue Foundation, São Paulo, Brazil; [3]Heart Institute, São Paulo, Brazil*

Altered platelet function has been reported in pulmonary hypertension (PH) with "exausted" platelets being detected in some instances. In view of the central role played by glycoprotein IIb/IIIa (GP IIb/IIIa) in platelet physiology, we decided to analyze the behaviour of GPIIb/IIIa and two important signalling molecules, pp60c-src and pp125FAK in four adult patients with advanced PH in whom decreased platelet aggregation was observed. Platelets were analyzed at rest and following thrombin-stimulation. Platelet cytoskeleton was analyzed as the Triton-insoluble fraction. Proteins were semiquantified by densitometric analysis of luminographs after Western immunoblotting. Total platelet GP IIb/IIIa and its attachment to platelet cytoskeleton following stimulation was 40% decreased in patients in comparison with normals. This was associated with a 30% reduction in phosphorylated pp125FAK (P-pp125FAK) in comparison with controls following thrombin-stimulation, although total platelet pp125FAK was not decreased. In patients, platelet levels of pp60c-src and phosphorylated pp60c-src (P-pp60c-src) were close to normal at rest and following stimulation. P-pp60c-src increased approximately 45% after stimulation in both groups. Platelet pp60c-src phosphorylation was an activation-independent phenomenon, with considerable amounts of P-pp60c-src being present in resting platelets in patients and controls. In contrast, negligible amounts of P-pp125FAK were present in unstimulated platelets. Our findings suggest that altered platelet function in these patients was partly due to abnormal content and physiology of GPIIb/IIIa. In particular, since pp125FAK phosphorylation is a GPIIb/IIIa-mediated phenomenon, reduced platelet GPIIb/IIIa may have accounted for reduced levels of P-pp125FAK following thrombin stimulation.

P638 Transient coronary occlusion stimulates microvascular platelet deposition in remote myocardium

J.A. Barrabés[1], D. Garcia-Dorado[2], M. Mirabet[2], B. Soriano[3], F. Padilla[2], L. Trobo[2], J. Soler-Soler[2]. *[1]Hospital General Vall d'Hebron, Servicio de Cardiología, Barcelona, Spain; [2]Hospital General Vall d'Hebron, Servicio de Cardiología, Barcelona, Spain; [3]Hospital General Vall d'Hebron, Dept. de Medicina Nuclear, Barcelona, Spain*

Acute coronary syndromes are associated with activation of circulating platelets and with the development of a systemic inflammatory response. These phenomena may lead to increased endothelial adhesiveness and thrombogenicity of the macro and microvasculature in remote territories, with potential adverse consequences. In the present study, we aimed to investigate the magnitude of microvascular platelet deposition in a remote myocardial region after a transient coronary occlusion, and its association with the thrombotic activity at the culprit lesion and with the severity of myocardial damage in the reperfused zone.

Methods: Nine thiopental-anesthetized, open-chest pigs (34 ± 2 kg), in which platelets had been labeled with 99mTc and re-injected on the previous day, were submitted to catheter-induced mechanical injury of the left anterior descending coronary artery (LAD) followed by a 48-min ligation and two hours of reflow. Then, the heart was excised and the aortic root perfused for several minutes to wash the coronary vasculature. Myocardial platelet content was assessed by gamma counting of samples (3.6 ± 0.1 g) from reperfused myocardium and from myocardium supplied by the right coronary artery. Neutrophil content was quantified by measuring the myeloperoxidase (MPO) activity, and infarct size by triphenyltetrazolium chloride staining.

Results: Animals had 10 ± 3 cyclic flow reductions in the LAD during the reperfusion period. Platelet content (x107/g) in the control and ischemic zones averaged 1.42 ± 0.16 and 4.27 ± 0.93, respectively (P=0.008), MPO activity was 0.13 ± 0.05 and 0.25 ± 0.07 U/g, respectively (P=0.07), and infarct size averaged 5.6 ± 1.2% of ventricular mass. Platelet content in the control region was not associated with the number of cyclic flow reductions in the LAD, but was correlated with platelet content (r=0.74, P=0.02) and MPO activity (r=0.56, P=0.12) in reperfused myocardium, as well as with infarct size (r=0.72, P=0.03). Thus, the results suggest that transient coronary occlusion stimulates an active microvascular platelet deposition in remote myocardium, whose magnitude correlates with the severity of ischemic injury.

P639 Abnormal platelet Na^+/H^+ exchanger activity in patients with cardiac syndrome X is not associated with platelet activation in vivo

E. Romagnoli[1], G.A. Lanza[1], E. De Candia[2], R. De Cristofaro[2], A. Sestito[1], R. Landolfi[2], F. Crea[1], A. Maseri[1]. *[1]Policlinico A. Gemelli, Istituto di Cardiologia, Rome, Italy; [2]Policlinico A. Gemelli, Istituto di Semeiotica Medica, Rome, Italy*

An enhanced activity of the Na^+/H^+ countertransport has previously been suggested in red blood cells of patients with syndrome X (SX). In this study we investigated whether the activity of the Na^+/H^+ exchanger (NHE) is also increased in platelets of SX patients and whether this abnormality is associated with platelet activation in vivo.

The activity of platelet NHE was evaluated in 21 SX patients (12 women, 9 men; age 59±7 years)and in 18 matched controls (8 women, 10 men; age 54±5 years) by measuring the rate of cytoplasmic pH recovery of BCECF-loaded platelets in response to different degrees of acid loading, obtained by platelet exposure to increasing sodium propionate concentrations. A significant linear correlation between the intracytoplasmic pH value reached with increasing cytoplasm acidification (pHi) and the maximal velocity of platelet pH recovery (Delta-pHi, which reflects NHE activity) was found in all subjects of both groups. The slope of the regression curve and the Delta-pHi value intercept at pHi=6.6 on the regression curve were calculated for each patient and control by linear regression analysis. Delta-pHi in response to increasing acid loading resulted significantly higher in SX patients, compared to controls (0.75±0.29 vs. 0.5±0.23, respectively, p=0.01); accordingly, the intercept Delta-pHi value at pH=6.6 was also significantly increased in SX patients (0.24±0.1 vs. 0.17±0.1 in patients and control, respectively, $p<0.05$). There was no evidence of increased platelet activation in vivo in SX patients, since no significant difference was observed in 24-hour urinary 11-dehydro-TXB2 excretion between patients (median 920 pg/mg creatinine, range 358-3625, n=15) and controls (median 765 pg/mg creatinine, range 498-1175, n=15) (Mann-Whitney, p=0.32, NS).

Thus, our data show increased platelet NHE activity in response to acid loading in SX patients, suggesting a possible role of NHE abnormalities in the pathophysiology of this syndrome. The increased platelet NHE, however, did not seem to be associated with platelet activation in vivo.

P640 Persistent increased of sympathetic tone after thrombolysis is associated with angiographic no-reflow phenomenon

O. Manfrini[1], C. Pizzi[1], M. Metalli[2], R. Bugiardini[1]. [1]*University of Bologna, Med. Intern., Cardioangiol., Epatol., Bologna, Italy;* [2]*Imola, Ospedale Nuovo, Bologna, Italy*

Background: Prolonged ischemic injury evokes sympathetic reflexes that result in alpha-adrenergic microvascular constriction. We assessed the hypothesis that changes in autonomic nervous system activity may contribute to the no-reflow phenomenon following thrombolysis (TL).
Methods: We studied 59 pts with diagnosis of acute myocardial infarction, admitted to CCU, and treated with medical therapy (including beta-blockers) and systemic TL (rt-PA) within 6 hrs from the onset of symptoms. At admission pts underwent 24 hrs ECG-Holter monitoring for evaluating frequency domain measures of heart rate variability. Measurements were done before TL (T1), and 30 minutes (T2) and 24 hours (T3) after TL. Low (LF: 0.04-0.15) and high frequencies (HF: 0.15-0.40) were assumed to be the expression of sympathetic and parasympathetic activity, respectively. LF/HF ratio was used to estimate the overall autonomic nervous system balance. Clinical correlates of successful reperfusion were considered the occurrence of >50% reduction of ST segment elevation within 90 minutes and/or a CK-MB peak within 12 hours from the onset of TL. Pts performed diagnostic coronary angiography within 7 days from admission.
Results: 49/59 pts showed clinical signs of reperfusion. At angiography they were found to have a TIMI flow grade 3 in the infarct related artery (G1). The remaining 10 pts did not show clinical signs of reperfusion. Angiography showed a TIMI flow grade 1-2 (G2). Residual coronary stenosis following TL were comparable in G1 and G2. At T1, LF/HF ratio was not significantly different in G1 and G2 (5.6 ± 2.7 and 5.4 ± 2.9, respectively). At T2, LF/HF was dramatically increased (sympathetic activation) in G1 and G2 pts (9.2 ± 1.7 and 12.1 ± 2.7, respectively; $p < 0.001$). At T3 LF/HF was still high in G2 but not in G1 (7.5 ± 1.2 vs 1.9 ± 1.1; $p < 0.001$).
Conclusions: (1) Persistent increased of sympathetic tone after TL is associated with angiographic no-reflow phenomenon (TIMI flow grade 1- 2) of the infarct related coronary artery. (2) Cardiocardiac sympathetic reflexes may result in alpha-adrenergic microvascular constriction, which may contribute to no-reflow phenomenon after TL. (3) Alpha-adrenergic blockers might be beneficial in improving coronary blood flow following acute myocardial infarction.

P641 Regulation of local fibrinolytic activity in vivo in man

T. Hrafnkelsdottir[1], U. Wall[2], T. Gudnason[2], C. Jern[2], S. Jern[2]. [1]*Department of Medicine, Clin Experimental Research Laboratory, Göteborg, Sweden;* [2]*Clinical Experimental Resch Laboratory, Department of Medicine, Göteborg, Sweden*

Background: Tissue-type plasminogen activator (tPA) is the key enzyme of the endogenous fibrinolysis. The endothelium is the main source of tPA in plasma and stimulation of its release may be a physiologic counter-regulatory mechanism to prevent formation of occlusive intraluminal thrombi. However, free active tPA is rapidly inactivated by plasminogen activator inhibitor-1 (PAI-1), which is found in molar excess in plasma. We now investigated in a large invasive study how the local availability of free active tPA is regulated during basal and stimulated conditions.
Methods: Ninety-six healthy subjects participated in an invasive perfused-forearm study. Local release of fibrinolytic proteins was assessed by arteriovenous concentration gradients and plasma flow, at baseline and during stimulation by sodium nitroprussid (SNP; 10 μg/mL/min), methacholine chloride (Mch; 4 μg/mL/min), and desmopressin (DDAVP; 70 ng/mL/min).
Results: In the morning there was a low-rate continuous secretion of tPA antigen in the order of 80 fmol/min/L tissue. At noon, tPA release had increased by 45% and the free tPA fraction rose 3-fold. In spite of a 5 to 10-fold molar excess of the arterial input of active PAI-1, between 34% and 72% of the released tPA remained in its free active form. Stimulation by SNP, Mch, and DDAVP induced a 3 ($p=0.04$), 6 ($p<0.0001$), and 12-fold ($p<0.0001$) increase in local tPA release, respectively. Again, despite a large arterial supply of PAI-1, a even greater proportion of the released tPA appeared in the free tPA fraction which increased 5.5 ($p=0.01$), 8.5 ($p<0.01$), and 18-fold ($p<0.0001$), respectively. The correlation between the total tPA release and increments in free tPA became stronger as the release rate of tPA increased ($r=0.38$, $p<0.05$ to $r=0.85$, $p<0.001$), indicating that total tPA was the major determinant of free tPA production, while PAI-1 input had a diminutive influence on the availability of free tPA.
Conclusion: During high release rate of tPA from the vascular endothelium the free active fraction of tPA increases profoundly and tPA is not inactivated despite a several-fold molar excess of PAI-1. Thus, the magnitude of the activation of the local fibrinolytic system in response to stimulation is mainly determined by the capability for tPA release and not the level of circulating PAI-1.

P642 Effect of delapril-manidipine combination versus irbesartan-hydrochlorothiazide combination on fibrinolysis in hypertensive diabetic patients

R. Fogari, A. Mugellini, A. Zoppi, G. Derosa, A. Rinaldi, P. Preti. *IRCCS Policlinico S.Matteo, Internal Medicine and Therapeuthic, Pavia, Italy*

Aim: to compare the effect of delapril-manidipine combination vs irbesartan-hydrochlorothiazide combination on plasma tissue plasminogen activator (t-PA) and inhibitor 1 (PAI-1) activity in hypertensive type 2 diabetic patients.
Methods: after a 4 weeks placebo run-in period 80 hypertensive patients (DBP ≥ 95 ≤ 105 mm Hg) with well controlled type 2 diabetes were randomized to delapril 30 mg o.d. or irbesartan 150 mg o.d. for 8 weeks: then manidipine 10 mg o.d. was added to delapril and hydrochlorothiazide 12,5 mg o.d. was added to irbesartan for further 8 weeks. The last day of the placebo run-in period, of the monotherapy period and of combination therapy period blood pressure was measured and a blood sample was taken to evaluate plasma PAI-1 and t-PA activity (at the same hour in the morning).
Results: the results of the study are shown in the table.

	Placebo	Delapril	Delapril + Manidipine	Placebo	Irbesartan	Irbesartan + HCTZ
SBP (mmHg)	161.9	144.5**	131.9***	160.8	144.8**	132.3***
DBP (mmHg)	101.8	88.8**	80.0***	100.9	90.1**	81.5***
PAI-1 (IU/ml)	25.5	15.4*	14.9*	26.1	30.4	33.2
t-PA (IU/ml)	0.49	0.50	0.8*	0.47	0.46	0.30*

* $p < 0.05$ ** $p < 0,01$ *** $p<0,001$ vs placeboHCTZ = hydrochlorothiazide

Conclusion: these results suggest that in patients with imparied fibrinolysis an ACE inhibitor - Ca antagonist combination could improve the fibrinolytic balance more than the single drugs and more than an Angio II antagonist – hydrochlorothiazide combination. It represents a further indication to the use of ACE inhibitor - Ca antagonist combinations in hypertensive diabetic patients, where it is diffcult to reach the required blood pressure target with a single drug.

P643 Differential regulation of plasminogen activator inhibitor type 1 expression by statins in human vascular smooth muscle cells

J. Lohrmann[1], G.N. Franke[1], K. Peter[1], B.E. Sobel[2], C. Bode[1], T.K. Nordt[1]. [1]*University of Freiburg, Department of Cardiology, Freiburg, Germany;* [2]*University of Vermont, College of Medicine, Burlington, United States of America*

Background: Plasminogen activator inhibitor type 1 (PAI-1) has been established as an independent risk factor for cardiovascular disease. HMG CoA reductase inhibitors are known to induce other beneficial effects besides inhibiting synthesis of cholesterol. So far, no comparison of all clinically used statins with respect to their ability to modulate pathologically increased PAI-1 expression has been reported. Therefore, this study was designed to characterize potential statin-mediated modulation of PAI-1 synthesis in human vascular smooth muscle cells (HVSMC) known to play a pivotal role in atherogenesis.
Methods: HVSMC (passages 4-7) from healthy donors were exposed to selected concentrations (0, 0.1, 1, and 10 μM) of statins in the presence or absence of 1 ng/ml TGF-β known to be involved in atherogenesis and to be one of the most potent agonists of PAI-1 expression. PAI-1 protein concentration in conditioned media was quantified by ELISA, PAI-1 gene expression by Northern blotting.
Results: After 24 h, PAI-1 protein concentration decreased by up to 12% with pravastatin (p=ns), 37% with simvastatin ($p=0.018$), 39% with lovastatin ($p=0.003$), 44% with atorvastatin ($p=0.003$), 46% with fluvastatin ($p=0.014$), and 50% with cerivastatin ($p=0.027$) in the presence of TGF-β (each n=9), concomitantly with decreased PAI-1 gene expression (n=3). In contrast, under basal conditions PAI-1 expression was not significantly affected by statins. Total protein concentration was not altered in either case. In time-course experiments (4, 12, 24, 48, and 72 h), the inhibitory effect of statins increased over time and was maximal at 72 h (n=3).
Conclusion: Thus, the clinically used statins differ substantially in their ability to reduce pathologically increased PAI-1 expression. By selecting specific statins and by developing corresponding derivatives the beneficial effect of statins in cardiovascular disease may be potentiated in patients with concomitantly increased PAI-1 expression.

COMPUTERS IN CARDIOLOGY

P644 Unjustified prehospital fibrinolytic therapy using different means of electrocardiogram diagnosis of myocardial infarction

E.J.P. Lamfers[1], T.E.H. Hooghoudt[2], A. Uppelschoten[2], P.W.J. Stolwijk[3], E. Boersma[4], M.L. Simoons[4], F.W.A. Verheugt[5]. [1]*Nijmegen, Netherlands;* [2]*Canisius Wilhelmina Hospital, Cardiology, Nijmegen, Netherlands;* [3]*Hospital Rijnstate, Cardiology, Arnhem, Netherlands;* [4]*University Hospital Dijkzigt, Cardiology Dept., Rotterdam, Netherlands;* [5]*UMC St Radboud, Cardiology Dept., Nijmegen, Netherlands*

Background: Two cities in The Netherlands, Rotterdam and Nijmegen, have a well organised prehospital fibrinolytic therapy (FT) program for acute myocardial infarction (MI). Reports in the literature give an estimation of 5-10% of patients receiving fibrinolysis without having MI, but none differentiate between aborted MI (dynamic ECG criteria, no rise of cardiac enzymes), acute coronary syndrome (ACS) and unjustified treatment. We studied the incidence of unjustified FT using different ways of diagnosing MI in prehospital settings, and compared the results with in-hospital treated patients (Arnhem).
Methods: In Nijmegen ECG's of patients with chest pain are made by the ambulance staff, and transmitted to the CCU using a transtelephonic data transmission system. The diagnosis is confirmed by the attending cardiologist, if more than 0.6 mV of ST-elevation is seen. In Rotterdam acute MI is confirmed if more than 0.3 mV ST-elevation in at least more than 2 precordial leads or more than 0.4 mV ST-elevation in at least more than 2 extremity leads are measured by a mobile computer system. Unjustified FT was retrospectively assessed if there was no rise in cardiac enzymes and a diagnosis of aborted MI or ACS could be ruled out.
Results: (table). In-hospital therapy does not differ in unjustified FT compared to prehospital FT (p=0.33).

Unjustified FT

	patients	unjustified FT	mean ST-elevation
Rotterdam	118	2 (1.7%)	0.96 mV
Nijmegen	132	2 (1.5%)	1.20 mV
Arnhem	269	1 (0.4%)	0.84 mV

Prehospital (Rotterdam & Nijmegen)and in-hospital (Arnhem) strategy, and unjustified FT

Conclusion: Computer and cardiologist assisted ECG diagnosis of MI result in a similar incidence of unjustified FT and does not differ significantly from in-hospital FT. Our data support the use of simple computer diagnosis of MI leading to a further shortening of delay.

P645 The problems of evaluating computer-based analysis of paediatric electrocardiograms

R M. Hamilton[1], A B. Houston[2], K. McLeod[2], P W. Macfarlane[1]. [1]*Glasgow Royal Infirmary, Medical Cardiology, Glasgow, United Kingdom;* [2]*Royal Hospital for Sick Children, Department of Medicine, Glasgow, United Kingdom*

Introduction: Computer analysis of paediatric ECGs is a relatively neglected area. There are few paediatric cardiologists skilled in ECG analysis and hence it is difficult to evaluate computer-assisted reporting techniques.
Aim: The aim of this study was to evaluate the performance of the Glasgow program in a paediatric population by comparing the computer interpretations of RVH and LVH with those of two paediatric cardiologists.
Methods: 984 ECGs were recorded on both inpatients and outpatients, ranging in age from the first day of life to 18 years. The cardiologists were given the 12-lead ECG traces together with the age and sex of the child with the computer interpretation and all other remaining information removed. In 671 ECGs, the clinical indication for the ECG was available and this was shown on the ECG; the remaining 313 ECGs had no further information available and were reported 'blind' without the clinical indication, e.g. atrial septal defect.

Sensitivity and specificity of program versus the cardiologists

	RVH				LVH			
Cardiologist	1		2		1		2	
Reported blind?	Yes	No	Yes	No	Yes	No	Yes	No
No. of cases	19	117	19	100	17	62	11	44
Sensitivity (%)	63.2	37.6	57.9	44.0	41.2	32.3	25.0	36.4
Specificity (%)	98.0	94.9	97.6	95.1	97.3	96.9	96.0	96.3

Results: The sensitivities and specificities of the program are shown in table 1. The cardiologists were designated '1' and '2' and the results subdivided according to whether or not ECGs were reported blind. 'RVH' and 'LVH' include definite, probable and possible hypertrophy. The performance of the program was markedly better when compared with the cardiologists reporting blind (except for LVH by cardiologist 2) than when the cardiologists were provided with the clinical indication. There were also differences between the two cardiologists which were most pronounced for the reporting of LVH blind.
Conclusion: The results of this study illustrate the difficulties in evaluating computer software. The sensitivity of the program varies from 37.6% to 63.2% for RVH and from 25.0% to 41.2% for LVH. The specificities are much more consistent (from 94.9% to 98.0% for RVH and from 96.0% to 97.3% for LVH).

P646 PRIME-ECG mapping in the diagnosis of acute myocardial infarction

R. Blank[1], H. Darius[1], M. Ries[1], H. Vermöhlen[1], A. Victor[2], J. Meyer[1]. [1]*University Mainz, II. Medical Clinic, Mainz, Germany;* [2]*University Clinic Mainz, Institute of Medical Statistics, Mainz, Germany*

Introduction: In up to 50% of patients with acute coronary syndromes (ACS) the classical 12-lead ECG shows no pathological findings. Several other ECG modifications were developed to raise diagnostic sensitivity for coronary ischemia; e.g. in the 70s the principal of surface mapping. Recently, a fully automated system has been developed in order to make daily use and diagnostic easier. The aim of this study was to evaluate sensitivity and specificity of Prime-ECG in patients with acute coronary syndrome admitted to an emergency room.
Methods: We included 41 patients; 20 patients with proven acute myocardial infarction (defined as Tn-T positive and/or elevated CK values).
PRRIME-ECG recordings (BPSM-System; Meridian Medical Technologies) using a vest with 80 electrodes - including the classical 12-lead ECG - were taken at time of enrolment (time 0) and 3 and 6 hours thereafter (time 3/time 6) always simultaneous with analysis of CK and troponin T (Tn-T). The extent of the ischemic area was defined as the number of leads showing ST-segment deviations > +1mV or ≤ -0.5 mV if analysed according to manufacturers instructions.
Results: The results are shown in the table below (Se: Sensitivity/Sp: Specificity).

St-deviations	Positive Markers of Cardiac Ischemia (number n)	Negative Markers of Cardiac Ischemia (number n)
< +1mV	8	10 (Sp: 48%)
> + 1mV	12 (Se: 60%)	11
> -0.5 mV	7	8 (Sp: 38%)
< -0.5 mV	13 (Se: 65%)	13

Conclusions: In our series of patients admitted to an emergency room the PRIME-ECG exerted a low sensitivity and specificity in the diagnosis of acute myocardial infarction. With regards to the higher diagnostic costs and time demand the Prime-ECG seems to be less advantageous than biochemical markers for daily routine in an emergency room setting.

P647 Can "P"-wave wavelet analysis predict atrial fibrillation post CABG surgery?

V. Vassilikos[1], G. Dakos[1], I. Chouvarda[2], N. Maglaveras[2], S. Mochlas[3], P. Spanos[4], K. Pappas[2], G. Louridas[3]. [1]*AHEPA Hospital, Cardiac, Thessaloniki, Greece;* [2]*Aristotle University, Medical Informatics, Theassaloniki, Greece;* [3]*Aristotle University, Cardiac, Thessaloniki, Greece;* [4]*Aristotle University, Cardiac Surgery, Thessaloniki, Greece*

The aim of this study was to evaluate the predictive value of the P wave wavelet analysis for the development of postoperative atrial fibrillation (PAF) in CABG patients.
Methods: The P wave was analyzed using the Morlet wavelet in 37 patients who underwent successful CABG surgery. Group A consisted of 13 pts, mean age 67.2 ± 6.3, who developed post-CABG PAF and Group B consisted of 24 pts, mean age 63.2 ± 8.3, who remained arrhythmia free. Recordings using a 3-channel digital recorder (Galix Biomedical Instrumentation, Inc. USA) were obtained from all patients at resting conditions for 10 minutes. All ECGs were digitized with a sampling frequency of 1000Hz. Using a custom-made software wavelet parameters expressing the mean and peak energy of the P wave were calculated for each ECG orthogonal lead (X,Y,Z) and the vector magnitude (VM) at three frequency bands (200-160Hz, 150-100Hz and 90-50Hz). The P wave duration was also measured in these axes. Multiple regression analysis and the boot-strapping technique based on these parameters were used for the calculation of the pathologic cut-off point value. Sensitivity (Sn), specificity (Sp), positive and negative predictive value (PPV, NPV) were also calculated.
Results: The pathologic cut-off point value was calculated at –1.64. This led to a Sn 92.3%, Sp 87.5%, PPV 80% and NPV 95.4%.
Conclusion: The P wave Morlet wavelet analysis is a very sensitive and specific method in distinguishing patients who are going to develop atrial fibrillation after CABG surgery.

P648 Reconstruction of 12-lead electrocardiograms from reduced lead sets

S. Nelwan[1], J.A. Kors[2], S.H. Meij[3], M.L. Simoons[3], J.H. van Bemmel[2].
[1]ROTTERDAM, Netherlands; [2]Erasmus University, Dept. of Medical Informatics, Rotterdam, Netherlands; [3]University Hospital Rotterdam, Department of Cardiology, Rotterdam, Netherlands

Background: In clinical practice, continuous recording of all leads of the 12-lead ECG is often not possible. We wanted to assess how well the 12-lead ECG can be reconstructed from a subset of leads and how well lead reconstruction performs over time.
Methods: Two sets of 12-lead ECGs were used, one consisting of 2372 10-second ECGs and the other consisting of 234 24-hour ECG recordings. These sets were divided in equally-sized training and test sets. Precordial leads were systematically removed, and for all lead subsets including both limb leads and at least one precordial lead, the missing leads were reconstructed using general and patient-specific reconstruction. Reconstruction performance was measured by correlation between the original and reconstructed leads, by average and maximum absolute ST-differences, and by agreement when a clinical decision rule was applied. Reconstruction performance over time was evaluated using the 24-hour recordings.
Results: Reconstruction accuracy was high (correlation >0.98, ST-difference <30μV, agreement >99%) with general reconstruction for lead sets with one or two precordial leads removed, but was less satisfactory when more leads were missing. Patient-specific reconstruction performed well when up to 4 precordial leads were removed (correlation >0.98, ST-difference <19μV, agreement >99%). When reconstruction coefficients derived from one set were applied to the other set, similar results were obtained. Patient-specific reconstruction performance initially slightly decreased and then stabilized over time, but remained much better than general reconstruction after 24 hours.
Conclusions: Accurate reconstruction of the 12-lead ECG from lead subsets is possible. General reconstruction allows reconstruction of 1 or 2 precordial leads, whereas up to 4 leads can be reconstructed well using patient-specific reconstruction.

P649 Wavelet based analysis of ventricular conduction in post infarction patients with and without ventricular tachycardia

V. Vassilikos[1], I. Chouvarda[2], G. Dakos[1], N. Maglaveras[2], S. Mochlas[3], K. Pappas[2], G. Louridas[3]. [1]AHEPA Hospital, Cardiac, Thessaloniki, Greece; [2]Aristotle University, Medical Informatics, Theassaloniki, Greece; [3]Aristotle University, Cardiology Department, Thessaloniki, Greece

Wavelet analysis is a novel spectro-temporal technique which can reveal dynamic changes within each frequency band during the duration of the cardiac cycle length. The aim of this study is to identify if there are any differences in electrical conduction in post-myocardial infarction (PMI) patients with or without history of ventricular tachycardia (VT) using the Morlet wavelet analysis.
Methods: We studied the QRS interval based on the Morlet wavelet analysis in 22 PMI patients (Group A: 11 patients without history of VT, 8 males, mean age 65±6 years - Group B: 11 patients with history of VT, 9 males, mean age 64±5 years) and compared them with 11 normal individuals (Group C, 8 males, mean age 56±16 years). Recordings using a specially designed 3-channel digital recorder (Galix Biomedical Instrumentation, Inc. USA) in X, Y and Z-axes were obtained from all individuals at resting conditions for 10 minutes. All ECGs were digitized with a sampling frequency of 1000Hz. Using a custom-made software the mean and maximum energies in 3 frequency bands (200-160Hz, 150-100Hz and 90-50Hz) were calculated for the QRS complex in the three axes X, Y, Z and in the vector magnitude (VM).
Results: There were no differences in QRS duration between Group A patients and normal individuals. QRS complex was significantly prolonged in Y, Z and VM axes in Group B ($p<0,03$) compared to normals, and in Y axis compared to Group A. Wavelet analysis revealed decreased energy distribution in Z and VM axes for Group A and in Y, Z and VM axes for Group B compared to normals. These findings were similar in all frequency bands for both mean and max energies.
Conclusions: These findings suggest that PMI patients with VT display a different depolarization pattern compared with PMI patients without VT and normal individuals.

P650 The long-term ST database: reference for automated ischaemia detection systems and for studies of transient myocardial ischaemia

F. Jager[1], A. Taddei[2], G. Moody[3], M. Emdin[4], G. Antolic[5], A. Smrdel[1], C. Marchesi[6], R.G Mark[7]. [1]University of Ljubljana, Faculty Computer & Information Science, Ljubljana, Slovenia; [2]CNR Institute of Clinical Physiology, Biom.Engineering - Medical Informatics, Pisa, Italy; [3]Harvard - M.I.T., Div. Health Sciences and Technology, Cambridge, United States of America; [4]CNR Institute of Clinical Physiology, Cardiology, Pisa, Italy; [5]University Medical Center, Cardiology, Ljubljana, Slovenia; [6]University of Firenze, Engineering, Systems and Informatics, Firenze, Italy; [7]Beth Israel Deaconess Medical Center, Cardiology Division, Boston, United States of America

The Long Term ST database is a result of multinational effort in the field of annotated electrocardiogram databases. The database is a research resource for development and evaluation of automated systems to detect transient ST segment changes in ambulatory electrocardiograms, and for physiologic studies of transient myocardial ischemia. Ambulatory records of the database were selected in routine clinical practice settings in the United States and Europe between 1994 and 2000. Records were pre-processed, heart beat reference points were determined manually, time series of diagnostic and morphologic feature were derived, and significant transient ST segment events were annotated.
Due to enormous amount of data, we used automated techniques as much as possible. Interactive graphic editor tools and automated techniques developed allowed to work paperless and facilitated international co-operation via the Internet.
The database contains two and three-channel 24-hour annotated ambulatory records from 80 patients (all together 86 records).
The database record files are in standard WFDB format to be consistent with the MIT-BIH, AHA, and the European Society of Cardiology ST-T databases.
The files contain detailed clinical information for the subjects, waveform data, true QRS annotations, ST segment annotations, and ST segment measurements obtained on average heart beats. The database records are stored on a DVD-ROM. The database is intended as a complement to the European Society of Cardiology ST-T database, and to the MIT-BIH and AHA databases. We wish to better represent the wide variety of "real-world" data, including long-term ambulatory records with many examples of transient ischemic and non-ischemic ST segment events while ST segment measurements were obtained on average waveforms, and to permit researchers to study physiologic mechanisms and dynamics of transient ischemia.

P651 Signal-adapted wavelet preprocessing for support vector machines for detection of ventricular tachycardia

J. Jung[1], D. Strauss[2], S. Siaplaouras[1], A. Buob[1], G. Steidl[2], M. Boehm[1]. [1]Medizinische Universitätsklinik, Innere Medizin III, Homburg/Saar, Germany; [2]University of Mannheim, Faculty of Mathematics, Mannheim, Germany

The use of morphology based detection criteria may enhance specificity of the detection of ventricular tachycardias (VT) in implantable cardioverter-defibrillators (ICD). The aim of the study was to compare the efficacy of a VT detection algorithm using a hybrid signal-adapted wavelet-support vector machine (SVM) to a detection scheme using correlation waveform analysis (CWA) with best fit alignment of bipolar right ventricular electrograms (EGM).
Methods: EGM were obtained during an electrophysiological study in 10 patients (pts) (mean age: 66 years, male: 81%, coronary artery disease: 86%, mean ejection fraction: 0.42) with inducible monomorphic VT. The filtered (10-500 Hz) and digitized (2 kHz, 12 bit) EGM were recorded during sinus rhythm (SR) and VT. 480 consecutive EGM (VT:240, SR:240) were analyzed. For each pt, 8 consecutive EGM during SR and VT were used for training of SVM. CWA and SVM were applied to the remaining 320 EGM.
Results: By using SVM, all arrhythmia episodes were classified correctly. By using CWA, VT could not be discriminated from SR in 4/10 pts (Fig. 1).

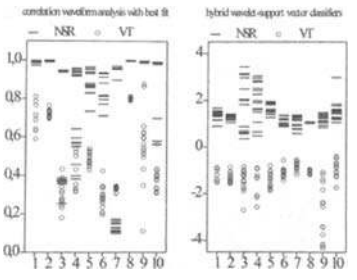

Fig. 1: CWA vs. SVM.

Conclusions: Analysis of EGM morphology in the wavelet-domain seems to be feasible for discrimination of SR from VT. This algorithm may contribute to an improved arrhythmia recognition in ICD-systems.

P652 Left ventricular ejection fraction in magnetic resonance imaging as compared with Tc99 GSPECT

M. Pasowicz[1], P. Klimeczek[1], W. Tracz[2], M. Kostkiewicz[2], P. Podolec[2], P. Banys[1]. [1]*Cardiac and Vascular Diseases,* [2]*Institute of Cardiology, The John Paul II Hospital, CM UJ, Krakow, Poland*

Purpose: Impaired left vetricular (LV) function with decreased ejection fraction (EF) represents a frequent finding in patients with ischaemic heart disease. The present study aimed to assess the concordance of ejection fraction measured by MRI and scintigraphy,
Material: 30 patients (11 women, 19 men, mean age 57 SD 8 years) underwent MRI and Tc99 GSPECT during 3 consecutive days under the same treatment regimen. Patients were examined with a 1.5 T Magnetom Vision MRI-Scanner (Siemens, Erlangen, Germany). Global and segmental cardiac function were established with cine-Gradient Echo sequences (2-chamber transversal slice perpendicular to long axis of LV, slice thickness 8 mm) using ARGUS software. Cardiac cavity and myocardium were delineated manually in every single slice and phase of the cardiac cycle.
Ejection fraction in scintigraphy was assessed by gated-SPECT. Perfusion images were synchronized to electrocardiograms allowing for the measurement of segmental and global LV function.
Results: Mean LV EF measured by MRI was 46% SD 12%, mean LV EF measured by gated-SPECT was 44% SD 14%. NS, correlation r = 0.87,

Short axis two-chamber view.

Conclusion: Ejection fraction by MRI is highly concordant with gated SPECT, MRI is a non-invasive technique obviating the need of isotope injection.

P653 A generic approach for the integration of DICOM worklist management in cardiology

M S. Claus, J. Riesmeier, T. Wilkens. *OFFIS, Oldenburg, Germany*

Introduction Today, almost all modern image acquisition devices in medicine are equipped with a DICOM interface allowing for the exchange of DICOM images via network. In addition to the image data each DICOM object contains patient related and administrative data (i. e. patient's name and birth date, identifiers, examination date and time). Especially identifiers and patient data are needed to integrate the images in a picture archiving and communication system (PACS) and/or information system. The conventional way to store this kind of data in DICOM images is to re-enter it manually to the console of the acquisition device. However, this approach cannot ensure that the data is consistent with the information system. Furthermore, it takes time to enter the required information several times in different systems. To avoid these problems DICOM offers a dedicated service, called Modality Worklist Management. This service allows a modality to query a list of scheduled procedures from an information system. In cardiology DICOM Worklist Management is now supported by all major manufactures of catheterisation laboratories and ultrasound devices.
Material and methods: In our project we were faced to both different medical devices and different data models in the information systems. Therefore, apart from the implementation of the DICOM Worklist Management we had to solve the following issues:
– Translation of DICOM queries to SQL queries
– Freely configurable mapping of DICOM attributes and database elements
– General purpose database interface to support different database systems
Based on a freely available DICOM toolkit we developed a Worklist Management server that allows to query "work lists" from a database via SQL statements. A typical DICOM query consists of only a few matching attributes (e.g. date and time range). Our implementation first translates this query to a corresponding SQL statement which returns a set of procedure identifiers. In a second step, for each of these procedures the requested attributes are selected from the database, composed to a DICOM Worklist and sent back to the querying modality.
Conclusion The use of DICOM Worklist Management as a standardised network protocol in co-operation with an SQL database showed the following benefits:
– It is no longer required to enter data multiple times.
– Data inconsistencies are eliminated.
– A single program allows to communicate with different databases and modalities. Attaching a new system to the network only requires to adjust the configuration files.

P654 Changes of baroreflex latency during parasympathetic stimulation or inhibition support DeBoer model of cardiovascular system

J. Simek[1], D. Wichterle[1], J. Kofranek[2], V. Melenovsky[1], J. Malik[1], L. Rychly[1]. [1]*General University Hospital, 3rd Dept. of Internal Medicine, Prague, Czech Republic;* [2]*Institute of Pathophysiology, Prague, Czech Republic*

Purpose: There is growing evidence that prolonged phase shift (PS) between systolic blood pressure and heart rate oscillations may contribute to an unstable regulation of heart rate in patients with cardiac disease. Experimental studies have shown that inhibition of vagal activity caused the prolongation of PS and vice versa. DeBoer computer model of cardiovascular system (DBM) is based on beat-to-beat simulation of fast vagal and slow sympathetic action. It has already been shown that some features of the model are in agreement with the results of experimental studies. The aim of our study was to investigate whether changes of PS observed during experimental parasympathetic inhibition or stimulation could be explained by DBM.
Methods: 5-min records of systolic blood pressure and heart rate were generated by DBM for basal, decreased and increased vagal activity (100 simulations for each model setting). PS in low frequency band was assessed by cross-spectral analysis.
Results: PS under the baseline vagal tone (-55,7° ± 2,7°) was prolonged to -86,8° ± 0,4° or shortened to -35,0° ± 4,7° by the 50% reduction or 50% increase of vagal tone, respectively.
Conclusion: Results of the simulation are fully compatible with the findings of experimental studies and broadly support the validity of DBM. Although low frequency (baroreflex-related) oscillations represent resonance phenomenon due to the sympathetic and parasympathetic interactions, corresponding changes in baroreflex delay may be explained by the changes of parasympathetic modulation alone.

P655 Artificial neural networks versus bayesian classifiers for risk stratification following uncomplicated myocardial infarction

R. Bigi[1], A. Desideri[2], F.A. Chiarotto[3], G.M. Toffolo[3], D. Gregori[4], L. Cortigiani[5], S. Coscarelli[6], L. Celegon[2]. [1]*Cardiovascular Research Foundation, Cardiology, Castelfranco Veneto, Italy;* [2]*Cardiovascular Research Foundation, Cardiology Dept., Castelfranco Veneto, Italy;* [3]*University of Padua, Electronics and Computer Science Dept., Padua, Italy;* [4]*IRCAB Foundation, Cardiology Dept., Udine, Italy;* [5]*"Campo di Marte" Hospital, Cardiology Dept., Lucca, Italy;* [6]*Cardiovascular Research Foundation, Castelfranco Veneto, Italy*

Background and Aim: Artificial Neural Networks (ANN) are distributed networks of computing elements capable of identifying relations in input data that are not apparent with common analytic techniques. Although ANN have been applied to different problems in the diagnosis and treatment of coronary artery disease, definite data on prognostic value are lacking. This study was aimed to compare ANN and Bayesian classifiers in predicting outcome following myocardial infarction (MI).
Methods: 18 different clinical, exercise ECG and stress echo variables by 496 patients with uncomplicated MI were retrospectively analyzed to predict the cumulative end-point of cardiac death, nonfatal MI and unstable angina. Patients undergoing revascularization were censored. Short- (200 days), medium- (400 days) and long-term (1000 days) observation intervals, including 50%, 75% and 90% of the events and 477, 367 and 300 patients, respectively, were considered. At each interval any patient was binary assigned to the "event" or "no event" class. A Multi-layer Feedforward Network with 5-40 neurons/layer was built-up and trained using a Back Propagation algorhythm including variable learning rate and momentum term. The hold-out technique was used to separate training from validation set. Robust Bayesian classifier (RoC) using the leave-one-out technique was also derived. The accuracy of both analytic techniques in predicting outcome for each observation interval was compared to that obtained by assigning all subjects to the largest class (default accuracy, DA).
Results: 14 death, 27 nonfatal MI and 29 unstable angina occurred during 660± 549 days follow-up. The accuracy of ANN and RoC in predicting outcome are reported in the table.

	ANN			RoC		
	DA (%)	Acc (%)	Acc/DA	DA (%)	Acc (%)	Acc/DA
200 days	79	74	0.93	78	81	1.03
400 days	57	67	1.17	56	73	1.30
1000 days	61	64	1.04	62	68	1.10

Conclusions: 1) ANN do not improve the prognostic classification of patients with uncomplicated MI as compared to Bayesian Classifiers. 2) In particular, short-term prognostic accuracy seems insufficient.

P656 Dynamic SPECT with ^{123}I-BMIPP in patients with congestive heart failure: effect of angiotensin II type-1 receptor blockade

Y. Takeishi, O. Minamihaba, S. Yamauchi, A. Fukui, M. Okuyama, N. Nozaki, O. Hirono, I. Kubota. *Yamagata University School of Medicine, The First Department of Internal Medic, Yamagata, Japan*

Enhanced washout of iodine-123 beta-methyl-p-iodophenyl-pentadecanoic acid (BMIPP) from 30 min to 4 hr images has been reported in patients with congestive heart failure (CHF). To investigate BMIPP kinetics in the early phase soon after tracer injection in patients with CHF, we performed dynamic single photon emission computed tomography (SPECT). We also examined effects of angiotensin II type-1 (AT1) receptor blockade on BMIPP washout in CHF patients. Twenty-nine patients with CHF and ten control subjects were examined. The consecutive 15 images of 2-min dynamic SPECT were acquired for 30 min after tracer injection. Echocardiography was carried out in all patients to evaluate left ventricular end-diastolic dimension and left ventricular ejection fraction. In the early phase after injection (0 to 4 min), a significant amount of radioactivity exists in the blood pool. After 6 min, myocardial BMIPP images were clear, and washout rate of BMIPP from 6 to 30 min was calculated. Washout rate (6 - 30 min) of BMIPP from the myocardium was faster in CHF than in control (8 ± 4% vs. -5 ± 3%, $P < 0.01$). Washout rate (6 - 30 min) of BMIPP from the myocardium demonstrated positive correlation with left ventricular dimension ($R = 0.54$, $P < 0.02$) and inverse correlation with left ventricular ejection fraction ($R = 0.53$, $P < 0.02$). Patients were given an AT1 receptor antagonist, candesartan, for 3 to 6 months, and dynamic SPECT was repeated. Enhanced washout rate of BMIPP from the myocardium in CHF was reduced after the treatment with candesartan (to -1 ± 4%, $P < 0.05$). These data suggest that 1) enhanced washout of BMIPP from the myocardium was observed soon after tracer injection in CHF patients, 2) the activation of angiotensin II signaling pathway is involved as an intracellular mechanism for enhanced BMIPP washout, and 3) improvement in fatty acid metabolism may represent a new mechanism for beneficial effects of AT1 receptor blockade on cardiac function and survival in CHF patients.

P657 Non-invasive magnetic resonance coronary artery imaging with CLARISCAN. Results from an international phase II trial

E. Nagel on behalf of the NC205 MC Participants. *German Heart Institute, Cardiology - CMR, Berlin, Germany*

Background: The non invasive diagnosis of coronary artery disease (CAD) with magnetic resonance techniques is burdened by a relatively low singal- and contrast-to-noise ratio. CLARISCAN (CS) is a strictly intravascular contrast agent based on iron. Aim of the study was to assess the efficacy and safety of CS for use with MR for imaging of the coronary arteries.
Methods: Seventy-nine patients were recruited in 10 centers in Europe and the United States using either breath hold or navigator techniques as different approaches for the diagnosis of CAD. Seventy-six patients were evaluable for safety, 73 for efficacy. Forty-five patients of the efficacy population were imaged with breath holding techniques, the remaining 28 with navigators to suppress breathing motion artifacts. Up to three MR-scans were performed for each patient with cumulative doses of £ 1.25 to 5.0 mg Fe/kg body weight. All patients were followed for 72 hours and examined with CXA for clinical indications before or after the MRA. The presence of significant stenoses (≥50% diameter reduction) was determined and compared to CXA in a blinded fashion.
Results: 123 significant stenoses (left main coronary artery: 3; right coronary artery: 40, left circumflex coronary artery: 35, left anterior descending coronary artery: 39, posterior descending coronary artery: 6) were found by CXA. In the most promising dose group (> 2.5-3.75 mg Fe/kg b.w.) diagnostic accuracy of MRA was 81.3% for the right and left main coronary artery. No serious adverse events were observed.
Conclusions: The use of CS for noninvasive MR coronary artery imaging is safe, the most promising dose group was >2.5-3.75 mg Fe/kg b.w. Diagnostic accuracy was improved in comparison to recent literature.

P658 Cardiac phosphorus-31 magnetic resonance spectroscopic imaging (^{31}P-MRSI) in patients with hereditary haemochromatosis

B. Metzler[1], M. Schocke[2], W. Vogel[3], G. Poelzl[1], P. Steinboeck[1], O. Pachinger[1], W. Jaschke[2]. *[1]University Hospital Innsbruck, Dept of Cardiology, Innsbruck, Austria; [2]Dept of Radiology, University Hospital, Innsbruck, Austria; [3]Dept of Gastroenterology, Innsbruck, Austria*

Purpose: Hereditary hemochromatosis (HHC) causes increased iron storage and is often associated with liver cirrhosis, liver cancer, and restrictive cardiomyopathy. The purpose of this study was to detect alterations of cardiac high-energy phosphate metabolism in patients with hereditary hemochromatosis prior to the development of structural heart diseases. Therefore cardiac phosphorus-31 magnetic resonance spectroscopic imaging (31P MRSI) was employed.
Methods: 24 male patients (mean age 47.2 ± 12 a) with homozygous hemochromatosis and 24 male healthy volunteers (mean age 47 ± 11 a) as age matched controls were included in this study. Transthoracal echocardiography was employed to all subjects in order to exclude structural heart diseases. Using a 1.5 Tesla whole-body MR scanner ECG-triggered transversal 31P MRSI was performed. For each subject a mean PCr/β-ATP value of the left ventricle was determined.
Results: No significant differences in blood lipid levels between hemochromatosis patients and healthy volunteers were observed. Left ventricle mean PCr to β-ATP ratio of patients with hereditary hemocromatosis (1.64 ± 0.35) was significantly decreased ($p<0.001$) in comparison to healhy volunteers (2.26 ± 0.52). Additionally, we detected a moderate correlation between PCr to β-ATP ratios and ejection fractions ($r=0.54$; $p=0.003$)
Conclusion: This study shows that 31P MRSI permits the detection of alterations of cardiac high-energy phosphate metabolism in patients with hereditary hemochromatosis prior to the development of structural heart diseases. The decreased PCr to β-ATP ratios in HHC might be caused by mitochondrial impairment due to cardiac iron overload.

P659 High-dose dobutamine stress MRI for follow-up after coronary revascularization procedures in patients with wall motion abnormalities at rest

A. Wahl, S. Roethemeyer, I. Paetsch, S. Huehns, C. Klein, E. Fleck, E. Nagel. *German Heart Institute Berlin, Cardiology, Berlin, Germany*

Introduction: We determined the value of high-dose dobutamine stress MRI (DSMR) for diagnosis of ischemia in patients (pts) with known coronary artery disease (CAD), prior coronary revascularization procedures, and wall motion abnormalities at rest.
Methods: 160 consecutive pts (59±8 years; prior myocardial infarction: 63%; prior percutaneous or surgical revascularization in 90% and 28%, respectively) underwent DSMR (1.5 T Philips) prior to clinically indicated invasive coronary angiography. Images were acquired at rest and during a standardized high-dose dobutamine-atropine protocol in 3 short-axis, a 4- and a 2-chamber view, using a single-slice segmented turbo gradient echo technique (TR/TE/flip 5.6/1.9/25; spatial resolution ≤ 1.5x2.5x8 mm; temporal resolution<30 ms). Regional wall motion was assessed by consensus between 2 blinded observers using a multiple screen format (MASS 4.2, Medis), a 16 segment model and a four-point scoring system. A new or worsening wall motion abnormality in ≥1 segment was considered positive for ischemia.
Results: 195 significant coronary artery stenoses (≥50% diameter by QCA) were found in 119 pts (74%). High-dose DSMR was successfully performed with diagnostic image quality in all pts. However, target heart rate was not reached in 9 pts (6%), due to end of protocol in negative submaximal examinations in 4 pts (3%), and limiting side effects in 5 pts (3%), including ventricular extrasystoly (n=2), severe chest pain (n=1), nausea (n=1) and asymptomatic decrease in blood pressure (n=1). Other major side effects included a case (0.6%) of sustained ventricular tachycardia (VT) with hemodynamic compromise requiring external defibrillation, 2 cases (1.3%) of non-sustained VT, as well as one case (0.6%) of atrial fibrillation with rapid ventricular rate. Overall sensitivity and specificity of DSMR for diagnosis of significant CAD were 89% and 85%, respectively. Diagnostic accuracy was 88%, positive and negative predictive value 94% and 73%, respectively. Sub-group analyses for pts with prior myocardial infarction or coronary artery bypass grafting yielded similar results. Overall sensitivity for detecting significant CAD in pts with one (n=64), two (n=34) or three (n=21) diseased vessels was 87%, 91% and 100%, respectively.
Conclusions: High-dose DSMR is reasonably safe and feasible in pts with known CAD, and can be used for follow-up after coronary revascularization procedures. Diagnostic accuracy is similar to MR data reported for pts with suspected CAD, and compares favorably with other established noninvasive techniques.

P660 Coronary flow reserve: a clue to the explanation of Tl-201 redistribution patterns early after reperfusion therapy for myocardial infarction

F. beygui[1], C. Le Feuvre[1], G. Helft[1], C. Maunoury[2], A. Vacheron[1], J.P. Metzger[1]. [1]*Necker Hospital, Adult Cardiology, Paris, France;* [2]*Necker Hospital, Nuclear Cardiology Dept., Paris, France*

Tl-201 reverse redistribution is commonly observed on stress-redistribution Tl-201 scintigrams (SPECT) after successful reperfusion therapy for acute myocardial infarction (AMI). The pathophysiology of such phenomenon remains unclear.

Methods: We studied 41 consecutive patients with successful primary stenting for a first AMI and single vessel disease. All patients underwent dipyridamole stress-redistribution SPECT 6-10 days after the AMI followed within 24 hours by coronary and left ventricular angiography, and intracoronary doppler assessment of coronary flow reserve (CFR). SPECT, Coronary and left ventricular angiography were repeated at 6 month follow-up.

Results: In-hospital SPECT showed fixed defect in 8, stress defects with significant rest redistribution in 7, reverse redistribution in 21 and absence of defect in 5 patients. On follow-up SPECT only 5 patients showed reverse redistribution. The comparison of patients with rest redistribution and those with reverse redistribution is reported in the table.

Rest versus reverse redistribution

	Rest redistribution (n=7)	Reverse redistribution (n=21)	p
In-hospital stress defect (%)	22±22	12±14	NS
In-hospital rest defect (%)	17±19	18±16	NS
LV end systolic volume (ml/m^2)	36±9	25±11	0.02
Coronary flow reserve	2.8±0.9	2.2±0.5	0.03
Follow-up rest defect (%)	11±15	10±16	NS
Segments with contractility recovery (n)	1.3±1.7	3.1±2.1	0.04

LV: left ventricular

Conclusions: Compared to the redistribution pattern, reverse redistribution is associated with lower CFR but less remodelling and better contractility recovery despite similar infarct size. These findings are suggestive of a deeper myocardial functional injury in the redistribution pattern and a reversible decrease of vasodilator reserve in the infarct-related artery in the reverse redistribution pattern.

P661 Real-time two-dimensional cardiac strain imaging utilizing cardiac echo-elastography for the quantitative evaluation of coronary artery disease

C. Breburda[1], T. Varghese[2], P. Rahko[1], J. Zagzebski[2]. [1]*Univ. of Wisconsin/ Clinical Science C, Medicine, Madison, WI, United States of America;* [2]*Univ. of Wisconsin, Medical Physics, Madison, United States of America*

We developed real-time cardiac elastography as a novel method for obtaining two-dimensional (2-D) strain (the degree of deformity) by imaging myocardial displacement and displaying strain in a 2-D parametric image. Doppler tissue derived strain imaging is one-dimensional, angle dependent and limited by cardiac translation. We thus utilized two-dimensional gray scale (2-D) radiofrequency (RF) data to derive strain images.

Methods: 5 subjects (2 CAD pts, 3 normals) were examined with a GE Vivid FiVe echo unit. RF data were displayed as 2-D elastogram cine-loops. Elastograms are obtained by comparing subsequent RF frames, using cross-correlation to detect tissue displacements, whose gradient is strain. The imaging frame rate was 50 frames/second, which enables tracking of small compressions (1%) of the heart muscle and limits motion artifacts. Strain can then be displayed in parametric images with uni or two-directional color scales. Two observers performed qualitative visual assessments (QVA) of the strain distribution. Spatial and dynamic 2-D and spatial A-mode interrogation allowed for the quantitative assessment of regional and dynamic strain throughout the cardiac cycle. In the parasternal long axis view % peak strain of the anteroseptal (AS), posterior wall (PW) and papillary muscle (PM) was measured.

Results: Inhomogeneous spatial and temporal strain distribution was observed both in normal subjects and in patients. Peak strain was greatest in patients at the level of the papillary muscle at both endsystole and enddiastole and strain distribution was heterogene. Normal subjects showed a more uniform distribution of spatial strain within the heart and of temporal strain throughout the cardiac cycle.

Conclusions: 1) Differences in the heterogenicity of spatial and temporal strain can be observed in real time and two-dimensionally between normal subjects and patients with coronary artery disease using this novel method, which we call 'echo-elastography'.

2) 2-D, real-time derived cardiac echo-elastography provides qualitative and quantitative strain imaging without translation artifacts, and may be feasible for a novel comprehensive evaluation of regional left ventricular function in coronary artery disease.

GENETIC AND DIAGNOSTIC ASPECTS IN HYPERTROPHYC CARDIOMYOPATHY

P662 Hypertrophic cardiomyopathy: clinical expression of Arg278Cys missense mutation in the cardiac troponin T gene

A. Theopistou, A. Anastasakis, A. Miliou, A. Rigopoulos, D. Markou, S. Stamatelopoulos, C. Stefanadis, P. Toutouzas. *University of Athens, Department of Cardiology, Athens, Greece*

Introduction: The clinical characteristics of patients with hypertrophic cardiomyopathy (HCM) differ depending on the particular genetic mutation. Mutations in the cardiac troponin T (cTnT) gene are considered associated with reduced penetrance, onset on adolescence, mild cardiac hypertrophy and a high incidence of sudden death at a young age.

Methods: We studied, clinically and genetically, 143 consecutive unrelated patients with HCM. Family members whose probands had an Arg278Cys mutation were also studied. All underwent physical examination, ECG and echocardiography. Clinical records and family histories were obtained. DNA was extracted from peripheral blood and the hot-spot exons 2, 3, 4, 6, 7, 8, 9, 10, 11, 12, 14, 15 and 16 of the cTnT gene were amplified by polymerase chain reaction (PCR). Automatic sequencing identified the presence of misalignments and a new PCR was performed for each suspicious case. Results were verified by resequencing 3 times in forward and reverse order as well as with single strand confirmation polymorphism (SSCP). Family members and 100 normal individuals were screened by automatic sequencing, SSCP and restriction enzyme analysis for areas of interest.

Results: An Arg278Cys missense mutation was identified in two probands. In the first family, the mutation was identified in one other living member with HCM. The disease in this family is characterized by late onset (mean age 43.3±9.8 years), mild cardiac hypertrophy (mean wall thickness of 17±3 mm) and a high incidence of sudden death at older ages (six cases of sudden death at a mean age of 66±3.6 years). Based on clinical data, the second proband seems to carry a de novo mutation. He was a boy with asymmetric septal hypertrophy (maximum wall thickness of 22 mm) who died suddenly at the age of 15 years. Neither parent fulfilled the diagnostic criteria reported for HCM in 1st degree relatives of patients and the family history was free from cardiac disease and sudden deaths.

Conclusions: Our data suggest that the Arg278Cys mutation in the cTnT gene can present with a clinical profile which deviates from what is currently expected for the cTnT gene mutations. Furthermore, the same mutation can have a different clinical expression in different families.

P663 Mybpc3 not myh7 is the predominant gene mutated in a large cohort of unrelated consecutive patients with hypertrophic cardiomyopathy

J. Erdmann[1], S. Dähmlow[2], U. Werner[2], M. Senyuvan[2], N. Tanis[2], M. Hummel[2], R. Hetzer[2], V. Regitz-Zagrosek[2]. [1]*University Hospital Regensburg, Cardiology, Regensburg, Germany;* [2]*Deutsches Herzzentrum Berlin, Cardiac and Thoracic Surgery, Berlin, Germany*

Defects in ten sarcomeric genes are known to cause hypertrophic cardiomyopathy (HCM). Mutation types and frequencies in large cohorts of consecutive and unrelated patients have not yet been determined. We therefore screened 108 unrelated and consecutive HCM patients for mutations in six sarcomeric genes: cardiac myosin-binding protein C (MYBPC3), β-MHC (MYH7), Troponin T (TNNT2), a-Tropomyosin (TPM1), Troponin I (TNNI3), and Troponin C (TNNC1).

HCM was diagnosed by echocardiography (septum > 15 mm, septal/posterior wall >1.3), angiography or based on a state after myectomy. Single-strand conformational polymorphism (SSCP) analysis was used for mutation screening, followed by sequencing. Sensitivity was determined in comparison with denaturing high-performance liquid chromatography (DHPLC) and reached > 97%. A total of 34 mutations in 36 out of 108 patients were identified: 18 mutations in MYBPC3 in 20 patients, two of them being founder mutations; 13 missense mutations in MYH7 in 14 patients, one of them being a founder mutation (R870H); one amino acid exchange in TPM1, TNNT2 and TNNI3, respectively. No disease-causing mutation was found in TNNC1. Twenty-eight of the 36 mutation carriers (78%) reported a positive family history with at least one affected first-grade relative, only 8 mutations occurred sporadically (22%).

MYBPC3 was the gene that most frequently caused HCM in our cohort of unrelated patients. Systematic mutation screening in large samples of HCM patients leads to a genetic diagnosis in about 30% of unrelated index patients and in about 57% of patients with a positive family history.

P664 ^{123}I-MIBG scintigraphic assessment of sympathetic innervation in hypertrophic cardiomyopathy patients with and without severe tachyarrhythmias

G. Buja, P. Zanco, L. Leoni, P. Melacini, A. Nava, G. Thiene. *Policlinico Universita, Interventional Cardiology, Padova, Italy*

Aim: We sought to evaluate scintigraphic myocardial sympathetic innervation in hypertrophic cardiomyopathy (HCM) patients (pts) with and without lifethreatening ventricular.
Methods: We studied 40 HCM pts: n.10 with ventricular tachycardia or fibrillation (Group A); n.10 with ventricular myocardial dysfunction (Group B); n.10 with other sudden death risk factors (Group C); n.10 with absence of any previous features (Group D), and ten healthy subjects (controls). Myocardial sympathetic innervation and perfusion were assessed by Iodine-123-metoidobenzylguanidine(I-123-MIBG) and N-13 ammonia (NH3) scintigraphic imaging, respectively. Heart/lung ratio for I-123-MIBG uptake (H/L) and a score index (higher values=lower uptake) of NH3 uptake (SI-NH3) as well as of myocardial areas having normal NH3 with reduced I-123-MIBG uptake (SI-MIBG) were provided.
Results: Reduced H/L ratio and higher SI-MIBG were found in the HCM pts compared to the controls (H/L=1.29±0.1 vs 1.61±0.1, p<0.0001; SI-MIBG=8.5±2.9 vs 2.2±2.2, p<0.0001).Group A HCM pts with ventricular tachycardia/fibrillation, when compared with groups B+C+D pts, had lower SI-MIBG uptake (2.5±1.7 vs 10.3±3, p=0.0001), younger mean age (33yrs±16 vs 49yrs±12, p=0.004), and increased maximal left ventricular wall thickness (25mm±4 vs 20mm±4, p=0.04). Higher SI-MIBG characterized group B HCM pts with ventricular myocardial dysfunction (16.2±3.6 vs 5.9±2.7of groups A+C+D, p< 0.0001).
Conclusions: In HCM, normal sympathetic innervation is detectable in patients with severe ventricular tachyarrhythmias, while remarkable denervation is correlated with ventricular myocardial dysfunction. These findings may entail potential impact on diagnostic and therapeutic approach of HCM pts.

P665 Evidence for the detection of intramural fibrosis in hypertrophic cardiomyopathies by contrast-enhanced MRI

J. Schulz-Menger, D. Messroghli, T. Pötsch, M. Friedrich. *Franz-Volhard-Klinik; Charité, Cardiology, Berlin, Germany*

Background: Fibrotic areas in patients with hypertrophic cardiomyopathies (HCM) were described in different histological studies. Applying contrast enhanced Magnetic Resonance Imaging (MRI) it is possible to characterise myocardial infarctions. The visualisation is based on the phenomenon of the decelerated contrast wash-in/washout leading to "delayed enhancement" (DE).
Patients and methods: We investigated 21 patients with different forms of HCM (non obstructive, NHCM: n=10; obstructive; HOCM, n=11) in a 1,5T MR system (Signa CV/i, GE Medical Systems). Applying an inversion-recovery prepared T1-weighted gradient echo sequence, DE patterns were assessed after intravenous application of a bolus of GD-DTPA (0.2 mmol/kg BW).
Results: The patient groups (HOCM; NHCM) show significant differences in the mass (NHCM 199±14 vs HOCM 278±32, p< 0,01), no differences in the age, maximal septal wall thickness (MSWT) and in the left ventricular ejection fraction. (EF). In 64%of the patients with HOCM and in 50% of the patients with NHCM a local DE was detectable. The contrast enhancement was mostly found in the septal wall. No correlation was found between the presence of DE to mass, EF, or MSWT. DE distribution was focal, neither subendocardial nor transmural.

Fig. 1: Focal septal contrast enhancement.

Discussion: Contrast-enhanced MRI shows areas of increased contrast uptake in HCM not related to the extent of hypertrophy or the functional status. The localisation and extent also differs from that of classical myocardial infarction. Thus, the detected areas are likely to represent "myocardial disarray" or areas of fibrotic tissue transformation. The prognostic value of these findings has to be further elucidated.

P666 Right ventricular myocardial function in either physiological or pathological left ventricular hypertrophy: a tissue Doppler study

A. D'Andrea[1], P. Caso[1], M. Galderisi[2], M. Scherillo[1], S. Severino[1], B. Sarubbi[3], M. Cotrufo[3], R. Calabrò[3]. [1]*Ospedale Vincenzo Monaldi, Cardiology Dept., Naples, Italy;* [2]*Federico II Univ., Emergency Medicine Dept., Naples, Italy;* [3]*Second University of Naples, Cardiology Dept., Naples, Italy*

Aim of the study: to analyze right ventricular (RV) myocardial function in patients with left ventricular (LV) hypertrophy secondary to either hypertrophic cardiomyopathy (HC) or athlete's competitive endurance training.
Methods: Standard Doppler echo and pulsed Tissue Doppler (TD) of posterior septal wall, mitral and tricuspid annulus were performed in 32 top-level endurance athletes (AT) and in 26 patients with HC, all men, both having evidence of LV hypertrophy. The following parameters of both RV and LV myocardial function were assessed: systolic peak velocities (Sm), pre-contraction time (PCTm), contraction time (CTm), early (Em) and late (Am) diastolic velocities, Em/Am, relaxation time (RTm).
Results: the two groups were comparable for age and blood pressure, while AT showed lower heart rate (HR) and increased body surface area than HC. LV mass index was not significantly different between the two groups. However, septal thickness was higher in HC, while both LV and RV end-diastolic diameters and LV stroke volume were increased in AT. All transmitral and transtricuspid Doppler indexes were higher in AT, with increased E/A ratios. TD analysis showed in HC lower Sm, Em and Em/Am ratio as well as longer RTm and PCTm at the level of all the analyzed segments. These differences remained significant even after correction for age, HR and LV mass index. By univariate analysis, peak Em of tricuspid anulus was positively related to LV end-diastolic diameter in AT ($r = 0.76$, $p < 0.0001$) and inversely associated to septal thickness in HC ($r = -0.69$, $p < 0.001$). After adjusting for HR, age and LV mass index, distinct multiple linear regression models confirmed the independent positive association between RV peak Em velocity and LV end-diastolic diameter (β coefficient = 0.75, $p < 0.0001$) in AT, and independent inverse correlation of the same peak Em velocity of tricuspid annulus with septal thickness ($\beta = -0.62$, $p < 0.001$) in HC. Of interest, a RV Em peak velocity < 0.16 m/sec differentiated AT and HC better than standard Doppler (92% sensitivity and a 93% specificity).
Conclusions: Early diastolic right ventricular myocardial function is positively influenced by preload increase in AT and negatively associated to increased septal thickness in HC. Therefore TD may represent a useful tool in the differential diagnosis between athlete's heart and HC, underlining the different involvement of RV myocardial function in either physiological or pathological LV hypertrophy.

P667 The incidence of cardiac variant Fabry disease in patients with hypertrophic non obstructive cardiomyopathy (HNCM)

G. Beer[1], P. Reinecke[2], H E. Gabbert[2], W. Hort[2], F H. Gietzen[1], H. Kuhn[1]. [1]*Städtische Kliniken Bielefeld-Mitte, 2. Medizinische Klinik/Kardiologie, Bielefeld, Germany;* [2]*Universität Düsseldorf, Institut für Pathologie, Düsseldorf, Germany*

Introduction: Regarding the cardiac variant of Fabry disease (FD) there are several case reports in the literature; cardiac hypertrophy as the only manifestation of the disease mimicks the clinical features of HNCM. Based on recently reported therapeutic progress,major attention has been paid to FD. However, systematic investigations concerning the frequency of cardiac variant FD in HNCM are still lacking. Diagnostic pitfalls may arise from the fact that invasive diagnostic procedures are not provided in the diagnosis of HNCM. Especially concealed myocardial storage disease has to be excluded to avoid potential pitfalls in genetic studies and to avoid wrong therapeutic consequences.
Methods: Therefore, we performed right ventricular endomyocardial catheter biopsy (EMCB) for the first time in a systematic investigation in a large group of pts. (287 consecutive pts. and 13 non consecutive pts.)with HNCM (mean age 55 years;range 14 to 90 years).
Results: In unexpected many pts.(26 from 300 pts.; 8,7%) EMCB turned out concealed cardiac FD. This was only possible by electron microscopic evaluation of EMCB. In 12 of these pts. (4,0%) the diagnosis of FD was stated on the basis of electron microscopic evaluation.In 14 pts. (4,7%) the morphological alterations were not as pronounced as in the first group; therefore only the strong suspicion of FD was stated in these pts.. However,in 2 of these pts. alpha-galactosidase A was evaluated resulting in a pathological low residual enzyme activity in plasma. Evaluation by electron microscopy revealed in all pts. concentric lamellated structures with parallel orientation typical of FD.
Conclusion: The incidence of concealed cardiac FD in pts. with HNCM (26 of 300 pts.; 8,7%) is unexpected high. However these findings fit favourably with those of Nakao (cardiac variant FD in 7,5% of pts. with clinical suspicion of hypertrophic cardiomyopathy) and coworkers (Nakao et al.New Engl J Med 1995;333:288-293). Therefore invasive diagnostic procedures including EMCB are mandatory in all pts. with HNCM and concealed myocardial storage disease,especially cardiac FD has to be ruled out. This is of importance to avoid potential pitfalls in performing genetic studies. Additionally, based on recently reported therapeutic progress in enzyme replacement therapy of FD, this is of special clinical importance thus offering a potential causal therapeutic option in pts. with clinical features of HNCM.

P668 Serum markers of interstitial myocardial collagen in hypertrophic cardiomyopathy

R. Lombardi, S. Betocchi, C.G. Tocchetti, M.A. Losi, A. Cacace, M. Aversa, V. De Crescenzo, M. Chiariello. *Federico II University of Naples, Clin. Medicine, Cardiovascular Science, Naples, Italy*

Background: Increased interstitial collagen is a characteristic of hypertrophic cardiomyopathy (HCM) and is a determinant of increased myocardial stiffness. Our study aims at assessing if collagen turnover is altered in HCM.
Methods: We studied 35 HCM patients (27 men; mean age 35±9 years) and 13 age- and sex-matched healthy volunteers (9 men; mean age 35±11 years). Collagen turnover was assessed by measuring, by radioimmunoassay, serum concentrations of 3 by-products of collagen metabolism: procollagen III N-terminal propeptide (PIIINP), an index of collagen III synthesis; procollagen I C-terminal propeptide (PICP) and C-terminal telopeptide of collagen I (ICTP), indexes of collagen I synthesis and degradation, respectively. Besides, we measured by ELISA serum levels of matrix metallo-proteinase 1 (MMP-1), a collagenase: MMP-1 activity, free MMP-1 (i.e. the active form and its precursor), total MMP-1 (i.e. free MMP-1 and MMP-1 blocked by the tissue inhibitor of metalloproteinase-1 (TIMP-1)). In addition, we measured TIMP-1.
Results: Serum concentration of PIIINP, ICTP and TIMP-1 were higher in HCM than in controls (Table). As expected, total MMP-1 values were below the method's resolution for controls, as well as for HCM.

	Controls	HCM	p
PIIINP	2.45 ± 0.63	3.34 ± 1.29	0.003
PICP	184 ± 61	186 ± 68	N.S.
ICTP	2.37 ± 0.39	2.83 ± 0.74	0.046
MMP-1 activity	7.66 ± 4.56	8.38 ± 4.84	N.S.
Free MMP-1	9.80 ± 5.22	11.04 ± 6.35	N.S.
Total MMP-1	6.02 ± 0.65	5.98 ± 0.32	N.S.
TIMP-1	890 ± 177	1021 ± 167	0.045

Conclusions: In HCM patients, collagen III tends to build up, while collagen I is degraded. Degradation is altogether hampered as TIMP-1 is increased.

P669 Increased circulating levels of procollagen peptides in patients with hypertrophic cardiomyopathy

H. Saeki, M. Hamada, Y. Shigematsu, Y. Hara, T. Ohtsuka, A. Ogimoto, J. Suzuki, T. Matsunaka. *Ehime University School of Medicine, The 2nd Dept. of Internal of Medicine, Ehime Pref., Japan*

Background: Myocardial fibrosis is found in the ventricular wall and associated with myocardial dysfunction in patients with hypertrophic cardiomyopathy (HCM). Recent studies suggested that circulating levels of procollagen peptides are associated with myocardial fibrosis in heart disease. Therefore, this study was designed to elucidate whether the circulating levels of procollagen peptides are elevated in patients with HCM, especially to evaluate the effects of angiotensin II receptor blocker (ARB) on collagen synthesis in patients with HCM who had the occurrence of congestive heart failure (CHF).
Methods: Eighty-six patients with HCM and 10 normal control subjects participated in this study. The HCM patients were divided into 2 groups; 74 with HCM and 12 with HCM who had the history of CHF (HF-HCM). Serum levels of carboxy-terminal propeptide of procollagen type I (PIP) and procollagen type III amino terminal peptide (PIIIP) were measured. Left ventricular systolic function was examined using fractional shortening (FS) by echocardiographically examination. We also determined the effects of ARB on collagen synthesis in 6 patients of 12 patients with HF-HCM who had been treated with ARB.
Results: 1) Serum levels of PIP and PIIIP were significantly higher in patients with HF-HCM than those in patients with HCM and normal control subjects ($p < 0.0001$, $p < 0.05$, respectively). 2) There was a significant correlation between serum levels of PIP and FS in all HCM patients ($r = 0.471$, $p = 0.0012$). 3) PIP and PIIIP decreased in all 6 HF-HCM patients after the treatment with ARB ($p < 0.001$).
Conclusion: Our findings indicate that circulating levels of procollagen peptides may be related to the disease progression of HCM and that ARB has the potential to attenuate collagen synthesis and myocardial fibrosis in patients with HCM.

P670 Brain natriuretic peptide in hypertrophic cardiomyopathy with and without systolic dysfunction

M. Pieroni[1], C. Chimenti[1], R. Verardo[1], A. Maseri[2], A. Frustaci[1]. [1]*Catholic University, Department of Cardiology, Rome, Italy;* [2]*Istituto San Raffaele, Department of cardiology, Milan, Italy*

Background: Increased plasmatic levels of Brain Natriuretic Peptide (BNP) have been observed in both dilated (DCM) and hypertrophic cardiomyopathy (HCM). We determined whether BNP can be a biologic marker of HCM progressing to systolic dysfunction.
Methods: Patient population consisted of 10 HCM patients (pts) with normal systolic function (ejection fraction (EF) >60%) (Group 1) and 10 HCM pts with depressed contractility (EF<50%) (Group 2). The diagnosis of HCM was supported by 2D-echocardiography, cardiac catheterisation, coronary angiography and left ventricular (LV) endomyocardial biopsy. LV mass was calculated according to Devereux formula. BNP plasma concentrations were measured using specific immunoradiometric assay on plasma samples obtained from the femoral vein during cardiac catheterisation after at least 72 hours withdrawal of cardiovascular drugs. In 4 pts with systolic dysfunction, BNP levels were retrospectively assessed in plasma samples collected and stored at -80°C at the time of diagnosis when pts were on normal contractile function. As controls we used 10 healthy pts. Unpaired t-test was used to compare BNP levels and echocardiographic measurements.
Results: All patients were in sinus rhythm. No patient showed an intraventricular gradient. Mean LV end-diastolic diameter was 44.0±3.4 mm in Group 1 and 54.0±4.69 mm in Group 2. Mean EF was 63.4±3.82% vs 41.7±6.5%. BNP levels in HCM pts were higher than in controls and in Group 2 were significantly higher than in Group 1 (343.5±27.0 pg/ml vs 68.7±22 pg/ml) ($p<0.001$). In particular BNP levels in pts with HCM and systolic dysfunction were >4 times higher than in HCM with normal contractility. There were no statistically significant differences in left ventricular mass, left atrial dimensions and end-diastolic pressure between the two groups. A further increase of BNP was observed in the four pts who had BNP assessed during normal and depressed systolic function (316.2±21.0 pg/ml vs 88.9±24 pg/ml) ($p<0.001$).
Conclusions: In HCM plasma BNP is significantly higher in pts with systolic dysfunction than in pts with normal contractility. BNP can be used in HCM as a biologic marker of disease progression.

P671 Hypertrophic cardiomyopathy: significance of raised BNP levels

D.A. Brito[1], J.S. Matias[1], A. Pereirinha[2], M.J. Cabral[1], H. Madeira[2]. [1]*Hospital de Santa Maria, Dept. of Cardiology, Lisbon, Portugal;* [2]*Faculdade de Medicina de Lisboa, Lisbon, Portugal*

The significance of raised plasma BNP in hypertrophic cardiomyopathy (HCM) remains unclear and there is some controversy about the relationship between BNP levels and left ventricular diastolic dysfunction.
Methods: we studied 37 members of HCM families. Nineteen (group A) – mean age 51.5 ± 15.8 years, 11 women – were affected; 18 (group B) – 27.3 ± 12.7 years, 14 women – had no phenotypic expression of the disease. In group A, 3 pts. had sub aortic obstruction (OB), one of them also had moderate mitral regurgitation (MR). All the individuals had a non-dilated well contracting left ventricle (Ej.Fr.> 55%). Plasma concentrations of BNP were measured using specific electrochemiluminescence immunoassay for proBNP (Elecsys), values being expressed in pg/ml. A score of left ventricular hypertrophy (LVHS) was derived from the sum of the thicknesses of 9 segments (8 short axis view segments – 4 subvalvular, 4 at papillary muscles –and 1 apical view – apex). Four parameters that can be related to left ventricular diastolic function - left atrial dimension (LAD), left atrial fractional shortening (LAFS), difference in duration between reverse pulmonary wave (R) and mitral A wave and isovolumetric relaxation time (IVRT) - were calculated by ECHO. Values of BNP and ECHO parameters obtained in groups A and B were compared. In group A, BNP values were compared with ECHO findings.
Results: BNP levels did not correlate with age in both groups. Group A had abnormal BNP values and ECHO indices and differed significantly from group B (see table).

Comparison between group A and B

*BNP (pg/ml)	A - 951.4±1596.8	versus	B - 44.6±41.3	p<0.05
LVHS (mm)	A - 15.6±3.9	versus	B - 8.9±1.1	p<0.001
LAD (mm)	A - 44.0±8.1	versus	B - 34.0±4.2	p<0.001
LAFS (%)	A - 29.0±9.7	versus	B - 43.0±16.3	p<0.005
IVRT (ms)	A - 97.4±36.82	versus	B - 78.0±11.6	p<0.05

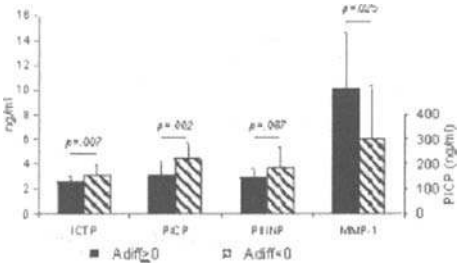
* (BNP value patient with OB - gradient 110 mmHg - and MR was 7147 pg/ml)

In group A, there was a positive correlation between BNP plasma levels and LVHS ($r = 0.63$; $p < 0.005$) but no correlation was found with the other ECHO parameters.
Conclusions: In hypertrophic cardiomyopathy, raised plasma BNP reflects the presence and severity of left ventricular hypertrophy rather than left ventricular diastolic dysfunction.

P672 Impaired passive diastolic function correlates to increased collagen synthesis and blunted degradation in hypertrophic cardiomyopathy

C.G. Tocchetti, S. Betocchi, R. Lombardi, M.A. Losi, Q. Ciampi, M. Aversa, G.L. D'Alessandro, M. Chiariello. *Federico II University of Naples, Clin. Medicine, Cardiovascular Science, Naples, Italy*

Background: Hypertrophic cardiomyopathy (HCM) is characterized by LV hypertrophy and increased interstitial fibrosis, which may contribute to diastolic dysfunction. We previously showed that patients with noninvasive signs of LV diastolic dysfunction had higher serum levels of PIIINP, a product of collagen III synthesis, and ICTP, a product of collagen I degradation.
Methods: We studied 36 HCM patients, 27 men, mean age 35±6 years. By echocardiography, we assessed diastolic function as: the pattern of LV filling (normal or impaired relaxation vs pseudonormal or restrictive), and the difference in duration between antegrade A wave and retrograde pulmonary vein flow (Adiff, ms): it indicates increased LV end-diastolic pressure if <0. Collagen turnover was assessed by measuring serum concentrations of PICP, a product of collagen I synthesis, PIIINP, and ICTP (radioimmuno assay), and in 28 of 36 patients serum activity of MMP-1 (Matrix Metallo-Proteinase-1, ELISA), a collagenase.
Results: ICTP and PICP were inversely related to age (r=-.462, and r=-.541, respectively, p<.005). Patients with Adiff<0 had higher ICTP, PICP, and, albeit not significantly, PIIINP, and lower MMP-1 (Figure). Patients with pseudonormal or restrictive filling patterns had higher values of ICTP and PICP (3.1±.8 vs 2.5±.5 ng/ml, and 208±69 vs 163±60 ng/ml, respectively, p<0.05), and lower values of MMP-1 (6.2±4.1 vs 10.3±4.7 ng/ml, p=0.02) than patients with normal or impaired relaxation filling patterns.



Conclusions: HCM patients with impaired passive diastolic function (as assessed by Adiff<0 and pseudonormal or restrictive filling patterns) tend to build up collagen, resulting from both increased collagen synthesis and blunted degradation.

RESUSCITATION AND AUTONOMIC EXTERNAL DEFIBRILLATOR

714 Risk factors for out-of-hospital cardiac arrest in the community. The Reykjavik study.

G. Thorgeirsson[1], G. Thorgeirsson[1], H. Sigvaldason[2], J. Witteman[3]. *[1]Landspitali-University Hospital, Medicine, Division of Cardiology, Reykjavik, Iceland; [2]Icelandic Heart Association, Reykjavik, Iceland; [3]Erasmus University, Rotterdam, Netherlands*

The purpose of our investigation was to study whether risk factors for out-of-hospital cardiac arrest could be determined among the baseline characteristics of the cohort of the Reykjavík Study, a prospective community based cohort study that started in 1967.
The correlation of potential risk factors and out-of-hospital cardiac arrest was investigated in this cohort of 8007 men and 9435 women,who were alive in 1987. From 1987 to 1996 181 individuals, i.e. 137 men and 44 women sustained out-of-hospital cardiac arrest due to cardiac causes. The cause for cardiac arrest was obtained from hospital medical records and the death certificates of those who died and had not been admitted to hospital.
The following variables were examined: age, height, weight, cholesterol, triglycerides, systolic and diastolic blood pressure,antihypertensives, smoking history, diabetes mellitus, family history of myocardial infarction, old MI, silent MI, angina pectoris, heart size on chest X-ray and erythrocyte sedimentantion rate. The electrocardiogram was examined for arrhythmias and various other abnormalities, classified by the Minnesota Code. The independent contribution of each of these variables was determined by Cox regression analysis. The summary of significant variables by multivariate analysis is presented in the table.
Conclusion: The risk of sustaining out-of-hospital cardiac arrest is significantly increased in men with higher age, increased BMI, high cholesterol, hypertension, smoking, and a history of MI. For women, the risk was increased by elevated levels of cholesterol and triglycerides, systolic blood pressure and increased voltage on ECG.

Summary of significant variables

	Men RR (95%CI)	P	Women RR (95%CI)	P
Age 1987	1.04(1.02-1.07)	0.0005		
BMI,kg/m^2	1.06 (1.02-1.11)	0.008	0.87 (0.80-0.95)	0.0013
Cholesterol mmol/L	1.45 (1.26-1.68)	0.0000	1.38 (1.12-1.70)	0.0026
Triglycerides mmol/L			2.18 (1.10-4.32)	0.0256
Hypertension	1.54 (1.09-2.19	0.0157		
Systolic blood pressure mmHg			1.01 (1.00-1.03)	0.0315
Current smoker	1.75 (1.14-2.46)	0.0014		
Sustained MI	3.87 (2.41-6.21	0.0000		
ECG (increased voltage)			14.4 (5.46-38.45)	0.0000

715 Tripling survival from sudden cardiac arrest via early defibrillation, without traditional education in cardiopulmonary resuscitation

A. Capucci[1], D. Aschieri[1], M. Piepoli[2], M. Arvedi[1], G.H. Bardy[3]. *[1]General Hospital, Cardiology, Piacenza, Italy; [2]Piacenza, Italy; [3]University of Washington, Cardiac Research Seattle Institute, Seattle, WA, United States of America*

Background: Sudden cardiac arrest (SCA) claims an estimated 350,000 lives per year in the United States, representing a major public health problem. The vast majority of SCA is caused by ventricular fibrillation (85%) where early defibrillation is the most important intervention affecting survival. After 10 minutes, very few resuscitation attempts are successful (0-2%). The major determinants of survival after witnessed out-of-hospital SCA include bystander initiation of cardiopulmonary resuscitation (CPR) with early defibrillation and the rapidity with which defibrillation is accomplished. However, traditional CPR is difficult to teach, to be correctly performed and to retain the skill if not performed routinely. To improve public access to early defibrillation, we established "Piacenza Progetto Vita", (PPV) the first system of out-of-hospital early defibrillation by first responder volunteers, trained in use of the external biphasic defibrillators (AED), without traditional education in CPR
Methods: The system serves a population of 173,114 residents in the Piacenza region, Italy. Equipment for the system comprises 39 semi-automatic (AEDs): 12 placed in high-risk locations, 12 in lay-staffed ambulances and 15 in police-cars; 1285 lay volunteers were respond to all cases of suspected SCA, in co-ordination with the Emergency Medical System (EMS).
Results: During the first 22 months, 354 SCA occurred (72±12 years, 73% witnessed). The PPV volunteers treated 143 SCA cases (40.4%) with an EMS call to arrival time of 4.8±1.2 min (vs. 6.2±2.3 min for EMS, p=0.05). Overall survival rate to hospital discharge was tripled from 3.3% (7/211) for EMS intervention to 10.5% (15/143) for PPV intervention (p=0.006). The survival rate for witnessed SCA was tripled by PPV: 15.5% vs. 4.3% in the EMS treated group (p=0.002). A "shockable" rhythm was present in 23.8% (34/143) of the PPV patients vs. 15.6% (33/211) of the EMS patients (p=0.055). The survival rate from shockable dysrythmias was higher for PPV vs. EMS: 44.1% (15/34) vs. 21.2% (7/33), p=0.046. The neurologically intact survival rate was higher in PPV vs. EMS treated patients: 8.4% (12/143) vs. 2.4% (5/211), p=0.009.
Conclusion: Broad dissemination of AEDs for use by non-medical volunteers without traditional education in cardiac-pulmonary resuscitation, enabled early defibrillation and tripled the survival rate from out-of-hospital SCA.

716 Prediction of neurological outcome after cardiac arrest by serial determination of serum neuron-specific enolase – experience with 100 patients

J. Reisinger[1], T. Winter[1], K. Wiesinger[2], M. Mori[1], A. Steinhuber[1], K. Höllinger[1], P. Kühn[1]. [1]*Krankenhaus Barmh. Schwestern, Internal Medicine, Linz, Austria;* [2]*Krankenhaus Barmh. Schwestern, Laboratory Medicine, Linz, Austria*

Neuron-specific enolase (NSE) is increasingly used as a marker of hypoxic brain damage. The purpose of this prospective study was to evaluate the prognostic value of NSE after cardiopulmonary resuscitation.

Methods: We examined 121 consecutive patients (pts) (80 men, 41 women, age 16 to 89 years, mean 66) who returned to spontaneous circulation after cardiac arrest (ventricular fibrillation in 68, asystole in 23, and pulseless electrical activity in 30) but were unconscious and mechanically ventilated. Serum NSE concentrations (Cobas Core NSE EIA, Roche, normal range 0-15 ng/ml) were determined at admission (day 0) and on the following 4 days. Hemolytic samples were discarded. Pts were classified according to the "best-ever achieved" Glasgow-Pittsburgh cerebral performance categories (CPC, 1 to 5) of the Utstein recommendations. Twenty-one of the 121 pts were excluded from the study because they died while under analgesia sedation, leaving 100 patients for analysis.

Results: 61 of the 100 included pts were discharged from intensive care after a median (range) of 6 (1-76) days with good cerebral performance (CPC 1 in 21 pts), moderate cerebral disability (CPC 2 in 25 pts) or severe cerebral disability (CPC 3 in 15 pts). The remaining 39 pts were discharged in a comatose state (CPC 4 in 28 pts) or died (without having regained consciousness) (CPC 5 in 11 pts) after a median (range) of 7 (1-23) days.

With serial determination, serum NSE concentrations of more than 70 ng/ml on at least two out of four days after resuscitation predicted a bad neurological outcome (CPC 4 or 5) with a sensitivity of 54%, a specificity of 100%, a positive predictive value of 100% and a negative predictive value of 77%.

Conclusion: Serial determination of serum NSE concentration after cardiac arrest is highly predictive of neurological outcome.

717 Potential impact of public access defibrillators on overall survival following out of hospital cardiopulmonary arrest

J. Pell[1], J.M. Sirel[2], A.K. Marsden[3], I. Ford[4], N.L. Walker[2], S.M. Cobbe[2]. [1]*Greater Glasgow NHS Board, Public Health, Glasgow, United Kingdom;* [2]*University of Glasgow, Department of Medical Cardiology, Glasgow, United Kingdom;* [3]*Scottish Ambulance Service, Headquarters, Edinburgh, United Kingdom;* [4]*University of Glasgow, Robertson Centre for Biostatistics, Glasgow, United Kingdom*

Background: Early defibrillation improves survival following cardiopulmonary arrest. Public access defibrillators are being provided in increasing numbers for use prior to the arrival of an ambulance. The aim of our study was to model the potential impact of public access defibrillators on overall survival.

Methods: Retrospective cohort study using the Heartstart register of all out of hospital cardiopulmonary arrests due to cardiac disease in Scotland over seven years. Within those arrest sites where public access defibrillators could potentially be located, it was assumed that survival among those waiting more than 3 min for ambulance attendance would be increased to that among those who waited 3 min or less.

Results: Of the 15,189 eligible arrests, 12,004 (79.0%) occurred in sites where public access defibrillators would be unlikely to impact on survival, 453 (3.0%) in sites where they may impact and 2732 (18.0%) in obvious sites for locating defibrillators. Defibrillation was undertaken in 67.9% of arrests that occurred in possibly suitable sites for locating public access defibrillators and 72.9% of those in definitely suitable sites. Overall survival increased from 744 (5.0%) to a predicted value of 942-959 (6.3%-6.5%) depending on the assumptions made regarding defibrillator coverage.

Conclusions: The predicted increase in survival from targeted provision of public access defibrillators is less than that achievable from expansion of first responder defibrillation or bystander cardiopulmonary resuscitation. Therefore, priority should be given to the latter. The additional resources required for very wide-scale coverage of public access defibrillators are probably not justified by the marginal improvement in predicted survival.

718 DEFI 77 PROJECT: out-of-hospital cardiac arrest in a French semi rural area. A prospective study

G. Pochmalicki[1], M. Genest[1], C. Franchi[2], J Y. Letarnec[3], C. Merle[4] on behalf of Comité de Pilotage de DEFI 77. [1]*Centre Hospitalier de Provins, Cardiologie, Provins, France;* [2]*SDIS 77, Melun, France;* [3]*SAMU 77, Melun, France;* [4]*DDASS, Melun, France*

Early defibrillation by the first attending caregivers is without any doubt the only care for a patient with ventricular fibrillation or pulseless ventricular tachycardia. In Seine et Marne area of France(1.19 million of inhabitants), the DEFI 77 PROJECT started in January 2001.Its purpose was to determine the location and incidence of cardiac arrest to plan the most efficient placement of Semi Automated External Defibrillator(SAED),and to implement a public training program.

The results of the first 13 months experience are shown: the number of SAED(n=18) given to the first aid non-medical team was multiplied by 7 in 2001 while more than 700 first-aid workers and firefighters were trained in the use of SAED.

During this period,the Mobile Intensive Care Units (MICU) and Firemen, covering a surface of 5915 km^2, treated 325 out-of-hospital cardiac arrest patients, 11% of which were in public locations.The majority of cases(88%)were due to presumed heart disease.Only 12.7% of bystanders initiated CPR.External defibrillators were used in 72 patients whose initial cardiac rhythm was VF/VT.The clinically relevant time intervals were a mean of 10 ± 6 minutes from call to arrival of the first-aid-team, 25 ± 20 minutes from collapse to the delivery of the first defibrillation shock...The mean age was 65 ± 16y;71% were male.

Among these patients, 73% received advanced cardiac life support by a physician deployed with MICU.11% were admitted alive to hospital, 2.8% had coronarography and 0.31% implantable cardioverter-defibrillator.Obviously,the survival rate (0.9% with good outcome)in this large area with a low density of population, but at less than 1 hour from Paris remains too much low particularly in comparison with those previously described in places like Seattle, planes, casinos...,assessing the current inability of community educational interventions to modify patients'survival.

So,the first part of DEFI 77 PROJECT suggest that a large gap remains between the goal of 20% survival's rate for all eligible patients presenting sudden cardiac death and present results. Therefore, this is justifying our efforts to strengthen the first steps of the chain of survival, in training of caregivers,and in a larger utilization of SAED.The results of the efforts will be evaluated in the second part of DEFI 77 Project.

719 Managing patients with life-threatening ventricular arrhythmias: the Leiden out of hospital cardiac arrest trial, LOHCAT

A.E. Borger van der Burg, L. van Erven, M. Bootsma, E.E. van der Wall, M.J. Schalij. *Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Background: As ventricular arrhythmias (VA) are a major cause for sudden cardiac death, a careful evaluation is mandatory. Treatment is first aimed at elimination of reversible causes. Therefore, a systematic approach is necessary.

Methods: This prospective study evaluates the results of the LOHCAT protocol. From 1994 until 2000, 600 pts with life-threatening VA were included in this screening protocol, and data of these 600 pts will be presented at the meeting. The screening protocol includes: echocardiography, nuclear imaging, coronary angiography and EP study. In case the existence of arrythmogenic right ventricular cardiomyopathy (ARVC) was suspected, MR imaging was performed.

Results: Data from 444 consecutive pts (350 male, 59±13yrs), who were evaluated according to this protocol in the period 1994-2001 are presented in this abstract. Majority of them survived Ventricular Fibrillation (VF, n=235), the other pts had a (near) collaps due to Ventricular Tachycardia (VT, n=209). After screening, the underlying cause of these arrhythmias appeared to be previous myocardial infarction (MI) (n=242), acute MI (n=25), Idiopathic (n=50), Dilated Cardiomyopathy (n=50), Ischemia (n=29), Hypertrofic Cardiomyopathy (n=14), ARVC (n=14), congenital (n=12) and other causes (n=9). As a result of the screening protocol, pts underwent RF ablation of VT (n=63), ICD implantation (n=312), CABG (n=50), PTCA (n=45), and/or anti-arrhythmic drugs (n=227). More VT ablations were performed in the near collaps pts ($p<0.01$) than in the other group. During follow-up (26±24 months), a recurrence of VT/VF occurred in 93 pts (11 pts (17%) after RF ablation and 82 pts (26%) with an ICD, 6.5±10 shocks/pt, range 1-55). Thirty eight pts died (heart failure: 24, malignancy: 4, sepsis: 3, EMD: 3, recurrent VA: 2 and other: 2). One of them had an ICD, but unfortunately, there is no information available about the function of the ICD.

Conclusion: From these preliminary data, we conclude that a restricted ICD implantation strategy is appropriate, as only 2 pts died due to recurrent VT.

UPDATE ON CELLULAR EFFECTS OF LIPOPROTEINS

755 Impaired intravascular catabolism of chylomicron-like emulsions is a marker of clinical outcome in patients with stable angina

A. Sposito[1], R. Santos[2], P. Lemos[1], W. Hueb[1], E. Quintella[1], M.J. Chapmann[3], J.A.F. Ramires[1], R.C. Maranhao[1]. [1]*Univ. of Sao Paulo Medical School, Incor Heart Institute, Sao Paulo, Brazil;* [2]*Heart Institute, University of Sao Paulo Medical School, Sao Paulo, Brazil;* [3]*Hôpital de la Pitié Salepetriere, INSERM Unité 551, Paris, France*

Background: Despite evidence from case-control studies suggesting that chylomicrons and their remnants might directly enhance progression of coronary artery disease (CAD), data from longitudinal studies is lacking in order to confirm this hypothesis.
Methods and Results: Over a period of 4.5 ± 0.9 years, we followed 63 angiographically confirmed CAD patients (mean age 60.0 ± 10.0 years) in whom kinetic studies of the in vivo catabolism of chylomicron-like emulsions were performed. At enrollment into the study, fasting patients were injected intravenously with a chylomicron-like emulsion labeled with radioactive triglyceride (3H-TG) and cholesteryl esters (14C-CE) in order to determine the fractional clearance rate (FCR) of chylomicron-like particles. CAD patients displayed diminished FCR for 3H-TG (-26%;p=0.027) and 14C-CE (-37%;p=0.015) as compared with 35 control subjects (60.0 ± 10.0 years) without angiographically detectable CAD. In a multivariate logistic regression analysis, we found that FCR-CE was the only independent predictor of the presence of angiographically defined CAD. During follow-up, 21 CAD patients (33%) identified as the aggravating group (ACAD) presented refractory angina and increase of coronary angiographic severity. The remaining 42 CAD patients displayed a stable clinical evolution and were classified as the stable group (SCAD). Intravascular lipolysis and remnant removal from plasma of chylomicron-like emulsions, as expressed by the FCR for 3H-TG and 14C-CE, were significantly lower in the ACAD group as compared with that in the SCAD group.
Conclusion: This prospective study establishes that delayed intravascular turnover of triglyceride-rich chylomicron-like emulsions constitutes a predictive marker of the presence and outcome of CAD.

756 A novel oxidation product of 1-acyl-phosphatidylcholine, 1-stearoyl-2-azelaoyl-sn-glycerophosphocholine (SAzPC) induces platelet activation

A. Sellmayer[1], M. Goepfert[2], F. Siedler[3], S. Koerner[3], W. Siess[2]. [1]*University Hospital, Department of Cardiology, Munich, Germany;* [2]*Prophylaxe der Kreislaufkrankheiten, Munich, Germany;* [3]*Max-Planck-Institute Biochemistry, Martinsried, Germany*

Platelet activation is a key step in acute coronary syndromes after plaque rupture leading to acute coronary thrombosis. Oxidized LDL contained in the plaque is thrombogenic. However, the platelet activating components of oxidized LDL are not yet fully identified. To further characterize platelet activating components of LDL, its major phospholipid species 1-acyl-phosphatidylcholine (PC) was studied.
One-stearoyl-2-arachidonoyl-PC was oxidized by CuCl2 and H2O2 and oxidation products were separated by high performance liquid chromatography and analyzed by electrospray mass spectrometry (ESI-MS). Platelet shape change was determined with an aggregometer and cytosolic free calcium was measured fluorometrically after loading of platelets with Fura-2.
Based on the molecular mass of m/z 694, the almost complete derivatization of the compound with pentafluorobenzyl bromide proving the existence of a free carboxy-terminal side chain and the typical fractionation pattern of the compound by ESI-MS/MS, revealed that one major oxidation product is 1-stearoyl-2-azelaoyl-PC (SazPC). SAzPC dose-dependently induced platelet shape change with a maximal concentration of 10 μM. Platelet shape change by SAzPC was not altered by inhibitors of the receptors for platelet-activating factor (PAF), lyso-phosphatidic acid or thromboxane A2. In contrast to PAF, SAzPC did not increase cytosolic free calcium concentrations in platelets.
These observations demonstrate that oxidation of 1-acyl-PC results in the formation of a highly bioactive compound, SAzPC, which activates human platelets. SAzPC may be involved in athero- and thrombogenic processes in vivo.

757 Cultured human coronary artery smooth muscle cells express the scavenger receptor glycoprotein IIIB (CD36)

M. Bachem, A. Schmid-Kotsas, A. Gruenert, C. Haug. *University of Ulm, Clinical Chemistry, Ulm, Germany*

In the development of atherosclerotic plaques coronary artery smooth muscle cells (CA-SMC) change their phenotype from a contractile to a matrix secreting cell. Here we studied the effects of modified lipids on extracellular matrix synthesis of cultured CA-SMCs.
Methods: Human CA-SMCs (Clonetics) were used between passages 3-6. LDLs were isolated by sequential ultracentrifugation. LDL was oxidized in the presence of 5μM CuSO4 at 37°C for 24 h. Immunofluorescence microscopy was performed using cryosections of human coronary artery (CD36, iso-alpha-SM-actin) and cultured CA-SMC (CD36, iso-alpha-SM-actin, collagen types I and III and fibronectin).
c-fibronectin and collagen type I were measured by time-resolved fluorescence-immunoassay.DNA was quantified by fluorometry. Conventional and "real-time" RT-PCR was performed to measure the mRNAs of CD36, collagen I and III and fibronectin.
Results: Cultured human CA-SMC express the scavenger receptor glycoprotein IIIb (CD36). Foam cell formation was induced after addition of enzymatically (neuraminidase, cholesterol-esterase and trypsin) degraded LDL (eLDL) and VLDL (eVLDL) to cultured SMC (demonstrated by oil-red-O-staining and gas-chromatography of fatty acids after hydolysis of intracellular lipids). The CD36 blocking antibody OKM5 reduced uptake of fatty acids and foam cell formation. Oxidized LDL (oxLDL, 1-50μg/ml), malondialdehyde modified LDL (MDA-LDL, 1-50μg/ml), eLDL (1-10μg/ml) and eVLDL (0.1-4μg/ml) added to cultured SMC (4th - 7th passage) dose dependently increased the steady state levels of fibronectin- and collagen-mRNAs (within 8-12 h) and stimulated within 24 - 36h protein concentration of fibronectin and collagen type I in cell culture supernatants. Preincibation of the cells with OKM5 reduced the stimulatory effect of the modified lipids. Immunofluorescence demonstrated, that also cell associated collagen types I and III and fibronectin increased after addition of oxLDL, MDA-LDL, eLDL, oxVLDL and eVLDL to cultured MS-SMC. Higher concentrations of oxLDL (>50μg/ml), eLDL (>10μg/ml), oxVLDL (10μg/ml) and eVLDL (>4μg/ml) were cytotoxic.
Our data demonstrate that cultured human CA-SMC express the scavenger receptor CD36 which internalizes fatty acids and monoglycerides derived from enzymatically degraded LDL and VLDL forming hereby foam cells. Furthermore, oxLDL, MDA-LDL, eLDL and eVLDL stimulate the synthesis of extracellular matrix after binding to CD36.

758 Atherogenic levels of LDL downregulate vascular lysil oxidase gene expression: effect on endothelial cell permeability

C. Rodriguez, B. Raposo, J. Martinez-Gonzalez, L. Casani, L. Badimon. *Cardiovascular Research Center, IIBB/CSIC-HSCSP-UAB, Barcelona, Spain*

Background: Increase in vascular permeability associated to hypercholesterolemia is one of the earlier events in the atherosclerotic process. By differential display/RT-PCR we have identified lysil oxidase (LO) as a gene regulated by LDL in both human and porcine endothelial cells. LO is an enzyme involved in elastin and collagen crosslinking.
Objective: To analyze the molecular mechanisms involved in vascular LO downregulation and to assess the pathophysiological consequences of this effect in vitro and in vivo.
Methods: Quiescent porcine aortic endothelial cells (PAEC) or vascular smooth muscle cells (SMC) were incubated with increasing concentrations of LDL for 24 h. Pigs (Yorkshire-Albino, 32 ±4 kg) were randomized into two groups: normolipemic animals (n=6) which were fed with a normal chow (LDL-cholesterol: 35±10 mg/dL) and hyperlipidemic animals (n=10) which were fed with a cholesterol-rich diet for up to 100 days (LDL-cholesterol: 314±86 mg/dL). At this time animals have early/ mild atherosclerotic lesions (type I-II, AHA classification) in the arterial wall. LO mRNA levels in cell cultures and in porcine vessels were analyzed by RT-PCR. Endothelial permeability was determined by the exchange of fluorescein isothiocyanate(FITC)-dextran (Mr 40,000) in a Transwell" system. Signalling involved in this effect was analyzed using specific inhibitors.
Results: LDL (15 mg/dL, 24 h) decreased LO mRNA levels (3-fold) in porcine SMC. Interestingly, a similar decrease in LO expression (3-fold) was observed in vivo, in the vascular wall of hypercholesterolemic pigs ($p<0.01$). Moreover a strong and inverse correlation between plasma LDL concentrations and LO mRNA levels was observed ($p<0.001$ $r2=0.50$) suggesting a cause-effect relationship. Both nLDL (140 mg/dL) and an inhibitor of LO activity (b-aminopropionitril, 100 mM) increase FITC-dextran transfer through a endothelial monolayer. Pertussis toxin (protein Gi inhibitor), PD-098059 (MEK inhibitor) or SB-203580 (p38 MAPK inhibitor) did not block the effect of LDL.
Conclusions: Hypercholesterolemia downregulating vascular LO expression could modify extracellular matrix composition and vascular permeability. These changes could favor cellular and protein infiltration in the vessel wall, processes that are associated to the initiation and progression of atherosclerosis.

759 Lipoproteins differentially regulate the nuclear receptor Nor-1 in vascular cells

J. Rius, J. Martinez-Gonzalez, J. Crespo-Asensio, L. Badimon. *Cardiovascular Research Center, IIBB/CSIC-HSCSP-UAB, Barcelona, Spain*

Background: Lipoproteins play a key role in endothelial dysfunction and atherosclerosis. Recently we have shown that LDL induce expression of Nor-1, a member of the neural growth factor family of orphan receptors (NGFI-B family), in smooth muscle cells (SMC). These transcription factors seem to be involved in cell proliferation, differentation and apoptosis.
Objectives: To analyze the ability of lipoproteins (LDL and HDL) to modulate Nor-1 expression in vascular cells.
Methods: Porcine aortic endothelial cells (PAEC) and SMC were treated with LDL or HDL (from 5 to 60 mg protein/dL) and Nor-1 expression was analyzed by RT-PCR. The ability of lipoproteins to modulate Nor-1 transcription was assess by transfection assay. PAEC were transfected with a construct of Nor-1 promoter linked to luciferase using a liposome-based method (Lipofectin ®). 48 hours after transfection cells were expossed to lipoproteins (60 mg/dL) for 4 hours. The involvement of cAMP Response Element Binding Protein (CREB) in Nor-1 activation was analyzed by Electroforetic Mobility Shift Assay (EMSA) with the Nor-1 promoter cAMP response element (CRE). CREB activation was assessed by Western blot.
Results: LDL but not HDL strongly induced early Nor-1 expression in PAEC. LDL strongly induced (60.6 ± 11.9 - fold over controls) luciferase Nor-1 promoter dependent activity, while HDL did not produce significant effect (7.5 ± 3.2). EMSA results showed CREB binds to the CRE sequence present in the Nor-1 promoter. This effect was associated to an early (10 min) phosphorylation of CREB. In contrast, both LDL and HDL up-regulated Nor-1 mRNA levels in SMC.
Conclusions: LDL but not HDL induced Nor-1 expression in endothelial cells. Transfection assays suggest a transcriptional regulation of Nor-1 by LDL. Nor-1 seems to be involved in the genetic programs triggered by LDL in endothelium.

760 Modified lipoproteins reduce hepatocyte growth factor synthesis in human coronary artery smooth muscle cells

C. Haug, A. Schmid-Kotsas, U. Zorn, A. Gruenert, M.G. Bachem. *Institute of Clinical Chemistry, University Hospital Ulm, Ulm, Germany*

Low density lipoproteins (LDL) are known to play a crucial pathophysiological role in the development and progression of atherosclerotic lesions. Hepatocyte growth factor (HGF) is a potent epithelial and endothelial cell regeneration factor which also seems to stimulate the activity of matrix metalloproteinases. This study aimed to investigate the influence of modified LDL and very low density lipoproteins (VLDL) on HGF synthesis in cultured human coronary artery smooth muscle cells (Clonetics, USA). LDL and VLDL were isolated by sequential ultracentrifugation, and LDL was oxidized by incubation with copper sulfate. LDL and VLDL were enzymatically degraded (eLDL, eVLDL; cholesterol esterase, trypsin, neuraminidase) and the increase in free fatty acid concentrations was quantified by gas chromatography. LDL and VLDL concentrations were referred to the protein content. HGF release into the cell culture supernatants was measured with a specific ELISA (R&D Systems, Germany) and HGF mRNA expression was evaluated by quantitative real-time RT-PCR using the LightCycler technology. Oxidized LDL (oxLDL 1-10 μg/ml), eLDL and eVLDL (0.1-2 μg/ml) as well as higher concentrations of native LDL (nLDL 10-100 μg/ml) induced a significant reduction of HGF release (minima: oxLDL 10 μg/ml 53.7±4.7%*** n=8, eLDL 58.3±0.9%* n=3, eVLDL 60.0±2.3%** n=6, nLDL 100 μg/ml 75.1±6.7%**, controls 100±5.1% n=10; means±SEM, *:p<.0.5, **:p<0.01, ***:p<0.001 versus control, 48 hours incubation). In parallel, a decrease of HGF mRNA expression was observed (oxLDL 1 μg/ml: 63.2±8.0%, nLDL 10 μg/ml: 70.3±6.4%, % of controls, n=11, 3-6 hours incubation). Furthermore, it was observed that nLDL was oxidatively modified by the cells during the incubation period and that higher oxLDL concentrations (20-100 μg/ml) exerted a cytotoxic effect, indicated by an increased LDH release and impaired cell viability. In summary, our data demonstrate that modified lipoproteins reduce HGF synthesis in cultured coronary artery smooth muscle cells. Presently, the role of HGF in atherosclerosis is unclear. HGF might have a protective effect by stimulating endothelial cell regeneration, on the other hand it also might promote atherogenesis and plaque instability by stimulating smooth muscle cell migration and by enhancing extracellular matrix degradation. The present findings suggest an interaction of lipoproteins and HGF in smooth muscle cells and might stimulate further studies to elucidate the role of HGF in coronary atherosclerosis.

ALTERED HEARTS HARBOUR ALTERED GENES

761 Disruption of dystrophin (D) and dystrophin-related proteins (DRP) is a trigger of advanced heart failure of both hereditary and acquired origins

T. Kawada[1], J. Nakata[2], M. Nakazawa[3], M. Koshimizu[2], C. Hemmi[2], S. Fukuda[4], S. Takeo[5], T. Toyo-oka[2]. *[1]Niigata University Medical Hospotal, Div. of Pharmacy, Niigata; [2]University of Tokyo, Dept. of Organ Pathophysiology, Tokyo; [3]Niigata University, Dept. of Basic Biomedical Inform., Niigata; [4]University of Tokyo, Dept. of Pathology, Tokyo; [5]Tokyo University of Pharmacy, 1st Dept. of Pharmacology, Tokyo, Japan*

Background: We have reported that TO-2 hamster with DCM show gene mutation of delta (d)-sarcoglycan (SG) in DRP (Sakamoto et al., P.N.A.S., 1997), similar to human cases (Tsubata et al., J.Clin.Invest., 2000). D together with DRP stabilizes sarcolemma (SL) during the repeated SL expansion in systole and may require more resistance than skeletal muscle. In vivo transduction of recombinant adeno-associated virus (rAAV) vector with normal d-SG gene to TO-2 hearts induced long-lasting and efficient expressions of both transgene and transcript in myocardium and hemodynamics (Kawada et al., B.B.R.C., 2001). Most importantly, survival period of the animals was prolonged (Kawada et al., P.N.A.S., 2002). Acute heart failure (HF) model in rat by high-dose administration of isoproterenol induced translocation of D from SL to myoplasm but not d-SG degradation (Xi et al., J.Cardiovasc.Pharmacol., 2000). Thus, these results provide the hypothesis that HF of both hereditary and acquired origins is commonly caused by disruption of DRP or D.
Objective: To evaluate the contribution of DRP to the SL integrity, we examined the fine structure and stability of SL in cardiomyocytes of the TO-2 with or without the gene therapy. Furthermore, we evaluated the contribution of an endogenous protease, calpain, to the disruption of DRP.
Methods and Results: Double-stain of d-SG and D revealed co-localization of both proteins in SL of normal hearts, whereas TO-2 demonstrated D selectively. After the co-transduction of normal d-SG gene plus reporter (R) gene for 10 or 20 weeks, immuno-EM revealed patchy re-expression of transgene of d-SG along SL. The d-SG expression accompanied more intense staining of D than the case transfected by R gene alone. At 3 hours before sacrificing the animals, Evans blue (EB) was i.v. administered to identify membrane-degraded cells. The sustained transduction of d-SG reduced the cell area stained by EB after the gene therapy, denoting the improved SL stability. Incubation of both SL fraction and purified m-calpain from swine myocardium induced the proteolysis of D, alpha-, beta- and gamma-SG, but not d-SG in vitro the presence of Ca^{2+}.
Conclusion: These results indicate that SL degeneration would primarily induce the disruption of D or DRP by the endogenous protease and the lack of SL integrity is involved in the process of HF irrespective of the hereditary or acquired origins. Somatic gene therapy with potent rAAV vector would provide a new strategy for the treatment of advanced HF.

762 Changes in gene and protein expression for globins caused by mechanical decompression of the left ventricle through assist devices

J. Mueller[1], G. Wallukat[1], P. Ellinghaus[2], Y. Weng[1], R. Pregla[1], R. Hetzer[3]. *[1]Deutsches Herzentrum Berlin, Cardiac Surgery Dept., Berlin, Germany; [2]Bayer AG, Wuppertal, Germany; [3]Berlin Heart AG, Berlin, Germany*

Reduced wall stress resulting from unloading of the left ventricle with a cardiac assist device in patients with heart failure leads to changes in gene and protein expression in the myocardium. However, comparison of myocardial specimens from 28 patients showed that the changes in gene expression differed to a great extent. No set of a fairly large number of gene expression changes could be detected for all the samples. This may be due to different loading conditions for the left ventricle, may be disease related, or may represent individual differences. Gene chip technology was applied (>6,000 genes) to look for differences in gene expression in the myocardium of six patients between the time of device placement and the time of transplantation. Protein expression was examined for substances with the most pronounced changes in gene expression. Gene expression for ANP and BNP showed a very pronounced reduction by a mean factor of 14.3 and 20.7, respectively, and many other genes showed changes of expression of mean factors below 9 (which were not rated for methodological reasons). Interestingly, gene expression for globin alpha, beta, and gamma was down-regulated by a mean factor of 9.5, 10.7, and 43.4, respectively. Similarly, protein proof in the specimens at the time of implantation was high and was significantly lower at the time of transplantation (reduction of the number of globin positive cells; mean factor of 8, 12, 34, respectively).
Application of chip technology resulted in the detection of a large number of changes of gene expression in the myocardial specimens between the time of device implantation and removal. However, only a small number of genes were up or down-regulated by factors above 9. The physiological significance of the existence of globins in the myocardium is not yet clear. Hypothetically, cells with globin may be differentiated from stem cells in the myocardium or the cells containing globin may be created due to a missing factor instead of myocytes.

763 Dysfunction of mitochondrial respiratory chain complex I in human failing myocardium is not based on disturbed mitochondrial gene expression

R.J. Scheubel[1], M. Tostlebe[2], S. Rohrbach[3], D. Darmer[2], F.N. Gellerich[4], R-E. Silber[1], J. Holtz[2]. [1]*Martin-Luther-University, Department of cardiothoracic surgery, Halle (Saale), Germany;* [2]*Martin-Luther-University, Institute of Pathophysiology, Halle (Saale), Germany;* [3]*Martin-Luther-University, Department of cardiology, Halle (Saale), Germany;* [4]*Martin-Luther-University, Department of Neurology, Halle (Saale), Germany*

Disturbance of mitochondrial gene expression by oxidative stress is discussed to be the reason for impaired mitochondrial function in ageing myocardium. The failing myocardium is assumed to be a form of premature myocardial ageing and disturbances of mitochondrial gene expression have been observed in experimental myocardial failure. For this reason we investigated in human left ventricular myocardium of explanted terminally failing hearts (31 DCM, 12 ICM) and in 12 donor hearts enzyme activity of respiratory chain complexes (C) with mitochondrial encoded subunits (C-I, C-III, C-IV) in comparison with the activity of the exclusively nuclear encoded C-II. In addition mRNA expression of mitochondrial encoded genes was compared with nuclear encoded mitochondrial components.

In 43 explanted ventricles, the citrate synthase related enzyme activity of C-I (11,47±0,81 a.U.) was smaller than in 12 donor hearts (15,92±1,51 a.U.; DCM~ICM; $p<0,001$), whereas that of C-II was identically (19,21±1,82 vs. 18,36±1,01 in donors). At the first glance this appears in agreement with the hypothesis of disturbed mitochondrial gene expression, which predicts that complexes with mitochondrially encoded subunits (C-I) are disturbed in contrast to complexes with only nuclearly encoded subunits. However, the mRNA expression values showed neither for the mitochondrial encoded genes(ND1, ND2, ND3, ND4, ND4L, ND5, ND6, cytochrome b, COX-I, COX-III, 16S rRNA; semiquantitative RT-PCR controlled by Northern blot)nor for the MnSOD (nuclear encoded) significant differences, whereas mRNA of TNF-alpha (0,21±0,02 vs. 0,15±0,01; $p< 0,05$) and of Pro-ANP (0,63±0,15 vs. 0,15±0,06; $p<0,005$)was significant higher in explanted failing ventricles. The enzyme activity of C-III und C-IV in explanted failing ventricles, the intact mitochondrial wildtype DNA (Southern blot) and the protein expression of the nuclear encoded mitochondrial transcription factor (mtTFA; Western blot) were unchanged compared to donor organs.

We conclude that the observed selective reduction of the C-I enzyme activity in the failing human myocardium is not a consequence of a disturbed mitochondrial gene expression, but probably the result of an altered assembling of the macro complex.

764 The EDG-receptors are functional in human fibroblasts and are regulated in human heart failure

A. Steege, J. Bass, L. Herda, A. Doller, R. Pregla, H.R. Zurbrügg, R. Hetzer, V. Regitz-Zagrosek. *Deutsches Herzzentrum Berlin, Berlin, Germany*

The phospholipids lysophosphatidic acid (LPA) and sphingosine 1-phosphate (S1P) affect cell proliferation, survival during hypoxia, cytoskeleton architecture and embryonic development in rodent hearts. Their effects are mediated by a family of G-protein coupled receptors encoded by endothelial differentiation genes (EDG). These receptors bind LPA (EDG-2,-4,-7) or S1P (EDG-1,-3,-5,-6,-8) and act via Gq, G12/13 and Gi. Their presence has been demonstrated in rodent hearts, but not yet in human hearts. We determined their presence in the human heart, regulation in human cardiac disease and functionality in human fibroblasts.

In the first set of experiments, the expression of EDG-1,-2,-3,-4,-5 and -7 mRNA was assessed in human myocardial samples and in HT1080 cells, a human fibroblast cell line, by PCR and sequencing. In the next step, the mRNA for EDG-1 and -2 was quantitated by real-time PCR (PE 5700) in left ventricular samples taken during aortic valve surgery from patients with aortic valve stenosis (AS, LV EF: 44 ± 6%) and from explanted hearts with ischemic (ICM, n=7) and dilated cardiomyopathy (DCM, n=27) and in 15 controls (unused donor hearts with normal systolic function) after informed consent and agreement of an ethical committee. EDG mRNA was related to the stably expressed GAPDH mRNA. To analyse the effects of LPA and S1P on human fibroblasts, HT1080 cells were stimulated for 6h with 100 nM LPA or S1P and the activity of matrix-metalloproteinases (MMPs) was analysed by gelatine-zymography.

EDG-1,-2,-3,-5 and -7 were found in human myocardium and EDG-1,-2,-4,-5 and -7 in HT1080 fibroblasts. EDG-1 was significantly upregulated in DCM (200% of control, $p<0.05$), in ICM (216%, $p<0.01$), and AS (175%, $p<0.002$). EDG-2 was unchanged in DCM (159%, ns) and increased in ICM (198%, $p<0.05$) and AS (247%, $p<0.05$). In HT1080 cells, EDGs contributed to the regulation of matrix-metalloproteinases proMMP2, MMP2 and MMP9. Stimulation with S1P upregulated the activity of proMMP2, MMP2 and MMP9. Stimulation with LPA led to downregulation of the activity of these MMPs.

These results suggest that the EDG-receptors, particularly EDG-1 and -2, are present in the human heart and are regulated in human heart disease and may contribute to the control of extracellular matrix turnover in human fibroblasts.

765 Beta-sarcoglycan gene mutations cause plasma membrane dysruption in striated and smooth muscle, leading to severe dilated cardiomyopathy

P. Melacini[1], M. Fanin[2], C. Boito[2], E. Pegoraro[2], C. Angelini[2], S. Iliceto[1]. [1]*Policlinico, Cardiology, Padua, Italy;* [2]*University of Padova, Department of Neurology, Padova, Italy*

Background: The sarcoglycan (SG) complex (alfa-, beta-, gamma-, and delta-SG) is a component of the structural proteins localized to the plasma membrane of striated muscle, where it confers mechanical stability during muscle contraction. SG gene mutations cause limb-girdle muscular dystrophies (LGMD), but only rarely the myopathy is associated with overt cardiac involvement.

Material and Methods: We studied 4 patients (aged from 9 to 37 years, 2 males, t2 females) with beta-SG gene mutations and muscular dystrophy, to verify the presence of cardiomyopathy. The diagnosis was performed by skeletal muscle biopsy, SG proteins (immunohistochemistry, western blot) and genes analysis (SSCP, DNA sequence), ECG, 2D and Doppler echo-cardiography.

Results: All patients suffered from severe muscular dystrophy. Beta-SG gene mutations were small frameshift deletions, insertions or duplications (5/8 mutant alleles), missense mutations (2/8 alleles), and one nonsense mutation. Mutations in the beta-sarcoglycan gene caused the loss of the entire SG complex in the skeletal muscle with a consequent plasmalemmal damage and fiber necrosis. 2 patients (50%) showed cardiac involvement. Left ventricular (LV) diffuse hypokinesia (EF=38%) was present in one patient and biventricular severe dilatation and reduction of ejection fraction (LVEDV=118 ml/m^2, LVEF=32%) in the second patient, who died from cardiac failure at age 14 years.

Sex,age	LVEDV (ml/m^2)	LVEF (%)	Clinical phenotype	Gene mutations
M, 14 *	118	32	severe LGMD, DCMP, HF	4bp del.,8bp ins.
F, 9	66	53	severe LGMD	8bp ins., nonsense
F, 20	58	55	severe LGMD	missense homoz.
M, 37	67	38	LGMD, LV hypokinesia	32bp dupl.homoz.

Discussion: Since the SGs are expressed in striated muscle, SG gene mutations are expected to affect both the skeletal and cardiac muscle, due to the loss of structural and functional plasma membrane integrity. We demostrated that mutations in the beta-SG gene are a common cause of dilated cardiomyopathy. Unlike other SGs, beta-SG is additionally expressed in smooth muscle of the coronary vessels, thus a perturbation of vascular function would represent an additional mechanism. In the future, study of the coronary reserve may shed light on the pathogenesis of cardiomyopathy; in addition, pharmacological treatment with vasodilators merits further investigations as a potential therapeutic option.

766 Significant structural alterations in the mitochondrial D-loop control region may occur in cardiomyopathy

J. Marin-Garcia[1], M.J. Goldenthal[1], G.W. Moe[2]. [1]*The Molecular Cardiology Institute, Highland Park, NJ, United States of America;* [2]*University of Toronto, St.Michael Hospital, Toronto, Canada*

Damage in mitochondrial DNA (mtDNA) coding genes and reduced bioenergetic generation has been previously reported in human cardiac tissues with aging and in selected cardiac disorders. An age-dependent accumulation of point mutations in the non-coding control region of human mitochondrial D-loop has been recently found in cultured fibroblasts and skeletal muscle cells; whether these changes occur in cardiac tissue is unclear. Accordingly, we undertook the current study to examine mtDNA D-loop region in a series of patients with cardiomyopathy (CM) and normal controls. Also, the effect of age was evaluated.

Methods: We analyzed cardiac mtDNA for the incidence and distribution of point mutations in the D-loop control region involved in mtDNA replication and transcription (from 110-570 nt) in 47 patients with CM and 40 subjects with no history of cardiac disease. Frequency and distribution of mutations in relation to age, and cardiac disease were assessed, and compared to changes in a cytb fragment of roughly the same size in controls and patients.

Results: A total of 118 homoplasmic point mutations were found at 30 positions in patients with CM compared with 111 mutations at 34 positions in controls. However, mutations in important regulatory sites within the D-loop control region (including mtTFA sites and the conserved sequence blocks) were present in 8 patients (17%) and not found in controls. Patients with a combination of two of these alleles (n=3) have a more marked phenotype of mitochondrial dysfunction including both reduction in multiple respiratory enzyme activities and marked reductions in the level of cardiac mtDNA. No significant accumulation of point mutations in the D-loop control region or in cytb was found as a function of age.

Conclusion: Specific mutations at critical sites in the D-loop were found in CM and they were associated with significant respiratory enzyme defects. The combination of mutations and defective bioenergetics may play a pathogenetic role in a subset of patients. Contrary to findings in cultured fibroblasts and skeletal muscle cells age does not appear to be a factor in the accumulation of cardiac mtDNA D-loop mutations

REPERFUSION INJURY DURING CARDIAC SURGERY

771 Reperfusion after open heart surgery is the most damaging factor for myocardial tissue

E. Stefanovic. *Dedinje cardiovascular Institute, Department of pathology, Belgrade, Yugoslavia*

Aim: To assess ultrastructural changes of myocardial capillaries and cardiomyocytes due to ischemia and reperfusion during open heart surgery.
Methods: We evaluated 61 consecutive patients (pts) who underwent open heart surgery. 215 byoptical samples were taken from right ventricle anterior wall, and from the apical region. They were taken during ischemic pctiod (5,10, 20, 30 min starting cardioplegia (CPL), and at the end of CPL) and during reperfusion period (5-30 mm after beginning of this period). All samples were analyzed by electron microscope using quantitative stereological analysis. Volume fraction of the pinocite vesicles (PV), mitochondria (M), and endoplasmatic reticulum (EPR) were calculated. All pts were devided into 2 groups based on duration of CPL - ischemia; group 1 (CPL <65 min., 19 pts), and group 2 (CPL>65 mm, 42 pts).
Results: Damages of the endothelial cells and cardiomyocytes in all samples occurred 5 minutes after introduction of CPL and progressively increased during ischemic phase. The worse damage was found after 65 mm. of CPL usage: capillaries obstruction due to microclasmatosis, edema of the endothelial cells, widening of the cell junctions, degenerative changes of the cardiomyocytes. Stereological analysis confirmed that the larger damages were found during reperfusion in group 2 (table).

	Group I			Group II		
Variable	ischemia	reperfusion	p	ischemia	reperfusion	p
PV(Vv)	0.052	0.043	<0.05	0.033	0.028	<0.01
MV(Vm)	0.024	0.025	NS	0.022	0.017	<0.01
EPR(Vr)	0.026	0.026	NS	0.025	0.023	<0.01

Conclusion: Cells of myocardium are very sensitive to hypothermia, hypoxia and reperfusion during open heart surgery. Ultrastructural changes of endothelium and cardiomyocytes depend on the length of CPL usage time, and are particularly induced by reperfusion.

772 Insufficient protection of the conduction system during cardioplegic arrest – Necrosis but not apoptosis

F. Sayk[1], R.G. Leyh[1], J.F.M Bechtel[1], S. Krueger[2], A.C. Feller[2], H.H. Sievers[1], C. Bartels[1]. *[1]University of Luebeck, Cardiac Surgery, Luebeck, Germany; [2]Institute of Pathology, University of Luebeck, Luebeck, Germany*

Background: Conduction system disturbances after cardioplegic arrest remain an unsolved problem. We investigated whether ischemia/reperfusion injury due to cardioplegic arrest contributes to myocardial conduction cell (MCC) necrosis or apoptosis and whether MCC react differently from working myocardial cells (WM).
Methods: Under cardiopulmonary bypass conditions minipigs were subjected to 60 min. of crystalloid cold antegrade intermittent cardioplegic arrest followed by 180 min. of reperfusion (n=20). Hearts not subjected to any procedure served as controls (n=5). Subendocardial MCC and adjacent WM from the LV free wall and the RV septomarginal band were investigated histologically. HE and immunohistochemical staining for apoptosis-associated proteins (bax, bcl-2, CPP-32) was performed. DNA-breaks were visualized by TdT-mediated dUTP-biotin nick end labeling (TUNEL). Electron microscopy was performed in order to differentiate between apoptosis and necrosis.
Results: MCC of control animals constitutionally expressed bax, bcl-2, and CPP-32. After cardioplegic arrest with reperfusion, marked reduction of apoptosis-associated protein labeling was focally found in subendocardial MCC (15/20 hearts; Fig.1). In 6.3%±6.4 of subendocardial MCC, karyopycnosis and increased eosinophilia (HE) were observed. Positive TUNEL-staining was found in 2,8%±2,5 of subendocardial MCC. The average TUNEL-rate of the adjacent WM was < 0,1%. Electron microscopy demonstrated ischemic changes in MCC consistent with cellular necrosis.

Fig. 1: Bax - immunohistochemistry.

Conclusion: Ischemia and reperfusion injury due to cardioplegic arrest leads to significant subendocardial MCC damage, far exceeding damage of the WM. Ultrastructural and light-microscopic findings are consistent with coagulation necrosis, rather than apoptosis.

773 Inhibition of IkBa phosphorylation with BAY 11-7085 attenuates myocardial reperfusion injury in rabbits

M. Buerke, S. Rosellen, U. Buerke, J. Meyer, H. Darius. *Johannes Gutenberg University, II. Department of Medicine, Mainz, Germany*

Myocardial reperfusion injury has been attributed to neutrophil released mediators like oxygen derived free radicals, cytokine syntheis, loss of endogenous nitric oxide and increased neutrophil accumulation. Subsequent cellular activation with translocation of NFkB, transcription initiation, and synthesis of inflammatory molecules like TNFa, IL-6 and ICAM-1 will occur.
We studied the effect of BAY 11-7085, known to inhibit phosphorylation of IkBa following TNFa stimulation, in vivo in a rabbit myocardial reperfusion injury model (60 minutes ischemia followed by 3 hours reperfusion). BAY 11-7085 (0,2mg/kg) or its vehicle were injected 5 minutes prior to reperfusion. Myocardial injury following BAY 11-7085 treatment was significantly reduced compared to vehicle treated animals (16%±2.1% vs 32.6%±1.8% necrosis related to ischemic myocardium, $p<0.05$). Plasma creatine kinase (CK) activity, another marker for myocardial injury increased from 4.5±0.4 IU/g protein at baseline to 55.3±3.3 IU/g protein following 3 hours of reperfusion in the vehicle group. Administration of BAY 11-7085 significantly decreased plasma CK release throughout the reperfusion period (31.8±1.5 IU/g protein, $p<0.05$). In the necrotic zone myeloperoxidase (MPO) activity, a marker for polymorphonuclear leukocyte (PMN) accumulation, was significantly decreased in BAY 11-7085 treated animals compared to the vehicle group ($p<0.01$). Histologic analysis of ischemic reperfused myocardium of vehicle treated animals showed 56±6 PMN/mm^2. BAY 11-7085 treatment resulted in a significant reduction of neutrophil accumulation in the reperfused myocardium (28±5 PMN/mm^2, $p<0.01$). In vitro adhesion assays demonstrated reduced PMN adherence to ischmic reperfused arteries following BAY 11-7085 treatment. Similar, BAY 11-7085 significantly reduced PMN adherence to TNF-a activated vascular endothelium. Further, BAY 11-7085 inhibited NFkB translocation in vascular endothelial cells following TNF-a stimulation
Thus, blocking of phosphorylation of IkBa with BAY 11-7085 appears to be an effective mean to preserve ischemic myocardium from injury following reperfusion. The cardioprotective effect appears to be at least in part due to reduced PMN adhesion and infiltration with subsequent diminished myocardial necrosis.

774 Poly-ADP-ribose polymerase (PARP)-inhibition protects against myocardial and endothelial reperfusion injury after hypothermic cardiac arrest

G. Szabo[1], T.B. Andrasi[2], N. Stumpf[1], V. Buhmann[1], C.F. Vahl[1], C. Szabo[3]. *[1]University of Heidelberg, Department of Cardiac Surgery, Heidelberg, Germany; [2]Semmelweiss University Medical School, Experimental Cardiovascular Surgery, Budapest, Hungary; [3]Inotek Corporation, Beverly, United States of America*

Free radical production and related cytotoxicity during ischemia/reperfusion may lead to DNA strand-breakage which activates the nuclear enzyme poly-ADP-ribose synthetase (PARP) and initiates an energy consuming, inefficient repair cycle, with transfer of the ADP-ribosyl moiety of NAD+ to protein acceptors. We investigated the effects of PARP inhibition on myocardial and endothelial function during reperfusion in an experimental model of cardiopulmonary bypass
Twelve anesthetized dogs, underwent hypothermic cardiopulmonary bypass. After 60 minutes of hypothermic cardiac arrest, reperfusion was started after application of either saline vehicle (control, n=6), or PJ34 (10 mg/kg) a selective PARP-inhibitor (n=6). Left ventricular hemodynamic variables were measured by a combined pressure-volume-conductance catheter and the slope of the end-systolic pressure volume relationship (Ees) was calculated at baseline and after 60 minutes of reperfusion. Left anterior descendent coronary blood flow (CBF), endothelium-dependent vasodilatation to acetylcholine (ACH) and endothelium-independent vasodilatation to sodium nitroprusside (SNP) were also determined.
The admimistration of PJ34 led to a significantly better recovery (given as percent of baseline) of left ventricular systolic function (dP/dt: 61±7% vs. 38±10%, $p<0.05$ and Ees 67±6% vs. 46±6%, $p<0.05$). CBF was also significantly higher in PJ34 group (32±4 vs. 21±3, ml/min, $p<0.05$). While the vasodilatatory response to SNP was similar in both groups, ACH resulted in a significantly higher increase in CBF in the PJ34 group (59±10% vs. 28±15%, $p<0.05$).
PARP inhibition improves the recovery of myocardial and endothelial function after cardiopulmonary bypass with hypothermic cardiac arrest.

775 Immunomodulator rapamycin attenuates myocardial reperfusion injury in rabbits

M. Buerke, N. Burkhardt, T. Längin, U. Buerke, J. Meyer, H. Darius. *Johannes Gutenberg University, II. Department of Medicine, Mainz, Germany*

Myocardial reperfusion injury has been attributed to increased neutrophi accumulation with inflammatory injury. Cellualr adhesion and cytokines exert protein synthesis in the ischemic reperfused heart. The precise role of rapamycin in ischemia reperfusion is unknown.

We studied the effect of the immuno-suppressor/-modulator Rapamycin (Rapa) in vivo in a rabbit myocardial reperfusion injury model (60 minutes ischemia followed by 3 hours reperfusion). Rapa (1μg/kg) or its vehicle were injected 5 minutes prior to reperfusion. Myocardial injury following Rapa treatment was significantly reduced compared to vehicle treated animals (15%±3% vs 32%±2% necrosis related to ischemic myocardium, $p<0.05$). Plasma creatine kinase (CK) activity, another marker for myocardial injury increased from 2 ±0.2 IU/g protein at baseline to 36±3.3 IU/g protein following 3 hours of reperfusion in the vehicle group. Administration of Rapa significantly decreased plasma CK release throughout the reperfusion period (15±2 IU/g protein, $p<0.05$). In the necrotic zone myeloperoxidase (MPO) activity, a marker for polymorphonuclear leukocyte (PMN) accumulation, was significantly decreased in Rapa treated animals compared to the vehicle group ($p<0.01$). Histologic analysis of ischemic reperfused myocardium of vehicle treated animals showed 75±8 PMN/mm^2. Rapa treatment resulted in a significant reduction of neutrophil accumulation in the reperfused myocardium (33±5 PMN/mm^2, $p<0.01$). With proteome analysis we were able to demonstrate differences in protein expression following Rapa treatment (i.e. preserved expression of superoxide dismutase and heat shock protein).

Thus, blocking of translation with rapamycin appears to be an effective mean to preserve ischemic myocardium from injury following reperfusion. The cardioprotective effect appears to be at least in part due to preserved protein expression with subsequent reduction of PMN accumulation and myocardial necrosis.

776 Deferoxamine cardioplegia improves mitochondrial morphology in human myocardium

G.E. Drossos[1], A. Albanou[2], P. Kontogiorgi[1], O. Ananiadou[1], D. Katritsis[3], C.E. Anagnostopoulos[1]. [1]*University of Ioannina, Medical School, Ioannina, Greece;* [2]*University of Thessaloniki, Thessaloniki, Greece;* [3]*Athens EUROCLINIC, Cardiology, Athens, Greece*

Enhanced myocardial protection during ischemia using the oxygen free radical deferoxamine has been demonstrated experimentally and clinically. Mitochondria have marked functional and morphologic abnormalities and are very sensitive to ischemic damage. This study aimed at determining whether deferoxamine has a protective effect by preserving the morphology of mitochondria in human myocardium after ischemia-reperfusion.

Methods: Patients (pts) who underwent elective first-time operation of the aortic, mitral, or both valves were included in the study. They were randomly allocated to either St. Thomas? cardioplegic solution (group A) or cardioplegic solution supplemented with deferoxamine (group B).

Myocardial biopsy specimens were obtained from the sub-endocardial layer and were immersed immediately in gloutaraldeyde solution. After special processing, mitochondrial morphology was determined by electron microscopy x62,500. The severity of mitochondrial damage was graded as follows: 0=normal mitochondria, 1=swelling without architectural disruption and 2=architectural disruption. 154 mitochondria from group A (7 pts) and 281 from group B (7 pts) were included in the study. Student's t-test was used to analyze the data.

Results: There was a continuing improvement of mitochondrial morphology in all grades as presented in the table.

Severity of mitochondrial damage

	Group A	Group B	p
Grade O	15 (9.8%)	255 (90.8%)	<0.0001
Grade 1	106 (68.8%)	26 (9.2%)	<0.0001
Grade 2	33 (21.4%)	0	<0.0001
Total	154	281	

Conclusion: Deferoxamine appears to have a moderating effect on mitochondrial morphology in ischemia-reperfusion injury.

CAROTID STENTING

777 Routine use of cerebral protection during carotid artery stent implantation: procedural results of a multicenter registry of 692 procedures

B. Reimers[1], F. Castriota[2], T. Tuebler[3], N. Corvaja[4], C. Cernetti[5], A. Cremonesi[2], J. Schofer[3], A. Colombo[4]. [1]*Cardiovascular Department, Mirano, Italy;* [2]*Villa Maria Cecilia, Cotignola, Italy;* [3]*Center for Cardiology, Hamburg, Germany;* [4]*Centro Cuore and S. Raffaele Hospital, Milano, Italy;* [5]*Cardiovascular Department, Mirano, Italy*

Background: Cerebral protection devices are used during percutaneous carotid artery stenting to reduce distal embolization of debris, which may result in neurological deficit.

Methods and Results: 692 consecutive procedures (645 patients) of elective carotid stent implantation using cerebral protection performed in 5 different centers were included in a prospective registry.

Cerebral protection was attempted using filter devices (73.8% of procedures), occlusive distal balloons (23.6%), and endoluminal clamping of the common and external carotid artery (2.5%).

All lesions presented a >70% diameter stenoses (mean 80±9%). Mean age of the patients was 70±12 years, 83.2% were males, and 51.0% of patients had a previous, hemisphere related, stroke or transient ischemic attack. In 653 procedures (96.4%) it was possible to position a protection device. In 13 of 164 procedures with distal balloon protection, this was not tolerated by the patient (6.3%). In 683 procedures (98.7%) a stent was successfully placed. Neurological complications during the procedure, in-hospital and during 30 days of follow-up occurred after 36 procedures (5.2%). These were 5 major strokes (0.7%), 14 minor strokes (2.0%), 12 transient ischemic attacks (1.7%), 1 embolization of the retinal artery (0.1%), and 5 intracerebral haemorrhages (0.7%) of which 4 were without clinical sequels and 1 leading to myocardial infarction and death. Protection device related complications, all without neurological symptoms, occurred in 8 procedures (1.1%). These were 7 distal dissections of which 3 were covered with additional stents, 1 leading to occlusion of the internal carotid artery, and 1 filter entrapment requiring surgical removal. Major adverse cardiac events (MACE) during the 30 days of follow-up occurred in 3 patients (0.4%) and were 2 fatal and 1 non-fatal myocardial infarctions. Combined minor/major stroke rate was 2.7%, combined stroke/death rate was 2.9%, and combined stroke/MACE/death rate was 3.0%.

Conclusions: Routine cerebral protection during carotid artery stenting appears feasible and safe. In the present registry the incidence of stroke was low.

778 Emergency stenting for stroke after carotid endo arterectomy

F. Liistro[1], A. Chieffo[1], G. Stankovic[2], C. Di Mario[2], M. Montorfano[2], C. Briguori[1], R. Chiesa[1], A. Colombo[2]. [1]*San Raffaele, emodinamica, milan, Italy;* [2]*Columbus Hospital, Emo Centro Cuore, Milan, Italy*

Background: Carotid endoarterectomy (CEA) has been established as the standard treatment for carotid occlusive disease and has been shown to be beneficial in patients with high-grade carotid stenosis. Nevertheless this approach is not free of complications. Among these, perioperative stroke and death have been reported in 2.5-7.5% but the incidence can be as high as 18% in the high risk-patients. The management of perioperative neurological deficits complicating CEA is still controversial. We report immediate and long term result of emergency carotid stenting for stroke complicating CEA.

Methods and Results: From April 1998 to July 2001, 25 patients underwent emergency carotid angioplasty and stenting for perioperative stroke. Among all procedures, 21 were performed in the hemodynamic laboratory and the remaining 4 in the operating theatre. Carotid angiography was performed immediately (within 15 ± 5 min) after the appearance of neurological symptoms. Thrombosis at the CEA site was found in18 (72%) lesions and vessel dissection in the remaining 7 lesions (28%). Adjunctive carotid artery angioplasty with direct stent implantation was performed in all patients (within 35 ± 12 min) with a technical success rate of 100%. 3 (12%) deaths occurred in hospital, all related to neurological events (within 15 days). At a mean follow-up of 14 ± 9 months (rang 1 to 28) 1 (4%) death occurred after 3 months, not related to cerebral event. One patient (4%) had incomplete recovery. Complete neurological status recovery was observed in 21 patients (84%).

Conclusions: Emergency percutaneous transluminal angioplasty carotid stenting (PTACS) is feasible, safe and effective in the treatment of perioperative stroke after CEA leading to a complete neurological recovery in the majority of the patients.

779 Predictors of adverse events and impact of the learning curve in the carotid angioplasty and stenting free of emboli (CAFE) USA trial

G. Dangas[1], R. Mehran[1], S. Iyer[1], L. Satler[2], P. Whitlow[1], T. Ohki[1], M.B. Leon[1], G. Roubin[1]. [1]*Lenox Hill Hospital, Interventional Cardiology, New York, NY, United States of America;* [2]*Washington Hospital Center, Cardiology Dept., Washington DC, United States of America*

Background: Distal protection devices reduce the occurrence of periprocedural events in pts undergoing carotid artery stenting (CAS). The determinants of adverse neurologic events during CAS with "neuroprotection", and the impact of the learning curve are unknown.
Methods: CAFE-USA was a multicenter prospective registry that evaluated the utility of the PercuSurge GuardWire (GW) balloon occlusion and aspiration system in 212 consecutive pts undergoing CAS. To evaluate learning curve issues, outcomes in the first 106 pts (Group I) were compared to the last 106 pts (Group II). The CREST trial definitions were used for all events.
Results: Mean age was 72 ± 8 years; 66.5% were male. Most high-risk baseline features were equally prevalent in the 2 groups, though bilateral disease (63.2% vs. 48.1%, p=0.02) and history of CEA (20.8% vs. 8.5%, p=0.01) were more common in group I.

Procedural results

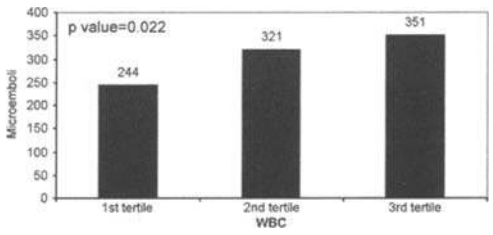
	Group I	Group II	P-value
Successful GW placement	93.4%	95.3%	0.55
Duration of balloon occlusion (min)	12.9 + 6.0	10.7 + 3.2	0.001
Total procedure time (min)	78 + 47	65 + 30	0.01
Contrast used (ml)	180 + 79	152 + 74	0.008
Hypotension post-CAS	27%	14%	0.02
Embolic stroke	1.9%	0.9%	1.0
Cummulative 30 day events:			
Neuro-death	2.7%	1.4%	1.0
Non-disabling stroke	4.9%	3.1%	0.72
Any neurologic event	7.6%	4.5%	0.44

By logistic regression analysis, GP IIb/IIIa inhibitor use (OR=8.17, p=0.02), prior stroke (OR=4.7, p=0.02), and prior MI (OR=4.52, p=0.02), were independent predictors of 30-day adverse events.
Conclusions: During CAS with neuroprotection, embolic stroke is extremely rare and appears to decrease overtime with experience. Patient selection baseline characteristics, and adjunct pharmacotherapy (NOT embolic events) drive the event rate in the CAS with neuroprotection.

780 White blood cell count predicts microembolic Doppler signals during carotid stenting: a link between inflammation and embolization

H.D. Aronow[1], M.H. Shishehbor[1], P.L. Whitlow[1], D.L. Bhatt[1], E.J. Topol[1], C.T. Bajzer[1], D.A. Davis[2], J.S. Yadav[1]. [1]*Cleveland Clinic Foundation, Dept. of Cardiovascular Medicine, F25, Cleveland, United States of America;* [2]*Cleveland Clinic Foundation, Dept. of Radiology, Cleveland, United States of America*

Background: A number of inflammatory markers, including white blood cell (WBC) count, predict clinical outcome in patients with atherosclerotic vascular disease. It has been hypothesized that the degree of systemic inflammation is related to the propensity toward atheroembolization, however this theory remains unproved.
Methods: We examined 46 consecutive patients who underwent a transcranial Doppler (TCD) examination of the ipsilateral middle cerebral artery during elective carotid stenting at our institution between 4/98 and 6/01. TCD offers real-time in vivo measurement of cerebral embolization. High intensity transient signals (HITS) recorded on TCD during wire manipulation, balloon pre-dilation and stenting were summed for each patient (1 second shower counted as 10 microemboli). Stepwise multiple linear regression was used to identify independent predictors of microembolization.
Results: In the overall cohort (median age 72, 74% male, 87% CAD, 24% diabetes, emboli protection device use 15%) median pre-procedure WBC count was 7.2 (interquartile range [IQR] 6.2-8.6) and median total HITS was 305 (IQR 217-402). Microembolization increased significantly in each successive WBC tertile [Figure]. After adjusting for age, gender, comorbidities, concomitant medical therapies and the use of emboli protection devices, increasing WBC count remained a significant and independent positive predictor of embolization (beta 38.4, standard error 14.6, p=0.012).
Conclusion: These data provide further support for an association between the degree of systemic inflammation and subsequent atheroembolization during percutaneous intervention. Other markers of inflammation should be evaluated in this setting.



781 Carotid angioplasty using coronary angioplasty equipment: acute results and long-term follow-up

K. Rabe[1], R.P. Rolf Perron[1], W.P. W Pfeil[1], C.R. C Rubel[1], R.T. R Theis[2], K.B. K-F Beykirch[2], H.S. H Sievert[1]. [1]*Cardioangiologisches Centrum Bethanien, Frankfurt/Main;* [2]*Bethanien, Neurology, Frankfurt/Main, Germany*

Introduction: Since February 1994, we treated 226 high-grade lesions of the internal carotid artery in 205 patients using coronary angioplasty equipment. In 146 lesions one of the following embolic protection devices was used: Percusurge in 46, Angioguard filter in 23, Arteria in 34, EPI filter in 19, TRAP in 14, Mednova in 7, MO.MA in 3. 62 Carotid Wall stents, 83 self-expending Nitinol stents and 98 balloon expandable stents where implanted. Follow-up investigations included a neurological examination and duplex ultrasound after 6 and 12 months, thereafter annually.
Results: The patients age ranged from 40- 88 years with an average of 70 ± 9 years. 122 lesions were asymptomatic, 104 symptomatic. 117 patients had a contralateral stenosis or occlusion and 47 patients additional vertebral or intracranial lesions. 67% of the patients suffered from coronary heart disease,65% from hypertension, 30,5% from diabetes mellitus, 43% from hyperlipidemia and 52% were previous or current smokers.
The procedure was technically successful in 224/226 lesions. 10 patients had one of the following acute or subacute (<30 days) complications: Cerebrovascular death in 0, non-fatal major stroke in 3, minor stroke in 1, central retinal artery occlusion in 1, asymptomatic occlusion in 1, non-cerebrovascular death in 4 patients. Follow-up investigations were performed after 6 and 12 months, thereafter annually up to 100 months, in average 17 ± 20 months after the procedure 128/205 patients (=128/226 lesions) had a 6 months follow-up. During follow-up (311 patient years) 4 major, 2 minor strokes and 16 asymptomatic re-stenoses occurred. 17 patients died from non-cerebral causes.
Conclusion: Carotid angioplasty and stenting using coronary angioplasty equipment and embolic protection devices leads to results which are at least comparable to the results of endarterectomy. Re-stenoses and late complications are rare.

782 Carotid stenting in high risk patients – a single center experience

M. Halabi[1], E. Nikolsky[2], A. Hoffman[3], A. Roguin[2], M. Suleiman[2], L. Gruberg[2], E. Kouperberg[4], R. Beyar[2]. [1]*Rambam, Cardiology, Haifa, Israel;* [2]*Rambam medical center, Cardiology, Haifa, Israel;* [3]*Rambam medical center, Vascular surgery, Haifa, Israel;* [4]*Rambam medical center, Neurology, Haifa, Israel*

Background: Carotid artery stenting (CAS) is emerging as a new alternative treatment for carotid artery stenosis.
Aim: To review our initial experience with this technique, using self-expanding stents in selected high risk and post carotid endatherectomy (CEA) restenosis patients.
Methods: 51 procedures in 47 patients were performed between April 1998 and November 2001. Our technique included the use of long femoral sheaths for carotid access and stent deployment. All patients underwent Duplex study before the procedure. Criteria for treatment was presence of stenosis >70% by angiography. Clinical follow-up was performed at 1, 3, and 6 and 12 months from the procedure and carotid duplex scan was performed at 3 months and one year. Endpoints were death, CVA, and target vessel revascularization during hospitalization and at follow-up period. Distal protection devices were used in 8 procedures. Transcranial Doppler was measured during the procedures in 23 patients.
Results: Mean age was 70 years (range 56 to 81) with 66% males. The indication for CAS was restenosis after CEA in 35 procedures, distorted neck anatomy in 6, and severe IHD in 13. The procedure was successful in 48 cases, while in 3 procedures the wire could not cross the lesion. In hospital complications included one death due to intracranial hemorrhage, and 2 TIA's. At 1-month follow-up (n=42) there were no additional events. At 1 year (n=20) 1 patient had a minor stroke and six patients had asymptomatic restenosis by Duplex. One patient underwent angiography and balloon angioplasty due to restenosis of 90%. Another patient who was asymptomatic had stenosis of 100% that we decided not to treat. And the other four patients the stenosis was 50-70%, all asymptomatic and we decided on conservative treatment and follow-up. TCD results show multiple microemboli during the procedure with peak at balloon deflations. However they were clinically silent.
Conclusions: Our initial experience shows that CAS is a safe method in high surgical risk and post CEA patients. The potential of distal protection devices for increasing the safety of the procedure will be answered by future studies.

IMAGING THE CORONARY ARTERY: ARE THE NEW TECHNIQUES COMPETITORS OR ADJUNCTS TO ANGIOGRAPHY?

783 Noninvasive measurement of diameter of the distal left anterior descending artery by thoracic echocardiography with a 10MHz transducer

S. Nakao, M. Ohyanagi, A. Goda, Y. Tsuzaki, M. Yuba, Y. Yoshida, S. Kobayashi, T. Iwasaki. *Hyogo college of medicine, Caridology, Nishinomiya, Japan*

Background: Transthoracic Doppler echocardiography provides information about coronary flow velocity in the left anterior descending artery (LAD) noninvasively. It was difficult to obtain the image of vessel wall due to the quality of two dimensional echocardiocardiography.
High frequency(10MHz) two-dimensional echocardiography allows visualization of the distal LAD.
Method: we evaluated 32 pts (14 myocardial infarction, 18 angina pectoris) using a commercially available VIVID 7 echograph(GE Yokogawa medical)
Distal LAD was imaged transectionally and longitudinally under the guidance of color flow mapping. At the region of maximal width of color flow mapping in the LAD, the vessel wall were imaged and diameter of LAD were measured.
We compared diameter of the distal LAD by echocardiography with diameter obtained by quantitative coronary angiogram.
Results: In 24 out of 32patients (75%), imaging of diatal LAD was obtained.
There were close correlations between transthoracic echocardiography and coronary angiographycal methods for measurement of diamter of the distal LAD (r=0.91, y=0.95x+0.1)
Conclusion: Noninvasive measurement of diameter of the distal LAD using a10MHz high frequency transducer accurately reflects invasive measurement of diameter of the distal LAD by coronary angiographycal method. Thus this method can provide useful information about the change of diamter of LAD under various conditions.

784 Effect of plaque debulking before stent implantation on in-stent neointimal proliferation: serial three-dimensional IVUS analysis

Y. Takeda[1], E. Tsuchikane[2], Y. Kobayashi[2], A. Nishibe[2], T. Nakagawa[1], M. Sakurai[1], N. Awata[2], T. Kobayashi[1]. [1]*Osaka medical center, cardiovascular surgery, Osaka, Japan;* [2]*Osaka medical center, The department of cardiology, Osaka, Japan*

Objectives: We report volumetric assessment of neointimal formation by three-dimensional intravascular ultrasound (IVUS) analysis, comparing primary stenting with adjunctive stenting following plaque removal with directional coronary atherectomy (DCA).
Background: Recent IVUS studies suggest a role for plaque burden in promoting neointimal hyperplasia after stenting.
Methods: Twenty-four patients (24 lesions) receiving DCA before stenting were matched to 24 patients (24 lesions) who underwent stenting without DCA in the same period. All used stents were a single Multilink stent (15 mm long only). Serial IVUS was performed before and after intervention and at 6-month follow-up. The same arterial segments as the stented segments on serial studies were analyzed using a computer based contour detection program. The following measurements were obtained: (1) lumen volume (LV), (2) stent volume (SV), (3) vessel volume (VV), (4) in-stent neointimal volume (ISV) calculated as SV-LV, and (5) percent in-stent neointimal volume (%ISV) calculated as (SV-LV/SV)*100.
Results: Preprocedural volume measurements were similar. At postintervention, both groups achieved a similar SV (140.0 ± 52.7mm^3 vs. 135.2 ± 30.7mm^3, DCA plus stent vs. stent alone). However, the follow-up ISV and %ISV were significantly smaller in the DCA plus stent group than in the stent alone group (19.6 ± 12.2mm^3 vs. 44.6 ± 29.5mm^3; p=0.00040)(15.3 ± 10.6%vs. 31.5 ± 17.7%; p=0.00040), respectively. Consequently, the DCA plus stent group showed the significantly greater follow-up LV (121.0 ± 51.5mm^3 vs. 91.5 ± 26.7mm^3; p=0.016).
Conclusions: Volumetric IVUS analysis demonstrates that plaque removal with DCA before stenting inhibits in-stent neointimal proliferation.

785 Detection of severe left anterior descending coronary artery stenosis by transthoracic Doppler echocardiography and venous adenosine infusion

P. Voci, F. Pizzuto, E. Mariano, P.E. Puddu, P.A. Chiavari, F. Romeo. *University of Rome "La Sapienza", Cardiac Surgery, Rome, Italy*

Background: Severe left anterior descending coronary artery (LAD) stenosis carries a high risk of acute coronary events, but nevertheless it cannot be reliably predicted by symptoms or standard noninvasive tools. Experimental work shows that coronary flow reserve (CFR) is damped (<1) in severe stenosis.
Aim of this study was to detect severe (>90%) LAD stenosis by transthoracic coronary Doppler ultrasound, an emerging method to noninvasively measure CFR as the ratio between hyperemic and basal coronary flow.
Methods: LAD peak diastolic flow velocity was recorded by transthoracic Doppler echocardiography at baseline and during 90 sec venous adenosine infusion (140 mcg/kg/min), and CFR was measured in 314 subjects, stable and without previous anterior myocardial infarction, 3.7±2 days before coronary angiography. According to angiography, patients were divided into: Group 1 (non-significant, 0-69% LAD stenosis); Group 2 (significant, 70-89% LAD stenosis), and Group 3 (severe, 90-99% LAD stenosis).
Results: Adequate Doppler spectra were obtained in 308/314 (98%) subjects. CFR was 2.86±0.65 in Group 1 (N=197), 1.76±0.52 in Group 2 (N=61), and 0.72±0.17 in Group 3 (N=50), respectively (p<0.001 between groups). A CFR<1 identified severe LAD stenosis with a sensitivity, specificity and positive predictive accuracy of 92%, 98% and 97%, respectively.
Conclusions: Transthoracic Doppler echocardiography allows noninvasive stratification of patients with LAD stenosis. A damped CFR clearly identifies patients with severe stenosis, which may be at high-risk of coronary events.

786 Intracoronary ultrasound of angiographically ambiguous left main coronary artery stenoses. Safety and effect on further clinical decision making

K. Doenges, R. Schiele, G. Taubert, K.-H. Seidl, C. Bergmeier, J. Senges, R. Zahn. *Herzzentrum Ludwigshafen, Cardiology, Ludwigshafen, Germany*

Purpose: In clinical practice the indications for intracoronary ultrasound (ICUS) have declined in the recent years. ICUS for angiographic uncertain results of the left main coronary artery (LMCA) is one of the more common indications. There is few data in literature about the safety and effect of ICUS on further clinical decision in those cases.
Methods: From September 1996 - July 2001 55 (25%) ICUS of the LMCA out of a total of 221 ICUS were consecutively registered in a large community hospital.
Results: Patients characterization: mean age 61 years, male sex 37 (67%), 40 (73%) stable angina pectoris and 15 (27%) unstable angina pectoris, known coronary artery disease 20 (36%), history of coronary artery bypass grafting (CABG) 10 (18%), history of coronary angioplasty 19 (35%). ICUS of the LMCA was performed due to 39 (71%) angiographically ambiguous ostial lesions (group 1) and 16 (29%) presumed distal lesions (group 2). ICUS was feasable in 100%. There were no major ICUS-related complications: 4 (7%) patients had asymptomatic, 1 (2%) had temporary symptomatic coronary spasms. The ICUS-results of both groups are shown in table 1. Only due to ICUS findings 12 (22%) CABG were performed because of severe LMCA-stenoses, 17 (31%) presumed high-graded LMCA-stenoses could be excluded, so that an intervention was unnecessary, ICUS confirmed 26 (47%) angiographically presumed results and therefore did not change the further clinical decision making.

LMCA-stenosis graded by ICUS:	Group 1 (n=39/55)	Group 2 (n=16/55)
Mild (< 40%)	8 (21%)	13 (81%)
Moderate (40-70%)	19 (49%)	3 (19%)
Severe (>70%)	12 (30%)	0 (0%)

Conclusions: In the daily clinical routine ICUS of the LMCA in cases with ambiguous angiographic results is feasable and save, if performed by a skilled examiner. With 25% of all performed ICUS it has become an important indication. ICUS was diagnostic in 100% and in more than 50% of cases ICUS-diagnosis made the further clinical decision.

787 Importance and role of multiplane transoesophageal echocardiography in diagnosis of anomalous origin of coronary arteries

F. Bovenzi[1], L. De Luca[2], P. Colonna[1], N. Signore[1], G. Rubini[3], F. Tunzi[1], I. De Luca[1]. [1]*Azienda Policlinico, Cardiology Division, Bari, Italy;* [2]*Azienda Policlinico, Cardiology Division, Bari, Italy;* [3]*University of, Dipt. Nuclear Medicine, Bari, Italy*

Background: Nowadays X-ray cineangiography has been the imaging modality of choice for coronary arteries assessment. However, this technique does not reliably delineate the proximal course of anomalous coronary arteries (ACA) in relation to the aorta or pulmonary trunk. This information is often critical to the management of these patients (pts). This study describes the importance of integration of data obtained from digital coronary angiography with Multiplane Transesophageal Echocardiography (MTE) in evaluating the anomalous origin and course of coronary arteries and their haemodynamic significance.
Methods: ACA were detected by coronary angiography (from November 1998 to September 2001) in 19 pts (12 males, 56.8±8.3 years old). All pts underwent MTE to evaluate the relationship of the ACA with Aorta and Pulmonary Artery. In all cases a Stress/Rest 99mTc Sestamibi myocardial perfusion single photon emission tomography (SPECT) was performed.
Results: The MTE showed a course of the ACA between the aorta and the pulmonary trunk in the 7 pts with right coronary artery originating form the left sinus of Valsalva and in the 2 pts with single coronary artery originating form the right sinus of Valsalva; all these 9 pts had a perfusion defect at SPECT. In the other 10 pts (6 with circumflex coronary artery form the right sinus of Valsalva and 4 pts with a high right coronary artery) the MTE showed a course of the ACA anterior or posterior to the aorta and the pulmonary trunk and no perfusion defect was detected at SPECT.
Conclusion: MTE is a non-invasive and accurate technique for detecting anomalous origin of coronary arteries. In this series, MTE correctly identified every anomalous course; an anomalous course between Aorta and Pulmonary artery was associated with a myocardial perfusion defect detected by SPECT. Evaluation of the haemodynamic importance of the ACA can be useful in programming corrective surgery.

788 Estimation of coronary artery stenosis with retrospective electrocardiogram-gated multislice CT

M. Pasowicz[1], P. Klimeczek[1], T. Przewlocki[2], P. Pieniazek[2], A. Kozanecki[2], M. Konieczynska[2], K. Zmudka[3], W. Tracz[2]. [1]*The John Paul II Hospital, Cardiac and Vascular Diseases, Krakow, Poland;* [2]*The John Paul II Hospital, Institute of Cardiology, CM UJ, Krakow, Poland;* [3]*Institute of Cardiology, Hemodynamics, Krakow, Poland*

We estimated the accuracy of multislice CT (MSCT) in the detection and quantification of significant (>50%) coronary artery stenosis, in comparison with coronary angiography.
Material and method: Between January and June 2001, 90 patients (43 women and 47 men, mean age 67 SD 14 years) with stable effort angina were included to prospective blinded study. All patients underwent MSCT and digital CA in consecutive five days. MSCT were performed on a MSCT scanner Somatom Plus 4 Volume Zoom (Siemens, Erlangen, Germany). CA were carried out by angiographer Coroscope (Siemens, Germany) (QCA). Every patient was medicated with beta blocker to reduce heart rate below 75 bpm. 2 ml/kg of non-ionic contrast was administered (4 ml/s). Acquired images were sent to a workstations and reconstructed and post- processed (Wizzard Siemens, Silicon Virtuoso Siemnes). The stenosis quantification with MSCT was done in each coronary segment by 1) 2 - reconstruction (curved MPR, 5 mm thin MIP) and 2) 3-D reconstruction. 559 coronary artery segments were assessed: 155 of right coronary artery (segments 1,2), 90 of left main (5), 165 of left anterior descendent artery (6,7), 149 of circumflex artery (11,12).
Statistical analysis: the 95% confidence intervals (CI) for the proportions were calculated with use of the exact binomial method.
Results: 161 (28.8%) segments out 559 had significant stenosis (> 50%) as determined by CA. Mean heart rate during MSCT examination was 59 SD 18 bpm.
The total true negative results were 323, true positive - 135, false negative - 26, false positive 75. Sensitivity and specificity were 83.8% (CI 76%- 84%) and 81.1% (CI 77% - 85%) respectively Positive predictive value was 64% (59% - 67%), negative predictive value was 92.5% (CI 81% - 94%)
Conclusion: MSCT is a promising instrument in non-invasive detection of coronary stenosisin a proximal and medial part of the arteries. This method may be an interesting alternative in patients with high-risc angiography.

NEW PATHWAYS OF ENDOTHELIAL CELL MODULATION

789 The arginase pathway in human endothelial cells: characterisation and role in pathophysiologic conditions

T. Bachetti[1], L. Comini[1], G. Francolini[1], D. Bastianon[1], B. Valetti[1], P.G. Grigolato[2], S. Curello[3], R. Ferrari[4]. [1]*Fondazione Salvatore Maugeri IRCCS, Cardiovasc. Pathophysiol. Res. Ctre, Gussago, Italy;* [2]*Spedali Civili, Division of Pathologic Anatomy, Brescia, Italy;* [3]*Spedali Civili, Department of Cardiology, Brescia, Italy;* [4]*University of Ferrara, Chair of Cardiology, Ferrara, Italy*

Arginase is a nitric oxide synthase-alternative breakdown pathway for L-arginine, leading to biosynthesis of urea and L-ornithine instead of nitric oxide. The arginase pathway is inducible by inflammatory molecules - such as cytokines and bacterial endotoxin - in different cell types (e.g. macrophages, smooth muscle cells).
Aim: To test whether the arginase pathway is present in human endothelium and susceptible of modulation by inflammatory molecules.
Methods: We have: (1) characterised the arginase pathway in terms of activity, isoform type and gene expression in a primary human cell line (HUVEC), (2) determined the effects of inflammatory molecules on the arginase pathway, (3) investigated the signal-transduction involved and (4) evaluated the functional implications of arginase pathway in cell proliferation.
Results: HUVEC showed a baseline arginase activity due to gene and protein expression of the mitochondrial arginase isoform (A-II). After addition of a cytomix (tumour necrosis factor-alpha + E. Coli lipopolysaccharides), arginase activity time-dependently increased reaching a peak after 48 hours. Such increase was not consistent with an increase in A-II protein expression or with A-I induction. Immunoprecipitation experiments showed that the cytomix increased the phosphorylation of A-II tyrosine residues. In addition, urea measurements with genistein (a tyrosine kinase inhibitor) and sodium orthovanadate (a tyrosine phosphatase inhibitor) confirmed a tyrosine phosphorylation-mediated control of arginase activity. Cell cycle analysis and nuclear factor Ki-67 immunostaining revealed that baseline arginase activity is fundamental for HUVEC proliferation. Cytomix, although inducing arginase activity, caused cell-cycle arrest, suggesting that other intracellular pathways may play a major role in the control of cell proliferation during inflammatory conditions.
Conclusions: The arginase pathway is present in HUVEC where it contributes to cell cycle regulation. The arginase activity is positively modulated by cytomix via a post-transductional mechanism.

790 Flow-induced haptoglobin expression is partly regulated via a NO-mediated pathway

M.B. Smeets[1], E. Velema[2], C. Borst[2], G. Pasterkamp[2], D.P.V. de Kleijn[2]. [1]*University Medical Center, Experimental Cardiology Laboratory, Utrecht, Netherlands;* [2]*University Medical Center Utrecht, Laboratory of Experimental Cardiology, Utrecht, Netherlands*

Background: Flow-induced remodeling is an attempt to restore local shear stress. Nitric oxide (NO) is an important mediator of this process and regulates cell proliferation, migration and gene expression. Previously, we demonstrated that arterial haptoglobin expression increased early after flow-induced remodeling. Haptoglobin was found to play an important role in cell migration during tissue restructuring. Haptoglobin expression is mainly regulated through interleukin-6 which expression is influenced by shear stress and NO. In the present study, we hypothesized that flow-induced haptoglobin expression depends on the upregulation of IL-6 via a NO-mediated pathway.
Methods: In 14 New Zealand White rabbits, the right carotid artery was completely ligated which resulted in a flow increase in the contralateral left carotid artery. Animals were terminated after 1 day. Rabbits received either L-NAME (a nonspecific NO synthase inhibitor) starting 5 days before intervention (L-NAME treated rabbits, n=7) or served as control group (control rabbits, n=7). The carotid arteries of 6 additional unoperated untreated rabbits were used for baseline values. Quantitative PCR and western blotting was performed to study haptoglobin and interleukin-6 (IL-6) expression.
Results: One day after ligation, a significant increase of haptoglobin mRNA (30-fold, $p=0.003$) and protein (1.6-fold, $p<0.05$) was observed in both carotid arteries of control rabbits. Compared to baseline values, haptoglobin mRNA (12-fold, $p=0.004$) and protein (1.4 fold, $p<0.05$) was also significantly increased in both carotid arteries of L-NAME treated rabbits. Absolute haptoglobin mRNA levels, however, were significantly lower compared to control rabbits (3-fold, $p<0.04$). IL-6 mRNA levels significantly increased in both carotid arteries of the control rabbits compared to baseline values (4-fold, $p<0.03$). No changes in IL-6 expression levels were observed in the carotid arteries of L-NAME treated rabbits.
Conclusions: Haptoglobin expression after flow changes is partly regulated via IL-6 in a NO-mediated pathway.

791 Calpain prevents p53 dependent apoptosis in vascular smooth muscle cells exposed to mechanical stretch

D. Sedding[1], M. Homann[2], U. Seay[2], H. Tillmanns[2], R.C. Braun-Dullaeus[2]. [1]*Medizinische Klinik I, Abteilung für Molekulare Kardiologie, Giessen, Germany;* [2]*Giessen University, Internal Medicine/Cardiology Dept., Giessen, Germany*

Background: Increased mechanic forces as ocuring in severe hypertension or venous bypass grafts cause rapid onset of apoptosis of vascular smooth muscle cells (VSMC), initiating chronic remodeling processes. Although involvment of the protease calpain for cell migration, proliferation, and apoptosis has been suggested, its role in early triggers of apoptosis after mechanic stress remains obscure. We hypothesized that calpain influences apoptosis induced by mechanic stress of VSMC in vitro.

Methods and results: Quiescent, mitogen-free rat VSMC were subjected to cyclic-stretch for up to 24 h (0,5 Hz at 120% resting length). 15 min of stretch increrased calpain activity 2.4±0.4 fold (*compared to unstretched cells, n=6, $p<0.001$) as measured by cleavage of the fluorigenic calpain substrate SLLVT-AMC. This rapid activation was dependent on calcium influx since inhibition of stretch-activated calcium channels with gadolinium (Gd3) or prevention of intracellular calcium release with TMB8 significantly reduced calpain activity (1.3±0.2 and 1.4±0.2 fold* respectively). Stretch resulted in a significant increase of apoptotic nuclei from 3±1% to 8±2% as measured by dUTP-biotin nick end labeling (TUNEL) after 24 h of stretch. The pharmacologic calpain inhibitors PD150606 or calpeptin dramatically augmented stretch-induced apoptosis rate to 35±4% and 30±6% of cells respectively. Immunoblot analysis of homogenates 24 h after stretch revealed that the stretch-induced increase in p53 level as well as p21 expression and Bax/bcl-2 ratio was further augmented in cells treated with calpain inhibitors.

Conclusion: Calpain is rapidly activated in VSMC exposed to cyclic stretch in a calcium dependent manner, regulating p53 expression levels and thereby preventing p53 dependent apoptosis. Targeting calpain may represent a novel strategy to influence vascular remodeling induced by mechanic overload.

792 Gene transfer of isolated beta-integrin cytoplasmic domains causes endothelial cell apoptosis via caspase activation in vivo

G. Vassalli[1], S. Fleury[1], A. Foletti[2], J. Bamat[2], D. Oguey[2], P. Werffeli-George[2], C. Rüegg[2]. [1]*CHUV, Cardiology, Lausanne, Switzerland;* [2]*ISREC, Centre pluridisciplinaire d'oncologie, Epalinges-Lausanne, Switzerland*

Integrins are a class of adhesion receptors that are necessary for vascular cell development and migration, as well as extracellular matrix assembly. The aim of the present study was to study the role of integrin in endothelial cell (EC) adhesion and survival.

Methods: We have constructed a recombinant adenovirus (Ad) vector expressing a chimeric protein consisting of the cytoplasmic and transmembrane domains of the integrin beta-1-subunit (CH1) fused to the extracellular L3T4 domain. An adenovirus vector expressing a chimeric protein consisting of the transmembrane but not the cytoplasmic beta-1-integrin domain fused to the extracellular L3T4 domain (CH2) was used as a control. These vectors were tested on EC monolayers (HUVEC) in vitro and in rat carotid arteries in vivo. Rat arteries were explanted at 8, 24, and 48 hours, and 6 days after gene transfer with Ad-CH1and Ad-CH2 (n = 2 per vector and time point). Transduced EC were detected by immunohistochemical double-labeling with antibodies to L3T4 and the von Willebrand factor (n = 20 sections/vessel). Apoptosis was detected by TUNEL and by immunohistochemistry using a monoclonal antibody that recognizes activated caspase-3.

Results: Ad-CH1caused EC detachment from several extracellular matrix substrates and apoptosis in a dose-dependent manner in vitro. Ad-CH1 and Ad-CH2 transduced ~20% of EC in rat arteries in vivo. CH1 expression was observed at 6 and 24 hours but not at later time points, whereas CH2 expression was observed at all time points. A large proportion of CH1-transduced EC lost their normal flattened morphology, rounded up and detached from the vessel wall. In contrast, CH2 transduced EC retained their flattened morphology. Positive TUNEL and caspase-3 activation was detected in EC transduced with CH1 but not CH2 constructs.

Conclusions: These findings provide first evidence that gene transfer of dominant-negative beta-integrin constructs induces endothelial cell detachment and apoptosis via caspase activation in vivo. Therefore, these results demonstrate that beta-integrins are essential for arterial endothelial cell adhesion and survival. Potential applications of this approach to pathophysiological processes involving integrin-dependent cell adhesion and migration may include dysruption of vessel integrity in tumor angiogenesis.

793 Amelioration of vasculopathy in diabetic db/db mice by the NHE-1 inhibitor cariporide

M. Loehn, S. Schaefer, U. Schindler, J. Huber, W. Linz, H. Ruetten, M. Bleich, A.E. Busch. *Aventis Pharma, Cardiovascular Diseases, Frankfurt am Main, Germany*

Diabetic vasculopathy is characterized by both vascular smooth muscle and endothelial dysfunction. In the present study we tested the hypothesis that chronic treatment with the NHE-1 inhibitor cariporide- mesylate improves endothelial function in a type II diabetic mouse model. Using standard organ bath techniques, we measured phenylephrine (500 nM)-mediated contraction as well as endothelium dependent (acetylcholine, 100 nM to 10 μM) and endothelium independent (sodium nitroprusside, 10 nM to 10 μM) relaxation in aortic rings from 37 week old male mice in three groups: a) lean, non-diabetic db/- mice (LEAN, n=5); b) obese, diabetic db/db mice (OB, n=5), and c) obese, diabetic db/db mice pre-treated with cariporide, 0.6% (v/v) in chow for 27 weeks (OB+CARI, n=6). Maximum tension in response to phenylephrine (500 nM) was increased in rings from OB (462 ± 54 mg) than from LEAN (326 ± 35 mg, $p<0.05$ vs. OB) and OB+CARI (342 ± 25 mg, $p<0.05$ vs. OB). The maximal endothelium dependent relaxation induced by acetylcholine (10 μM) was depressed in OB vs. LEAN (62 ± 6% vs. 100 ± 2%, $p<0.05$). Pre-treatment with cariporide ameliorated endothelium dependent relaxation (OB+CARI: 105 ± 13%, $p<0.05$ vs. OB). Endothelium independent aortic relaxation induced by sodium nitroprusside was not different between the three groups. In conclusion, diabetic vasculopathy in db/db mice is characterized by both smooth muscle hypercontractility and impaired endothelium dependent relaxation. Chronic treatment with the NHE-1 inhibitor cariporide ameliorates diabetic vasculopathy and improves endothelial function in this type II diabetes animal model.

794 Lessons from a DDAH transgenic mouse: role of ADMA in regulating NOS activity and blood pressure

H. Dayoub[1], J. Jacobi[1], K. Lin[1], A. Patterson[2], P. Tsao[1], J.P. Cooke[1]. [1]*Stanford University, Cardiovascular Medicine, Stanford, United States of America;* [2]*Stanford University, Anesthesiology, Stanford, United States of America*

Asymmetric dimethylarginine (ADMA) is a competitive inhibitor of nitric oxide synthase (NOS). ADMA is metabolized to citrulline and dimethylamine by dimethylarginine dimethylaminohydrolase (DDAH). We generated a transgenic mouse that overexpresses DDAH using human DDAH I cDNA, a human B-actin promoter and RNA processing signals from SV40, cloned into a pBluescript vector. Purified DNA was used for pronuclear microinjection. DNA from newborn mice was subjected to Southern blot analysis to identify the presence of the transgene. Western blotting confirmed human DDAH expression in all tissues. In all subsequent studies, heterozygous transgenic mice were compared to age, weight and sex matched wildtype controls. The DDAH transgenic mice appear normal at birth, and pathologic studies disclosed no anatomic abnormalities. Biochemical studies revealed that plasma ADMA levels were 50% of normal mice. The reduction in plasma ADMA was associated with a 2-fold increase in tissue NOS activity. This was confirmed by ex-vivo studies of transgenic endothelial cells which manifested an increase in NO production. Tail cuff measurements of blood pressure in conscious animals demonstrated a 6.8 mmHg reduction in systolic blood pressure in comparison to wildtype controls ($P<0.05$).

In conclusion, DDAH overexpression caused a decline in plasma ADMA levels which was associated with increased tissue and endothelial NO synthesis. The increase in NO synthesis was associated with a reduction in blood pressure. This is the strongest evidence to date that ADMA is an important regulator of NO synthesis, and also indicates that changes in DDAH activity may have physiologically and clinically relevant effects

MOLECULAR STUDIES IN ATHEROSCLEROSIS

795 Low density lipoprotein receptor-related protein expression, regulation and function in VSMC of normal and atherosclerotic human coronaries

V. Llorente-Cortes, M. Otero-Viñas, M. Berrozpe, L. Badimon. *Cardiovascular Research Center, IIBB/CSIC-HSCSP-UAB, Barcelona, Spain*

Background: Low density lipoprotein receptor-related protein (LRP) is expressed in normal vessels and atherosclerotic plaques. LRP expression may increase in rabbit atherosclerotic lesions. We have previously demonstrated that LRP binds and internalizes aggregated-LDL (agLDL) formed by interaction with the extracellular matrix proteoglycan versican in human vascular smooth muscle cells (VSMC).
Objectives: To analyze LRP expression, LRP regulation by agLDL and LRP function in VSMC of normal and atherosclerotic human coronaries.
Methods: Human coronary arteries were obtained from excised hearts and LRP expression in normal vessels (n=7) and atherosclerotic plaques (n=5) was analyzed by in situ hybridization and immunohistochemistry. Normal or plaque-derived VSMC (passage 2) were obtained by the explant technique analyzing mRNA and protein levels by semiquantitative RT-PCR and Western blot. Additionally, we analyzed the regulation of LRP expression levels in normal and plaque-derived VSMC in the presence of increasing concentrations of agLDL (from 50 mg/ml to 200 mg/ml). LRP function was analyzed by measuring the cholesteryl ester (CE) content of VSMC by TLC after 18 hours incubation with agLDL.
Results: Immunohistochemical analysis shows that LRP expression is increased in human atherosclerotic plaque VSMC. Plaque-derived VSMC express higher levels of LRP protein than normal VSMC (645.4±172 AU vs 332±95 AU; $p<0.05$). In agreement, plaque-derived VSMC accumulate higher intracellular CE levels than normal VSMC when exposed to agLDL (200 mg/ml) (110±15 mgCE/mg prot. vs 70±7.5 mgCE/mg prot; $p<0.05$). AgLDL induces higher LRP expression in plaque-derived VSMC (2.3-fold) than in normal VSMC (1.2-fold).
Conclusions: These results indicate that plaque-derived VSMC have higher LRP expression and capacity to internalize agLDL than normal VSMC. The LRP up-regulation in plaque-derived VSMC induced by agLDL suggests that LRP expression can be readily induced by aggregated intimal LDL and that the high LRP expression observed in atherosclerotic plaque VSMC might be conditioned by the enriched lipidic environment. LRP mediated internalization of intimal LDL by VSMC might be one of the main mechanisms contributing to atherosclerotic plaque progression

796 Molecular cloning and characterization of the human KIS gene promoter – a regulator of vascular smooth muscle cell proliferation

M.F. Crook, M. Boehm, T. Yoshimoto, L.M. Akyurek, M. Olive, S. Ganesh, E.G. Nabel. *National Institute of Health, Vascular Biology Branch, Bethesda, United States of America*

Vascular smooth muscle cell proliferation plays a major role in atherosclerosis and restenosis. The cyclin-dependant kinase inhibitor p27Kip1 arrests cell-cycle progression by inhibiting the phosphorylation of CDKs and the retinoblastoma gene family products. We have previously shown that p27Kip1 negatively regulates vascular smooth muscle proliferation. Using a yeast-2-hybrid screen and the C-terminal portion of p27Kip1 as bait, we have identified a novel kinase (hKIS) that phosphorylates p27Kip1 on serine 10, leading to degradation of p27Kip1 and cell-cycle progression. To investigate the mechanism of transcriptional hKIS gene expression, we isolated the genomic DNA fragment of the 5' flanking region of the hKIS gene and characterized its promoter region. The transcription initiation start-site was mapped by RNase protection assays to approximately 170 bp upstream of the translational start-site. Transient transfection assays using fusion reporters containing progressively truncated hKIS promoter fragments showed that a region of 250 bp upstream of the translational start site is sufficient for maximal transcription activity and is highly homologous to the mouse KIS promoter sequence. Deletion analyses have revealed several putative transcription-factor binding sites that are likely involved in the regulation of hKIS gene expression. In particular, deletion of consensus sequences for Sp-1, Ets-1 and GATA-2 showed a marked reduction in basal promoter activity suggesting that they may regulate the basal expression of hKIS. Thus, hKIS is transcriptionally regulated and potential inhibitors of hKIS gene expression are being defined to modify its expression. Such studies will be useful in expanding our understanding of the important roles that hKIS and p27Kip1 play in regulating vascular smooth muscle proliferation.

797 Cell-cell contact via cadherin-catenin complexes is essential for vascular smooth muscle cell survival

E. Koutsouki, A.C. Newby, S.J. George. *University of Bristol, Bristol Heart Institute, Bristol, United Kingdom*

Death of vascular smooth muscle cells (VSMCs) via apoptosis causes subsequent thinning of the fibrous cap and contributes to the propensity for plaque rupture. The cadherins and their adaptor proteins, the catenins, mediate calcium-dependent cell-cell contacts that maintain cell survival in some cell types, but little is known of their role in VSMCs. In this study cell-cell contact, without cell-matrix contact, was permitted by culturing VSMCs at high density on agarose-coated plates. The addition of 2mM EGTA chelated extracellular calcium and inhibited cell-cell contact. VSMC death assessed by trypan blue staining, was significantly higher in VSMCs grown without cell-cell contacts (EGTA-treated) for 24 hours, than in VSMCs grown at high density where cell-cell contacts formed, (57±16% v 20±9%: n=6; $p<0.05$). In situ end labeling and hoescht and propidium iodide staining confirmed trypan blue staining results. Expression of N- and T-cadherin proteins was significantly greater in VSMCs with cell-cell contact than in VSMCs in the absence of cell-cell contact. In addition, cleavage of the cadherin adaptor protein, beta-catenin was observed in VSMCs in the absence of cell-cell contact. To induce apoptosis VSMCs were cultured with a bcl-2 antagonist (HA-14 at 50μM). After 6 hours culture only a few cells showed apoptotic characteristics whilst 100% did at 16 hours. The level of N-cadherin protein expression was reduced by 72±21% at 6 hours (prior to appearance of apoptotic VSMCs) and by 100±0% at 16 hours, suggesting that this loss is not just a consequence of apoptosis. However, although T-cadherin protein expression was abolished at 16 hours, it was unaffected at 6 hours. This study indicates that cell-to-cell adhesion mediated by cadherins, particularly N-cadherin, acts as a survival signal for VSMCs. We suggest maintenance of cell-cell contacts via cadherins is a viable strategy for reducing VSMC apoptosis and plaque rupture.

798 Statins inhibit cyclooxygenase-2 protein and activity in human endothelial cells – Possible contribution to plaque stability

M. Massaro[1], A. Zampolli[2], R. Madonna[3], M A. Carluccio[1], C. Storelli[4], R. De Caterina[3]. *[1]CNR Institute of Clinical Physiology, Laboratory of Vascular Research, Lecce, Italy; [2]CNR Institute of Clinical Physiology, Laboratory for Thromb & Vasc Research, S.Cataldo - Pisa, Italy; [3]Chair of Cardiology, Univ. of Chieti, Ospedale S. Camillo De Lellis, Chieti, Italy; [4]Department of Biology, University, Lecce, Italy*

The 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitors (statins) are currently being investigated for cholesterol-independent properties, among which anti-inflammatory effects. Cyclooxygenase(COX)-2 expression within atherosclerotic plaques has been linked to plaque instabilization through COX-2-dependent expression of matrix metalloproteinases. Accordingly, statins reduce basal and stimulated metalloproteinase expression by macrophages. Since vascular endothelium plays a crucial roie in the development of atherosclerotic lesions, we investigated whether statins modulate endothelial COX-2.
Methods: Simvastatin and atorvastatin, in vitro activated by alkaline hydrolysis, were incubated with human umbilical vein endothelial cells (HUVEC) for 6 h, followed by stimulation with tumor necrosis factor (TNF), lipopolysaccharide (LPS) or phorbol myristate acetate (PMA) for further 12 h. After this time, COX-2 activity and protein were assessed by a radioimmunoassay for 6-keto-PGF1alpha (the stable hydrolytic metabolite of prostacyclin) and Western analysis, respectively.
Results: At 0.1-10 μmol/L, and in the absence of any toxicity, both simvastatin and atorvastatin reduced COX-2 expression and prostacyclin production without any effect on COX-I expression. Results for COX-2 protein expression at Western blot densitometry are shown in the Table.
The effect of both statins on COX-2 protein expression was totally reversed by the addition of 200 μmol/L mevalonate, indicating the requirement of a prenylated intermediate in the signal transduction pathway leading to COX-2 expression. 6-keto-PGF1alpha production was (pg/1000 cells) 0.22±0.01 in control conditions, 4.88±1.72 after PMA 6.3 ng/mL, 2.60±1.34 after PMA in the presence of simvastatin ($P<0.01$ vs PMA), and 4.42±1.36 after PMA with simvastatin + mevalonate (P = N.S. vs PMA).

The effect of statins on COX-2 protein

Stimulus	Simvastatin 1 μmol/L (% of stimulated control)	Atorvastatin 1 μmol/L (% of stimulated control)
PMA 6.3 ng/mL	15 ± 4**	38 ± 10**
LPS 1 microg/mL	67 ± 22*	79 ± 25*
TNF alpha 10 ng/mL	13 ± 4**	34 ± 9**

* = $P<0.05$; ** = $P<0.01$ vs stimulated control without statins

Conclusions: Statins reduce the induced expression and activity of COX-2 in human vascular endothelial cells. This effect may contribute to clinical benefits of statins, independent of cholesterol-lowering.

799 Nicotine efficiently stimulates T cell immune responses via dendritic cells and monocytes: potential role for atherosclerotic lesions progression

A. Aicher, C. Heeschen, A.M. Zeiher, S. Dimmeler. *University of Frankfurt, Molecular Cardiology, Frankfurt, Germany*

Atherosclerosis is a chronic inflammatory disease. Antigen presenting cells such as monocytes (MC) and dendritic cells (DC) are able to stimulate T cell proliferation in atherosclerotic lesions, contributing to formation and/or destabilization of atherosclerotic lesions. Our previous data demonstrate that nicotine stimulated progression of advanced atherosclerotic lesions. Accordingly, we investigated whether nicotine stimulates antigen presenting cells and their T cell stimulatory capacity. We used human monocyte-derived DCs and their monocytic precursors as antigen presenting cells. Nicotine dose-dependently (10-10to 10-6 M) induced expression of nicotinic acetylcholine receptors (nAChR), co-stimulatory molecules such as CD86, MHC class II molecules such as HLA-DR, and adhesion molecules such as CD54. Moreover, nicotine induced the secretion of the pro-inflammatory TH1 cytokine IL-12 in DCs and MCs (5.0-fold and 7.0-fold increase over control ($p < 0.01$), respectively). Nicotine-induced expression of surface molecules and IL-12 production was inhibited by the general nAChR antagonist mecamylamine and a7-nAChR antagonist a-bungarotoxin, respectively. To elucidate the functional relevance of nicotine-stimulated antigen presenting cells, we used mixed lymphocyte reactions (MLRs) where T cell activation was measured by induction of the T cell-specific cytokine IL-2. Nicotine-treated DCs and MCs showed a strong increase in IL-2 production by allogeneic T cells (4.2-fold and 2.7-fold induction over control ($p < 0.01$), respectively).
In conclusion, nicotine exerts a potent stimulatory effect on T cell stimulation via dentritic and monocytic cells. The activation of these immune competent cells may significantly contribute to the nicotine-promoted progression of atherosclerotic lesions.

800 Proteasome inhibition leads to NF-kB independent interleukin-8 transactivation in human endothelial cells through induction of JNK-kinase

I. Spyridopoulos[1], M.S. Hipp[2], P. Mayer[2], D. Hilbert[2], J. Wischhusen[2], M. Weller[3]. *[1]Universitätsklinikum Frankfurt, Department of Cardiology, Frankfurt, Germany; [2]Medizinische Klinik III, Cardiology, TUEBINGEN, Germany; [3]University of Tübingen, Dept. of Neurology, Tübingen, Germany*

Interleukin-8 (IL-8) is an important mediator of leukocyte trafficking and activation, participating in tumor angiogenesis, inflammatory processes and coronary atherosclerosis. Under flow conditions IL-8 triggers in conjunction with MCP-1 the firm adhesion of monocytes to the vascular endothelium. While previous studies have suggested the requirement of NF-kB for IL-8 secretion by endothelial cells, we investigated the possibility of IL-8 transactivation under conditions of NF-kB suppression.
Methods and Results: Inhibition of the proteasome by MG-132 or lactacystin completely blocked TNF-induced IkBalpha-degradation as well as NF-kB activity in human arterial endothelial cells. Surprisingly, basal secretion of IL-8 protein was 8 to 10-fold induced by proteasome inhibitors while MCP-1 expression was, as expected, completely downregulated. IL-8 was upregulated at the transcriptional level, and promoter studies prooved a more than 9-fold induction of AP-1 actvity to be the cause of increased IL-8 transcription. Mutation of the AP-1 binding site in an IL-8 promoter construct completely abrogated this effect, while mutation of the NF-kB motif did not influence IL-8 transactivation by proteasome inhibitors. DNA binding assays found a 7- to 8-fold induction of phosphorylated c-jun and hence JNK kinase activity under MG-132 treatment. Induction of JNK kinase appeared independent of the cell type, even in tumor cell lines not responding to proteasome inhibitors. Since neither inactivation of p53 in wild-type p53 cells nor reintroduction of functional p53 into p53-/- cells affected MG-132-inducible IL-8 secretion, a direct influence of p53 on IL-8 regulation could be excluded.
Conclusion: These results show that proteasome inhibitors can not only lead to functional AP-1 induction by enhanced c-jun phosphorylation, but also transactivate the IL-8 gene in human endothelial cells despite complete suppression of NF-kB activity.

CLINICAL CORRELATES IN ALTEROSCLEROSIS

801 Is there a reverse relation between serum paraoxanase activity and the angiographic extent of coronary atherosclerosis

E. Bozkurt[1], M.K. Erol[1], F. Polat[2], M. Yilmaz[1], M. Acikel[1], Y. Gurlertop[1], H. Senocak[1]. *[1]Ataturk University Medical Faculty, Cardiology, Erzurum, Turkey; [2]Ataturk University, Biochemistry, Erzurum, Turkey*

Background: HDL has been shown to prevent the oxidation of low-density LDL. The antioxidant activity of HDL is believed to reside in its enzymes, particularly paraoxanase (PON). PON has also been reported to be decreased patients with atherosclerosis. But, it is not investigated relation between serum PON activity and the extent of coronary atherosclerosis. This study was conducted to investigate possible relation between serum PON level and extent of coronary atherosclerosis in patients with unstable angina pectoris (UAP) and non-Q-wave acute myocardial infarction (NQAMI).
Methods: Consecutive 85 patients (68 male, mean age: 56.4 ± 9.3 years) with UAP and NQAMI (group I) and age-matched 40 healthy subjects (33 male, mean age: 55.7 ± 8.1 years) as control group (group II) were included in this prospective study. Coronary angiography was performed to all patients, and films from coronary angiography were viewed and scored using Sullivan's method to assess extent of coronary atherostherosis. Serum PON activity was measured by enzymatic activity.
Results: The serum PON activities were significantly lower in group I than in group II (respectively 64.3 ± 10.1U/ml, 95.6 ± 24.5U/ml; $p<0.0001$). There was a significant negative correlation between serum PON activities and Sullivan's extent score in patients with UAP and NQAMI (r: -0.82; $p<0.001$).
Conclusion: 1. Serum PON activity, which is prevent the oxidation of LDL, was significantly lower in patients with UAP and NQAMI. 2. There was significantly correlation between serum PON activity and the extent of angiographically determined coronary atherosclerosis.

802 Serum interleukin-18 is a strong and independent predictor of future cardiovascular events

S. Blankenberg[1], H.J. Rupprecht[2], C. Bickel[2], L. Tiret[3], J. Meyer[2]. *[1]Johannes Gutenberg-University Mainz, Department of Medicine II, Mainz, Germany; [2]Johannes Gutenberg-University, Department of Medicine II, Mainz, Germany; [3]Faculte de Medecine Pitie-Salpetriere, INSERM U525, Paris, France*

Introduction: Interleukin (IL) 18 is a pleitropic cytokine acting in acquired and innate immunity. Increased expression of IL-18 could be demonstrated in atherosclerotic, esp. vulnerable plaques. In light of its central role in the inflammatory cascade we evaluated the association of serum IL-18 with future cardiovascular events in a large cohort of patients (pts) with coronary artery disease (CAD).
Methods: In 1533 pts with documented CAD IL-18 [pg/ml], high sensitive C-reactive protein (hs-CRP) [mg/dl], fibrinogen [mg/dl], and white-cell count [/nl] count were determined. 1525 (99.6%) had a follow up (f/u) after a mean of 3.9 (maximum 5.2) years.
Results: During f/u 128 pts died because of cardiac reasons. Serum levels of IL-18 were significantly higher in pts suffering from future cardiovascular death (69.4 versus 58.8 pg/ml, $p<0.0001$). Increasing quartiles of IL-18 were associated with a 1.5 fold (95%CI 1.2 to 1.8; $P<0.0001$) increase in risk. This relationship was not weakend by fully adjustment for most potential confounders (see legend of table) as well as adjustment for other inflammatory markers like hs-CRP, fibrinogen, or white-cell count. By contrast, the latter markers lost its prediction after controlling for IL-18.

	Q1	Q2	Q3	Q4
range [pg/ml]	<45.2	45.2 - 60.3	>60.3 - 78.8	>78.8
% CV mortality	3.4	5.2	11.4	10.5
HRR	1	1.8	2.7	3.1
95% CI	–	0.8 - 4.4	1.2 - 6.1	1.4 - 7.2
P value multiv.	–	0.2	0.02	0.006

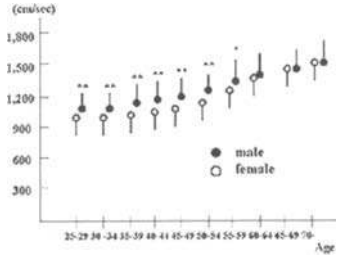
Fully adjusted model for age, sex, bmi, classical risk factors, clinical and therapeutic features including acute coronary syndrom, extent of vessel disease, history of MI, betablocker and statin medication, interventional therapy, and ejection fraction; HRR denotes Hazard Risk Ratio; cv cardiovascular.

Conclusion: We could demonstrate for the first time the strong and independent association between IL-18 serum concentration and future cardiovascular events. These results strengthens the role of IL-18 in atherogenesis and plaque destabilization and might offer a tool for a more accurate risk prediction.

803 Influences of age and gender on results of brachial-ankle pulse wave velocity measurement – a survey of 8607 normotensive health subjects

H. tomiyama, T. arai, K. hirose, T. nagao, Y. koji, T. chikamori, A. yamashina.
tokyo medical university, the second department, tokyo, Japan

The present study was conducted to evaluate the influences of age and gender on the results of noninvasive brachial-ankle pulse wave velocity (baPWV) measurement in apparently healthy subjects. A total of 8,607 healthy subjects (5,144 males and 3,463 females; range: 25 to 87 years) were studied, in whom coronary risk factors (hypertension, diabetes mellitus, dyslipidemia, obesity, and smoking) had been excluded. baPWV was measured using volume rendering method. In all subjects, results of baPWV were analyzed chronologically in 5-year age intervals (from 25 to over 70 years). The baPWV was lower in females than in males until age 60, and became similar in both genders over age 60. Step-wise multiple regression analysis of the relationship between baPWV and other clinical variables including pulse pressure and mean blood pressure demonstrated that age is an independent variable for baPWV in both genders (male: beta = 0.25 R-square = 0.33, female beta = 0.39 R-square = 0.53, $p<0.01$). In this analysis, not only the value of R-square but also the coefficient of the effect of age on baPWV are larger in females than in males. In the estimation of the regression curve, the relationship between age and baPWV demonstrated a quadratic curve in both genders {Male: baPWV = 0.19 x age2 - 11.01 x age + 1327.61 (r =0.24, $p<0.01$), Female: baPWV = 0.20 x age2 - 8.22 x age + 1076.33 (r =0.43, $p<0.01$)}.



Thus, aging influences baPWV, and its effect is more prominent in female. In this respect, menopause seems to be the crucial phenomenon to explain the augmented increase in arterial stiffness with aging in females.

804 Determinants of matrix metalloproteinases plasma concentration and activity in premature coronary atherosclerosis

S. Nanni[1], G. Melandri[1], R. Hanemaaijer[2], V. Cervi[1], L. Tomasi[1], C. Melloni[1], P. Tricoci[1], A. Branzi[1]. [1]*S.Orsola, Cardiology Dept., Bologna, Italy;* [2]*TNO-PG, Gaubius Laboratory, Leiden, Netherlands*

Background: matrix metalloproteinases (MMPs) are thought to participate in the pathogenesis of coronary artery disease (CAD), particularly in the occurrence of acute coronary syndromes (ACS). Little is known on determinants of MMPs concentration and activity in vivo.
Methods: we studied 80 young (<55 years) male patients with either myocardial infarction (MI) or angina (A) with angiographic evidence of CAD and 40 healthy male controls of similar age. Patients were subdivided into three groups as follows: 1)20 consecutive ST elevation acute MI (STEMI), 2)29 consecutive unstable A (UA) or non-STEMI (UA/NSTEMI group), 3)31 consecutive previous MI and/or stable A (SA) (stable CAD group; SCAD). We determine plasma concentration of gelatinase A (MMP-2), stromelysin-1 (MMP-3), gelatinase B (MMP-9) and specific tissue inhibitors of MMPs, such as TIMP-1 and TIMP-2. MMP-2 and MMP-9 total plasma activity was also measured along with serum concentration of C-reactive protein (CRP), haptoglobin (HPT), alpha 2-macroglobulin and tumor necrosis factor-alpha.
Results: MMP-9 concentration, but not total activity, was higher in ACS patients than in controls ($p<0.001$). Remarkably, neither MMP-9 concentration or total activity correlated with inflammation markers. MMP-2 total activity, but not MMP-2 concentration, was lower both in the whole population ($p=0.002$) and in ACS patients ($p<0.001$) compared to controls. MMP-2 total activity, but not concentration, correlated inversely with HPT ($r=-0.195$, $p=0.032$), blood glucose ($r=-0.250$, $p=0.006$) and total cholesterol levels ($r=-0.214$, $p=0.021$). MMP-3 concentration was similar in patients and controls. As regards TIMPs, the concentration of TIMP-1 was higher both in the overall population ($p<0.001$) and in ACS patients ($p=0.018$) with respect to controls. By contrast, TIMP-2 was lower in all groups of patients ($p<0.001$). TIMP-1 strongly correlated with blood glucose ($r=0.711$, $p<0.001$) and both CRP (0.594,$p<0.001$) and HPT ($r=0.276$,$p=0.005$). Among inflammation markers, only CRP and HPT were significantly higher in patients than in controls (both $p<0.001$).
Conclusions: in patients with premature CAD MMP-9 and TIMP-1 concentrations are increased and TIMP-2 concentration and MMP-2 total activity are decreased. The correlation of MMP and TIMP plasma levels with inflammation markers was restricted to TIMP-1 and MMP-2 total activity. These findings suggest that more attention should be focused on how inflammation and metabolic disorders could influence MMPs plasma concentration and activity.

805 Decreased baroreflex sensitivity depends on the atherosclerotic damage of the carotid arteries

B. Klosiewicz[1], W. Wasek[1], G. Raczak[2], A. Czepiel[1], P. Kulakowski[1], A. Budaj[1]. [1]*Grochowski Hospital, Department of Cardiology, Warsaw, Poland;* [2]*Medical University of Gdansk, II Department of Cardiology, Gdansk, Poland*

Low baroreflex sensitivity (BRS) in patients after acute myocardial infarction (AMI) has been proven as an independent risk factor of major cardiac events. It may be suspected that the atherosclerotic involvement of the carotid sinus may cause an impairment of the baroreceptors and influence BRS. To the best of our knowlege, this concept has not yet been tested in post AMI patients.
Methods: BRS was calculated from the measurement of the rate-pressure response to intravenous phenylehprine according to the protocol of the ATRAMI Study. Duplex Doppler ultrasonography of the carotid arteries was performed to identify the degree of the atherosclerotic lesions (ASC) in carotid sinus region. Intima-media complex (IMC) thickness was estimated as the mean value of 10 measurements performed 0.5 cm proximal to bifurcation. Advanced atherosclerosis (ASC +) was defined as bilateral concentric lesion involving >90% of the carotid sinus circumference. The involvement of less than 30% of the carotid sinus circumference was defined as non-significant atherosclerotic lesion (ASC -). Left ventricular (LV) systolic performance was estimated using ejection fraction (EF) and wall motion score index (WMSI) (using transthoracic echocardiography).
Results: The study group consisted of 38 patiens after AMI (mean 11.9 days after AMI, age 60.1 ± 12.6, men 68%). Mean IMC thickness was 0.74±0.18 mm. Mean value of BRS was 4.58±0.57 ms/mmHg. Significant negative correlation was found between BRS value and IMC thickness ($r=-0.74$, $p<0.0001$). Patiens with concentric, bilateral ASC more frequently had severely depressed BRS (<3 ms/mmHg) in comparison to the group without advanced ASC of carotid sinus (chi2=11.57, $p<0.001$)(table). No correlation was found between BRS and parameters of LV function - EF and WMSI ($p=0.88$ and $r=-0.03$, $p=0.51$ and $r=0.14$ respectively).

BRS (ms/mmHg)	ASC (+)	ASC (-)
<3	10 (26.3%)	5 (13.2%)
>3	2 (5.3%)	21 (55.2%)

Conclusion: The bilateral atherosclerotic involvement of the carotid arteries influence the BRS in patients after AMI despite the impairment of left ventricular function. The presence of bilateral, concentric atheromatic plaques results in very low BRS most likely due to baroreceptors damage.

Abstract 804 – Table

	STEMI (N=20)	UA/NSTEMI (N=29)	SCAD(N=31)	CTRL(N=40)	p
MMP-2 concentration (mcg/ml)	554.9±164.3	502.4±170.0	584.8±215.4	494.0±178.3	0.160

806 Cardiac calcification as independent predictor of increased mortality in patients with congestive heart failure: 29-month follow-up

G. Kamensky[1], E. Piknova[2], E. Polak[3], I. Ondrus[4], R. Sidlo[5]. [1]Ruzinov University Hospital, Dept. Noninvasive Cardiovasc. Diagnost, Bratislava, Slovakia; [2]Ruzinov University Hospital, Dept.Noninvasive Cardiovasc.Diagnost, Bratislava, Slovakia; [3]Ruzinov University Hospital, Dept. of Internal Medicine 1, Bratislava, Slovakia; [4]Ruzinov Faculty Hospital, Department of Internal Medicine 2, Bratislava, Slovakia; [5]University of Economy, Department of Statistics, Bratislava, Slovakia

Objectives: Multiple calcium deposits in the mitral annulus, aortic valve or aortic root are considered markers of CAD severity. However, no data are available concering the impact of those findings on mortality and morbidity in pts with CHF in a prospective follow-up study.
Methods: From January 1996 to January 2001 we prospectively studied 523 consecutive pts (223 males, 300 females, mean age 72±10y) admitted to hospital due to congestive heart failure (NYHA II-IV). Univariate and multivariate analyses were performed to test the association between the presence of aortic valve sclerosis (AVS), aortic root calcification (ARC) and mitral annular calcification (MAC) detected by 2D echocardiography, and 29-month mortality and morbidity. Results: The etiology of CHF was CAD in 218 pts (42%), HTN in 385 pts (74%), DM in 238 pts (46%), stroke in 50 pts (10%), dilated CMP in 17 pts (3%) and other in 103 (20%). AVS (1-Calc) was detected in 203 pts (39%), ARC (1-Calc) in 158 pts (30%) and MAC (1-Calc) in 189 pts (36%). AVS+ARC (2-Calc) were detected in 238 pts (46%) and AVS+ARC+MAC (3-Calc) in 311 pts (59%). No calcium deposits (0-Calc) were observed in 212 pts (40%). The mean follow-up was 28.6±16.3 months. Pts with 1-Calc, 2-Calc and 3-Calc were significantly older than those with 0-Calc (p=0.001). During the follow-up 47 (9%) pts of the 0-Calc group died compared to 165 (32%) pts of the 1-Calc,2-Calc and 3-Calc groups (p=0.001) and 8 (1.5%) pts of 0-Calc group suffered a stroke compared to 21 (4%) pts of the 1-Calc, 2-Calc and 3-Calc groups (p=0.01). Using the Kaplan-Meier survival curve model there was a 19% increase of total mortality in the 3-Calc group compared to pts in the 0-Calc group in the 29-month follow-up (log rank 47.3, p=0.001). After adjusted multivariate Cox proportional-hazard analysis, age (OR 1.05, p=0.0001, 95% CI 1.03-1.07), 1-Calc (OR 1.7, p=0.01, 95% CI 1.15-2.56), 2-Calc (OR 1.6, p=0.05, 95% CI 1.03-2.32) and 3-Calc (OR 2.2, p=0.0001, 95% CI 1.40-3.45) were the only independent predictor of increased mortality. Conclusion: Multiple cardiac calcification presents powerful independent predictor of increased mortality when risk factors for CHF are taken into consideration. This finding identifies a subgroup of pts with CHF as having 19% higher risk of mortality, which is independent of all confounding variables.

COST-EFFECTIVENESS OF CARDIOVASCULAR INTERVENTIONS

807 Carvedilol reduces the costs of medical care in severe heart failure: an economic analysis of the COPERNICUS study applied to the United Kingdom

S. Stewart[1], J.J.V. McMurray[1], A. Hebborn[2], A.J.S. Coats[3], M. Packer[4] on behalf of the COPERNICUS Study Group. [1]University of Glasgow, Glasgow, United Kingdom; [2]F. Hoffmann-La Roche AG, Pharma Division, Basel, Switzerland; [3]Royal Brompton Hospital, London, United Kingdom; [4]Columbia University, New York, United States of America

Aims: To determine the effect of carvedilol on the costs of treatment for severe heart failure (HF), we prospectively collected resource utilisation data (drug therapy, number of hospital admissions, length and type of hospital stay) in all patients randomized into the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) Study.
Methods: Costs for the treatment for HF within the National Health Service in the UK were applied to the COPERNICUS data. Unit-specific, per diem (hospital bed day) costs were used to calculate expenditures due to hospital admissions. We included costs of the drug, out-patient clinic visits and nursing home care based on estimates derived from prior evaluations of patterns of clinical practice in the UK.
Results: The estimated cost of carvedilol therapy and related ambulatory care (an average of 5.4 out-patient visits per patient for dosage adjustment) for the 1,156 patients assigned to carvedilol was £530,771 (£44.89 per patient/month of follow-up). However, those assigned to carvedilol were hospitalised less often and accumulated fewer and less expensive days of admission. Carvedilol was associated with a 27% reduction in all-cause hospital stay (7,124 versus 9,603 days: P = 0.0005). Consequently, the estimated cost of hospital care was £3.49 million in the carvedilol group compared with £4.24 million for the 1,133 patients in the placebo arm. The cost of post-discharge care (comprising outpatient and general practitioners visits in addition to nursing home care) was also less in the carvedilol than in the placebo group (£479,200 vs £548,300). Overall, the cost per patient treated in the carvedilol group was £3,889 compared to £4,209 in the placebo group. This equated to a cost of £385.98 vs £434.18, respectively, per patient per month of follow-up: an 11.1% reduction in health care costs in favour of carvedilol. In a series of sensitivity analyses it was found that treatment with carvedilol resulted in a reduction of overall treatment expenditure under a wide range of assumptions.
Conclusions: These findings suggest that carvedilol not only increases survival and reduces hospital admissions in patients with severe HF but likely cuts treatment costs in this patient population as well. This economic evaluation further supports the use of carvedilol in the treatment of HF.

808 A specialist nurse-led management programme in an outpatient population with stable congestive heart failure reduces annual health care costs

N.D. Palmer[1], B. Appleton[2], E.A. Rodrigues[2]. [1]The Cardiothoracic Centre, Cardiology, LIVERPOOL, United Kingdom; [2]University Hospital Aintree, Aintree Cardiac Centre, LIVERPOOL, United Kingdom

Background: A specialist nurse-led management programme reduces readmission rates and health care costs in patients hospitalised with severe congestive heart failure (CHF). It is unclear whether such a strategy in outpatients with stable CHF would have similar benefits. This prospective, randomized, single centre study assesses such a strategy with respect to hospital admission rates and healthcare costs over a one year period.
Methods: 55 patients (mean age 67 years) with stable CHF (NYHA II-IV) who were attending the cardiology clinic were assigned to receive either usual care (n=26) [Control] or a comprehensive nurse-led management programme which involved education on heart failure and self-management, regular review of medication and problems with compliance, and early identification of worsening CHF under the guidance of a consultant cardiologist (n=29) [Intervention]. Telephonic advice was made available to patients in this group throughout the study. All patients were followed up for 12 months. The main outcome measures were hospital admission rate and health care costs during the study period.
Results: Mean baseline characteristics were similar between the two groups including NYHA CHF class (2.7±0.5 vs 2.7±0.6, p=ns) and mean ejection fraction (31±14% vs 33±12%, p=ns). Reduced hospital (46.2% vs 13.8%, p=0.03) and CHF-related admissions (46,2% vs 6.9%, p=0.02) were noted in the intervention group. There was no difference in length of stay (7.3[10.2] days vs 7.5[11.4] days, p=ns). Mean clinic costs were higher in the intervention group (£294(23) vs £363(56), p=0.05). The mean hospital cost per patient were higher in the control group (£1114[542] vs £207[471], p=0.02). The mean overall annual healthcare cost was significantly lower in the intervention group (£570[512] vs £1409[581], p=0.03.

	Control	Intervention	p
All hospital admissions (%)	46.2	13.8	0.03
CHF-related admissions (%)	46.2	6.9	0.02
Mean hospital stay (days)	7.3(10.2)	7.5(11.4)	ns
Mean clinic/telephone costs (£)	294(43)	363(56)	0.05
Mean hosp. cost/patient (£)	1114(542)	207(471)	0.02
Mean total annual healthcare cost (£)	1409(581)	570(512)	0.03

Conclusions: In a population of outpatients with stable CHF, a specialist nurse-led management programme reduces total, and CHF-related, hospital admissions and is cost-effective.

809 Cost-effectiveness of valsartan in patients not receiving angiotensin-converting enzyme inhibitors at baseline

S.D. Reed[1], J.Y. Friedman[1], E.J. Velazquez[1], A. Gnanasakthy[2], R.M. Califf[1], K.A. Schulman[1]. [1]*Duke Clinical Research Institute, Durham;* [2]*Novartis Pharmaceuticals Corporation, East Hanover, United States of America*

Background: Val-HeFT was a multinational randomized trial conducted to evaluate the efficacy of the addition of valsartan to optimal pharmacologic therapy in 5,010 patients with NYHA class II-IV heart failure (HF). Subgroup analyses of 366 patients who were not receiving ACE inhibitors at baseline revealed a lower risk of within-trial mortality and morbidity among patients treated with valsartan.
Objective: To estimate the incremental cost-effectiveness of valsartan in patients not receiving concomitant treatment with ACE inhibitors.
Methods: A multinational cost-effectiveness analysis was conducted using data collected throughout the trial on resource utilization and clinical outcomes. An incremental cost-effectiveness ratio (ICER) is the appropriate measure of cost-effectiveness when a therapy is more effective and more costly. When a therapy is more effective and less costly, it is considered a dominant strategy. Direct medical costs were computed using unit costs from all 16 countries particpating in Val-HeFT (converted to 1999 U.S.$). To estimate the incremental difference in effectiveness, the area under the survival curve was calculated for both treatment groups during the trial period, and the difference is interpreted as life-years saved (LYS). Nonparametric bootstrapping was used to evaluate the variability in the joint distribution of costs and survival.
Results: The average period of follow-up was 23 months. Patients treated with valsartan experienced a 33% reduction in mortality, a 56% reduction in the number of HF-related hospitalizations (51 vs 117) and a 24% reduction in the number of all-cause hospitalizations (199 vs 262). Using point estimates of the differences in costs and survival, valsartan was shown to be a dominant treatment in patients not receiving an ACE inhibitor: mortality was significantly reduced and the within-trial costs were $929 lower on average [95% CI: -3,243 to $1,533]. The average within-trial survival benefit among patients treated with valsartan was estimated at ~2.2 months. When evaluating variability associated with these estimates, in 78.0% of the 1,000 bootstrap replicates, valsartan was less costly while reducing mortality. In an additional 17.9% of the replicates, an ICER of less than $10,000/LYS was computed. When combining these results, in 95.9% of bootstrap samples, treatment with valsartan was either cost-saving or had an ICER below $10,000/LYS.
Conclusions: Inhibition of the renin-angiotensin system with valsartan was shown to be a dominant or economically attractive therapy in patients not taking ACE inhibitors.

810 Drug-eluting stents in coronary artery disease: assessment of outcomes and cost effectiveness

M. Lamotte[1], L. Annemans[2], P. De Jong[3]. [1]*HEDM, Meise, Belgium;* [2]*University of Ghent, Ghent, Belgium;* [3]*Cordis Europe, Waterloo, Belgium*

Objectives: Restenosis limits the long-term success of coronary angioplasty in patients with coronary heart disease. Drug-eluting stents have been associated with very low restenosis rates (RAVEL and FIM trials). We assessed the economic value of the Sirolimus-eluting Bx-VELOCITY TM stent (CYPHER TM) in different indications with a high restenosis rate, with Belgium as case country.
Research design and methods: A decision model was developed to predict the 1-year cost-effectiveness comparing balloon angioplasty, conventional stenting, coronary artery bypass grafting (CABG) and CYPHER TM-stenting. Three indications were studied: small-diameter single-vessel disease, long single-vessel lesions and multi-vessel disease. Clinical data were obtained for small-diameter single-vessel from the RAVEL trial; for multi-vessel disease from the ARTS trial; and for long-lesions from a published clinical model. Given the experience with the RAVEL and FIM trials, the relative risk reduction in clinically driven re-intervention rate with CYPHER TM versus conventional stenting was assumed to be 95% for long lesions and equivalent to CABG for multi-vessel disease. Incremental cost-effectiveness is expressed as cost per revascularisation avoided.
Results: At a cost of 2,300 Euro per CYPHER TM-stent, incremental cost-effectiveness of CYPHER TM-stenting compared to conventional stenting varies between 1,119 Euro/revascularisation avoided in small-diameter single-vessel disease (see table) to 2,947 Euro in long-lesions. In multi-vessel disease CYPHER TM-stenting is dominant over CABG.

	Acute	Follow up	Total Cost	Incr. costs	Revasc.	Avoided	ICER
BALLOON	3914	1665	5579	-382	0.2651	-0.0414	9227
STENT	4586	1374	5960	–	0.2237	–	NA
CYPHER	910	285	6195	235	0.0139	0.2099	1119
CABG	12264	141	12405	6445	0.0400	0.1837	35075

ICER = incremental cost effectiveness ratio (cost per avoide revascularisation)

Conclusions: With the currently available data and applied profile, CYPHER TM-stenting is cost-saving in multi-vessel disease, and cost-effective in small-diameter and long single-vessel lesions.

811 Cost and cost effectiveness at 1 year in the stent or surgery trial (SoS)

W. Weintraub[1], E. Mahoney[1], Z. Zhang[1], J. Booth[2], J. Hutton[3], R. Stables[4], F. Nugara[2], M. Buxton[5] on behalf of SoS Investigators. [1]*Emory University, Atlanta, United States of America;* [2]*Royal Brompton & Harefield NHS Trust, London;* [3]*Medtap International, London;* [4]*Cardiothoracic Centre, Liverpool;* [5]*Brunel University, Uxbridge, United Kingdom*

Background Randomised trial data showed that balloon angioplasty had lower initial hospitalisation costs compared to coronary artery bypass grafting (CABG) but has higher down stream costs due to the increased need for repeat revascularisation. Stents add to the initial cost of angioplasty, but by reducing repeat revascularisation may make PTCA both more clinically and economically attractive. We compared the cost and cost effectiveness of CABG and percutaneous coronary intervention with stents (PCI).
Methods SoS is a multi-national randomised trial involving 53 centres in Europe and Canada. Patients with multi-vessel coronary disease who were accepted by the interventionist and the surgeon for coronary revascularisation were eligible. Cost is based on detailed resource use in both initial and additional revascularisations, on hospital length of stay (LOS) at the initial procedure and all follow up hospital admissions, complications (MI, stroke, bleed) and cardiac medications at UK costs. 'Quality adjusted life years (QALYs) were estimated from individual patient survival and EQ-5D classifications at 3 timepoints, valued using UK population health state utility values. Cost effectiveness was measured in cost per life year gained and cost per QALY gained.
Results A total of 988 patients were randomised: CABG group 500, PCI group 488. The initial hospitalization costs were higher in the CABG group compared to PCI: £7,316 versus £3,844 (difference = £3,471, 95% CI £3,071 to £3,880). At one year the cost difference narrowed but remained higher for CABG £8,900 versus PCI £6,257 (difference = £2,643, 95% CI £1,814 to £3,343). The incremental cost effectiveness ratio (ICER) for CABG compared to PCI is £192,474 per life year gained (95% CI £77,377 to £1,085,464). The cost utility of ratio of CABG compared to PCI is £1,719,582 per QALY gained (95% CI inestimable).
Conclusion Over a one year time period CABG is more expensive than PCI and offers little added benefit in terms of QALYS. It appears that the additional initial cost of CABG could only be justified if there were continued and significant cost savings compared to PCI with stents in subsequent years.

812 Australian analysis of the HOPE study: clinical and economic benefits of ramipril in terms of events avoided and the cost/life year saved

M. Smith[1], M. Neville[2]. [1]*Aventis Pharma, Health Economics, Lane Cove, Sydney, Australia;* [2]*The Lewin Group, Health Economics, Sydney, Australia*

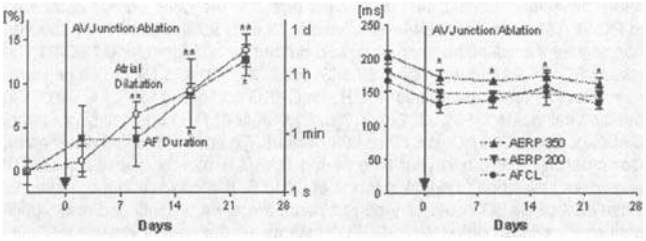
Objective: From an Australian perspective, to assess the clinical and economic impact of the use of daily ramipril 10 mg over a period of 5 years in an at-risk population as described in the groundbreaking Heart Outcomes Prevention Evaluation (HOPE) study.
Methods: Clinical benefits. To assess the clinical benefits, the result for each endpoint as reported in the HOPE paper (cardiovascular death, myocardial infarction, stroke & revascularisation) is converted to number-needed-to-treat (NNT). NNT is the reciprocal of the absolute risk reduction. The at-risk population, as defined by the HOPE investigators, was estimated nationally and per typical general practitioner from the relevant Australian statistics. The at-risk population is then divided by the NNT to estimate the potential number of strokes, CV deaths, MIs and revascularisations avoided.
Methods: Economic benefits. To assess the economic benefits, an incremental cost-effectiveness analysis was conducted. The model considered the costs and cost offsets arising from ramipril use for the 5 year period of the study. Costs were those associated with ramipril treatment and pathology testing. Cost offsets were those associated with: 1) a reduction in the use of other ACE inhibitors, and 2) a reduction in the primary endpoints of MI and stroke and in the secondary endpoint of revascularisation. Life years saved was approximated by calculating the difference in total years survived between the ramipril and control arms of the study. Net costs divided by life years saved is the cost per life year saved and this is reported in Australian dollars.
Results: Clinical benefits. Based on an Australian population of ~615,000 appropriate at-risk people, the use of ramipril 10 mg daily for 5 years is estimated to potentially prevent 9188 strokes, 14658 myocardial infarctions, 14317 CABG/PTCA procedures and 12534 cardiovascular related deaths. For a typical Australian general practitioner who has ~38 appropriate at-risk people, just under 1 of each type of these events (stroke, MI, CV death & revascularisation) can potentially be prevented.
Results: Economic benefits. The incremental cost effectiveness analysis estimates the cost per life year saved to be $17,214.
Conclusion: Based on the HOPE study, we have assessed the clinical and economic impact of daily ramipril 10 mg in an at-risk Australian population over a 5 year period. Ramipril provides clinically significant benefit both nationally and per general practitioner at a cost per life year saved which is comparable to other interventions.

FUNDAMENTAL ASPECTS OF ATRIAL FIBRILLATION

813 Atrial remodelling in the goat due to chronic complete atrioventricular block

H.-R. Neuberger, U. Schotten, J. Ausma, Y. Blaauw, S. Eijsbouts, A. van Hunnink, M. Allessie. *University Maastricht, Department of Physiology, Maastricht, Netherlands*

Atrial dilatation is an independent risk factor for the development of atrial fibrillation (AF) in humans. However little is known about the effects of chronic dilatation on atrial electrophysiology.
Methods: In 6 goats we implanted 2 atrial and 1 ventricular screw-in lead. At the tip of each atrial lead we mounted a pair of sonomicrometer crystals to measure the right atrial diameter. After a control period of 2 weeks (sinus rhythm, 120 bpm), radiofrequency ablation of the atrioventricular junction was performed and a stable ventricular escape rhythm of 50 bpm occurred. Atrial diameter, atrial refractory period (AERP), AF cycle length (AFCL) and the duration of AF episodes induced by burst stimulation were measured during 3 weeks of complete AV block.
Results: Chronic complete AV block caused progressive atrial dilatation up to 14% after 3 weeks (Fig. 1). Parallel to the increase in atrial size the duration of induced AF episodes prolonged from 13 seconds to more than 8 hours. Two days after AV junction ablation both AERP and AFCL decreased, but they kept constant during the following 3 weeks (Fig. 1).



Conclusions: Chronic AV block in the goat results in progressive atrial dilatation and prolongation of AF episodes. Shortening of the atrial effective refractory period (electrical remodeling) cannot explain the prolonged AF duration. The high correlation between atrial dilatation and AF duration suggests that atrial dilatation per se plays an important role in the creation of a substrate of persistent AF.

814 Gene expression profiling of human myocardium with atrial fibrillation by DNA microarray analysis

R. Ohki[1], K. Yamamoto[1], S. Ueno[1], H. Mano[2], K. Fuse[3], U. Ikeda[1], K. Shimada[1]. *[1]Jichi Medical School Hospital, Cardiology Dept., Tochigi, Japan; [2]Jichi Medical School Hospital, Division of Functional Genomics, Tochigi, Japan; [3]Jichi Medical School Hospital, Cardiovascular Surgery, Tochigi, Japan*

Background - The molecular mechanism causing atrial fibrillation in human myocardium remains incompletely defined. We here used powerful DNA microarray technology for transcriptional profiling of genes induced in atrium of the patients with atrial fibrillation.
Methods - We used right atrium of patients who underwent cardiac surgery. On the basis of electrocardiographic findings, the patients were divided into 2 following groups: sinus rhythm group (n=10) and atrial fibrillation group (n=7). Expression profiles of 12000 human genes using the Affymetrix GeneChip (Human Genome U95A) were investigated with mRNA obtained from the atria. Quantitative analysis of selected genes was performed by the real-time PCR method.
Results - In the atrial fibrillation group, 33 genes including an ion channel, an antioxidant, an inflammation, 3 cell growth/cell cycle, 3 transcription, several cell signaling and several protein genes, and 7 expressed sequence tags (ESTs) were significantly activated (>1.5 fold, $p<0.05$) compared with those in sinus rhythm group. In contrast, 63 genes including several cell signaling/communication such as sarcoplasmic reticulum Ca2 ± ATPase 2, several cellular respiration and energy production and 2 antiproliferative or negative regulator of cell growth genes, and 22 ESTs were decreased (<0.5 fold, $p<0.05$) compared with those in sinus rhythm group.
Conclusion - These findings suggest that these genes may play critical roles in the initiation or the persistence of atrial fibrillation and pathophysiology of atrial remodeling.

815 Atrial expression of matrix-metalloproteinases in fibrillating human atria

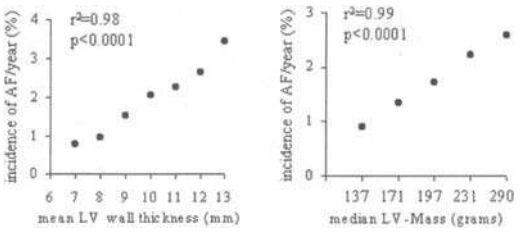
A. Goette[1], K. Nepple[1], M. Arndt[2], C. Röcken[3], C. Huth[4], S. Ansorge[2], H.U. Klein[1], U. Lendeckel[2]. *[1]University Hospital Magdeburg, Cardiology, Magdeburg, Germany; [2]University Hospital Magdeburg, Experminental Medicine, Magdeburg, Germany; [3]University Hospital Magdeburg, Pathology Dept., Magdeburg, Germany; [4]University Hospital Magdeburg, Cardiovascular Surgery, Magdeburg, Germany*

Background: Atrial tissue from patients with atrial fibrillation (AF) shows significant structural changes like fibrosis and degenerative alterations. In this setting, remodeling of the extracellular matrix by matrix metalloproteinases (MMP) may contribute to changes in atrial size and mechanical function. The purpose of the present study was to quantify atrial MMP expression in patients with and without AF.
Methods: Right atrial tissue samples from 28 patients undergoing open-heart surgery were examined. Fourteen patients had chronic persistent AF (> 6 months), the remaining 14 patients were in sinus rhythm (SR). Atrial expression of matrix metalloproteinases (MMP)-1, MMP-2 as well as TIMP-1 (tissue inhibitor of metalloproteinase-1) was quantified at the protein level by Western blotting. MMP-1 (collagenase) activity was analyzed by zymography. Immunohistochemistry was used to localize MMP expression in the tissue samples.
Results: Baseline clinical parameters were comparable in the two groups. The left atrial diameter was significantly increased in patients with AF (AF: 4.9 ± 0.2 cm vs. SR: 4.3 ± 0.2 cm; $p<0.05$). MMP-1 and MMP-2 were predominantly expressed in atrial fibroblasts and myocytes in both groups. The amount of MMP-1 protein was significantly reduced in patients with AF (SR: 5.3 ± 0.68 U vs. AF: 2.79 ± 0.60 U; $p<0.05$). In addition, the collagenolytic MMP-1 activity was also lower in fibrillating atrial tissue (SR: 1.73 ± 0.43 ng/μg protein vs. AF: 0.74 ± 0.17 ng/μg protein; $p<0.05$). In contrast, the amounts of MMP-2 (SR: 1.13 ± 0.2 U vs. AF: 0.93 ± 0.20 U; p=ns) and TIMP-1 (SR: 1.06 ± 0.20 U vs. AF: 0.82 ± 0.30 U; p=ns) were similar in both groups.
Conclusions: AF is associated with down-regulation of atrial MMP-1 activity. Reduced collagen degradation by collagenase may contribute to the structural remodeling and collagen accumulation in fibrillating human atria.

816 The degree of left ventricular hypertrophy predicts the incidence of atrial fibrillation

K. Neven, R.G. Tieleman, E.C. Cheriex, H.J.G.M. Crijns. *Maastricht, Netherlands*

Introduction: In population based studies, the presence of left ventricular hypertrophy is being associated with the development of atrial fibrillation. We further explored a possible "dose-response" relationship between the degree of left ventricular hypertrophy and the incidence of atrial fibrillation.
Methods: From a computerized database which contains the results from all echocardiograms (including rhythm notation) that were performed in our institution from 1986 until present, we retrieved all patients with multiple examinations and sinus rhythm during the first ultrasound. The development of atrial fibrillation during the latest echo was evaluated in relation to left ventricular wall thickness at presentation.
Results: In total 8056 patients were studied, their mean age was 58 ± 15 years, there were 4579 males. 514 Patients developed atrial fibrillation during a median follow-up between the 2 ultrasounds of 37 months, range 1 to 194 months. There appeared to be a strong correlation between the mean value of the septal and posterior left ventricular wall thickness and the incidence of atrial fibrillation during follow-up (see Figure 1). The same is true for the correlation between subsequent quintiles of left ventricular mass and the incidence of atrial fibrillation (see Figure 2).

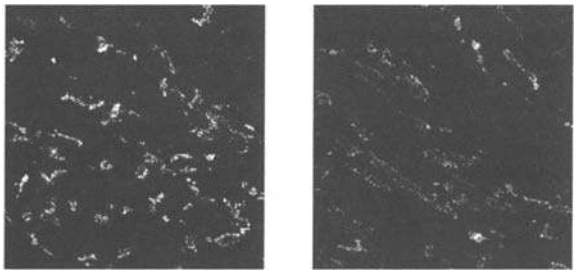


Conclusion: There is a strong linear correlation between the degree of left ventricular hypertrophy and the incidence of atrial fibrillation. Future studies are needed to clarify the mechanism behind this relation.

817 Connexin 40 is decreased in the right atrium of patients with persistent atrial fibrillation

M. Wilhelm[1], W. Kirste[1], C. Garlichs[1], K. Amann[2], W.L. Neuhuber[3], M. Weyand[4], W.G. Daniel[1]. *[1]University of Erlangen, Department of Internal Medicine II, Erlangen, Germany; [2]Institute of Pathology, Erlangen, Germany; [3]Institute of Anatomy, Erlangen, Germany; [4]Department of Cardiac Surgery, Erlangen, Germany*

Introduction: Altered expression of gap junction proteins (connexins, Cx) lead to abnormal electrical coupling between cardiomyocytes. Goats with pacing-induced atrial fibrillation (AFib) showed marked inhomogeneities in the pattern of Cx 40 distribution. We studied the distribution of Cx 40 and 43 in patients (Pts) scheduled for heart surgery.
Methods: Samples of right atrial appendages were frozen in liquid nitrogen. Sections of 10 μm were incubated with antibodies against Cx 40 or 43, stained with an Alexa Fluor 660 dye and examined with a confocal laser scanning microscope.
Results: Patient data and Cx distribution are presented in the table. Cx 40 was significantly decreased in Pts with persistent AFib compared to SR. There was no significant difference between Pts with intermittent or postoperative AFib.



Cx 40 in SR (left) and AFib (right).

Patient data and Connexin distribution.

	Group 1	Group 2	Group 3	Group 4
n	20	12	4	12
age	65±10	69±9	76±3	72±6
atrial size>45 mm (%)	5	50 *	25	17
Cx 40 (%)	3,7± 1,6	2,0±0,9 *	4,3±2,1	2,8±1,9
Cx 43 (%)	4,1±2,0	3,7±1,7	4,6±0,8	5,0±1,7

Group 1: Pts with SR,Group 2: Pts with persistent AFib>3 month,Group 3: Pts with intermittent AFib and preoperative SR,Group 4: Pts with postoperative AFib. * p<0,05

Conclusion: Decreased amounts of Cx 40 might contribute to the maintenance of AFib due to microheterogeneities in conduction velocity.

818 Correlation between the human sinoatrial node and the crista terminalis in the posterior right atrium

T. Matsuyama[1], S. Shin Inoue[2], Y. Youichi Kobayashi[3], T. Tsukasa Saito[3], T. Toshihiko Otsuka[3], T. Takashi Katagiri[3], H. Hidekazu Ota[1]. *[1]Showa University School of Medicine, Second department of pathology, Tokyo, Japan; [2]Showa University Toyosu Hospital, Department of Internal Medicine, Tokyo, Japan; [3]Showa University School of Medicine, Third Department of Internal Medicine, Tokyo, Japan*

Background: Several recent observations have suggested that conduction block or penetration of crista terminalis (CT) influence the type of atrial flutter and its perpetuation. The anatomical relationship of the CT and the sinoatrial node (SN), known as a structure adjacent to CT has not been fully understood in particular regarding its inferior margin. We examined the distribution of SN along CT in order to clarify the anatomical relevance to myocardial connection of the posteromedial right atrium.
Methods: Eighteen autopsied hearts aged 31 to 89 years (mean 64.0 years, 10 male and 8 female) were studied. None of the cases showed conspicuous supraventricular arrhythmia. The whole length of CT was excised after fixation with formaldehyde and cut perpendicular to the longitudinal axis into 10 mm thick slices. Each tissue sample was serially sectioned at a thickness of 10 micrometer and every 100th section was stained. We measured and reconstructed the distribution of SN on the endocardial aspect of the right atrium.
Results: The length of the SN ranged from 11 to 40 mm (mean 22 mm) and that of CT was from 26 to 60 mm (mean 44 mm). The SN usually located between CT and the posterior wall of the right atrium, and distributed from 24.4 to 85.7% (mean 52.6%) of the whole CT length. In many cases, the SN was adjacent to thick musculature of CT throughout its whole length, but in some cases the junction to the posterior right atrial myocardium showed fibrofatty replacement.
Conclusion: The distribution of the SN was highly variable and its length was unexpectedly long in some patients. This diversity of the length of the SN likely influences the conduction across the CT of patients with typical atrial flutter.

ATRIAL FIBRILLATION BURDEN REDUCTION BY PACING

819 Suppression of paroxysmal atrial fibrillation by a dedicated pacemaker: correlation between atrial tachycardia burden and quality of life

G. Groenefeld, C.W. Israel, J. Ehrlich, S.H. Hohnloser. *J.W. Goethe University, Cardiology, Frankfurt, Germany*

Recently, pacemakers with specific algorithms for suppression and atrial overdrive pacing therapy (DDDRP) in patients (pts) with paroxysmal atrial fibrillation (pAF) have been introduced. Preliminary results have demonstrated a reduction of atrial arrhythmia frequency with activation of the dedicated algorithms and beneficial effects on quality of life (QoL) in selected patients. The contribution of pAF, and the effects of DDDRP on the overall QoL in these patients, however, remain ill defined.
Methods: Consecutive pts with a class I indication for DDD pacing (P-ind) and prior documentation of pAF were implanted with a DDDRP device (Medtronic AT500). Atrial tachycardia burden (AtB) was defined as the percentage of total time while a patient suffers from pAF according to the monitored and stored electrograms of the device. All pts completed the short form health survey questionaire (SF-36) at implant, at 3 months (mo), and 12 mo follow-up.
Results: Data from 41 pts (60% male; mean age 68±9 years) were analyzed. Mean values for AtB remained unchanged with DDDRP from 8±15% at baseline to 9±17% at 3 mo and 13±27% at 12 mo (p=0.24). In 12 pts, a reduction in AtB occurred, AtB remained unchanged in 10 pts, while 19 pts had an increase of AtB during follow-up. In contrast to AtB, the mean value of 6/8 subscales of SF-36 significantly improved from implant to 3 mo follow-up, and remained stable until one year thereafter. Individual improvements on SF-36 were comparable in pts showing a reduction in AtB compared to non-responders. Pearson analysis found no correlation between AtB and any subscale of SF-36 at baseline or during follow-up.
Conclusion: The reduction of AtB in a subset of patients during 12 months after DDDRP implantation does not significantly impact on QoL according to SF-36. In pts with established P-ind, the observed improvement in QoL seems to be dominantly caused by the effects of antibradycardia pacing therapy.

820 Prevention of atrial fibrillation by DDD+ atrial overdrive pacing: final results of a randomized crossover study

P. Attuel[1], K.H. Konz[2], J. Brachmann[3], D. El Allaf[4], C. Gomes[5], I. Szendey[2], V. Schibgilla[3], D. Danilovic[6] on behalf of the Inos DDD+ Study Investigators. *[1]Ctr. Médico-chirurgical Parly 2, Le Chesnay, France; [2]Maria Hilf Clinics, Mönchengladbach; [3]Coburg Clinics, Coburg, Germany; [4]Hutois Hosp. Ctr., Huy, Belgium; [5]Heart Inst., Taguatinga, Brazil; [6]Biotronik, Erlangen, Germany*

Introduction: Dynamic atrial overdrive stimulation at a rate slightly above the intrinsic rate is a newly proposed method to suppress recurrences of atrial tachyarrhythmia (AT) in pacemaker (PM) patients (pts). Our study evaluated clinical efficacy of the DDD+ overdrive mode implemented in dual-chamber Inos2 CLS PMs (Biotronik, Germany).
Methods: 100 pts with paroxysmal AT and conventional pacing indications (71% SSS, 25% AVB) were randomized in 19 clinical centers to DDD+ or conventional DDD mode at 3 months after PM implantation. A bipolar atrial lead was placed in the right appendage (60%) or laterally (40%). The basic rate was programmed to 61.5 ± 4.3 bpm. Upon sensing an atrial event, the DDD+ mode increased the pacing rate by 8 ± 2 bpm (programmed range 4-12), which was followed by 1 bpm rate decrease after each 20 ± 3 atrial beats. Mode crossover took place 6 months after randomization and the pts were followed for additional 6 months in the other mode. The cumulative duration of sustained (>60 s) AT episodes was extracted from the PM memory and compared for the two modes on intrapatient basis (paired two-tailed t-test). The comparison was made for the entire study population as well as for different subgroups of pts in order to evaluate clinical predictors of the overdrive therapy outcome.
Results: Crossover data were collected in 75 pts; the remaining 25 pts were drop-outs. The percentage of atrial pacing (AP%) was increased from 58±32% (DDD) to 95 ± 11% (DDD+, p<0.001), and the mean heart rate from 66.9±6.1 bpm (DDD) to 72.8±7.8.bpm (DDD+, p<0.001). The AT burden in the entire population was reduced by 26%, from 16.3 (DDD) to 12.0 hours/wk (DDD+, p=0.066). In 32 pts with AT burden >2% of time, the reduction was 28%, from 37.8 (DDD) to 27.0 h/wk (DDD+, p=0.044). The subgroups of pts with the most significant reduction in AT burden by overdrive pacing were: 50 pts with <80% of AP% in DDD mode: 16.1 (DDD) vs 8.8 h/wk (DDD+, 45% reduction, p=0.016), 25 pts with the basic rate set to 65-75 bpm: 29.0 (DDD) vs 16.6 h/wk (DDD+, 43% reduction, p=0.011), and 37 pts who did not use class II antiarrhythmics: 18.2 (DDD) vs 9.2 h/wk (DDD+, 50% reduction, p=0.021). In the complementary groups to these 3 subgroups, there was no additional benefit of DDD+ over DDD pacing (0-11% reduction in AT burden, p-values 0.57-0.95).
Conclusions: The DDD+ overdrive pacing exerted comparatively strongest antiarrhythmic effect (vs. DDD pacing) in pts paced <80% of time in the DDD mode, in pts with basic rates set to 65-75 bpm, and in pts using no Class II antiarrhythmics.

821 Can we reduce atrial fibrillation by atrial overdrive pacing? Lessons from conventional DDD antibradycardia pacing

A. Yang, T. Lewalter, M. Hochhäusler, J. Schrickel, R. Schimpf, H. Bielik, J.O. Schwab, B. Lüderitz on behalf of the VIP Study Group. *University of Bonn, Department of Cardiology, Bonn, Germany*

The objective of the study was to evaluate the effectiveness of atrial pacing in the prevention of AF in patients with conventional DDD antibradycardia pacing.
Methods: 52 patients (66 ± 11 years) with dual chamber pacing (Vitatron, "Selection" Series) and a history of paroxysmal AF were included. AF preventive algorithms including atrial overdrive pacing ("PACE Conditioning") were switched off. The data obtained by the PM diagnostic features after a mean follow-up of 96 ± 28 days include: (1) number of premature atrial contractions per hour (PAC's/hour), (2) total AF burden (% of storage period), (3) mean episode duration (hours), (4) number of AF episodes/day, (5) percentage of atrial pacing. According to the frequency of atrial pacing the patients were divided into Group A (atrial pacing rate >50%) and Group B (atrial pacing rate <50%).
Results: Patients with a high rate of atrial pacing (Group A) not only presented significantly smaller numbers of PAC's/h during sinus rhythm (26.3 ± 27.3 vs. 100.8 ± 184.5, $p<0.05$), but also a significantly lower total AF burden (7.4 ± 13.5% vs. 25.0 ± 31.1%, $p<0.01$) and shorter mean AF episodes (1.2 ± 2.2 h vs. 9.0 ± 20.4, $p<0.05$). The number of AF episodes/day did not differ significantly between both groups (2.0 ± 3.4 vs. 2.8 ± 4.1, $p=0.46$).
Conclusions: 1. Atrial pacing during conventional DDD pacing reduces the PAC activity during sinus rhythm, total AF burden and duration of the AF episodes but not the AF recurrence rate. 2. These results may be explained by an electrical substrate modulation due to atrial pacing. 3. We conclude that "permanent" atrial overdrive pacing is suited for the AF preventive therapy, preferentially in patients with a low atrial pacing rate during conventional DDD pacing. Yet, the impact of overdrive pacing on the AF recurrence rate has still to be studied.

822 Comparison of atrial overdrive, DDDR and CLS pacing in reducing atrial fibrillation burden in Brady-Tachy syndrome patients

P. Santarelli[1], G. Critelli[2], G. Altamura[3], S. Favale[4], G. Pettinati[5], F. Capestro[6], A. Puglisi[7]. *[1]Columbus Hospital, Rome, Italy; [2]Policlinico Umberto I, Rome, Italy; [3]S. Giacomo Hospital, Rome, Italy; [4]Policlinico Consorziale, Rome, Italy; [5]F. Ferrari Hospital, Casarano (LE), Italy; [6]Lancisi Hospital, Ancona, Italy; [7]Fatebenefratelli Hospital, Rome, Italy*

Standard atrial overdrive pacing algorithms have been designed to reduce Atrial Fibrillation (AF) recurrences in patients (pts) with Brady-Tachy Syndrome (BTS); however they do not provide physiological rate modulation. The aim of this study is to compare atrial pacing percentage (AP%) and AF Burden, measured as time spent in AF, in BTS pts treated with conventional DDDR pacing, DDD+ overdrive or physiological Closed Loop Stimulation (CLS). We present a preliminary data analysis of the study. Methods: 131 BTS pts (72 female, mean age 76±9), received a dual chamber pacemaker (Philos DR, Inos2+, Biotronik). Ischemic heart disease was present in 12% of pts, hypertension 47% and other or no heart disease in 41%. After the first month, pts were randomized to DDDR, DDD+ or CLS pacing, and controlled at 4- and 7-months. At each follow-up AP% and AF Burden were analysed using F test or Kruskal-Wallis test, where applicable, and SNK test for multiple comparisons.
Results: (see table below). At 4-month follow-up (47 pts) AP% was significantly higher in CLS and DDD+ groups compared to DDDR group. This difference was not confirmed at 7-month follow-up (26 pts) but AP% in CLS group remained higher than in DDDR group. AF Burden, as expected, showed a great variability among groups. However, although not statistically significant ($p=0,08$ at 4-months and $p=0,12$ at 7-months), CLS mode was associated with a markedly lower AF Burden trend at both follow-up visits.

AP% and AF Burden

4 month follow-up	AP%	AF Burden (min/day)
DDDR (N=17)	78 ± 24 *^	86±199 (8%±16%)
CLS (N=13)	92 ± 18 ^	17±59 (2%±7%)
DDD+ (N=17)	94 ± 14*	154±303 (11%±17%)
7 month follow-up	AP%	AF Burden (min/day)
DDDR (N=10)	68 ± 25	130±302 (9%±17%)
CLS (N=7)	79 ± 17	6±15 (4%±9%)
DDD+ (N=9)	93 ± 9	178±417 (14%±20%)

*$p<0,05$, ^$p<0,05$

Conclusions: In BTS pts: 1. CLS and DDD+ pacing are associated with a higher AP% than DDDR pacing; 2. CLS pacing shows a better trend in terms of AF Burden Compared to the DDDR and DDD+ pacing; 3. These preliminary results seem to support the use of physiological heart rate modulation (CLS pacing) in the treatment of BTS pts.

823 Significant reduction of AF burden by the AF suppression™ algorithm

A. Beinhauer[1], P. Vock[1], H. Nobis[2], W. Kainz[3], M. Gruska[3], S. Winter[4], M. Migschitz[5]. *[1]A.ö. KH St. Poelten, Cardiology, St. Poelten, Austria; [2]Hospital Lainz, Cardiology, Vienna, Austria; [3]Hospital Hanusch, Cardiology, Vienna, Austria; [4]Hospital Elisabethinen, Cardiology, Linz, Austria; [5]St. Jude Medical, CRMD, Vienna, Austria*

Introduction: Successful suppression of paroxysmal atrial fibrillation (PAF) using the AF Suppression™ algorithm (St. Jude Medical) has been studied. AF Suppression™ paces the atrium just above the patient's natural circadian rate without employing a fixed high rate.
Methods: The international, multi-center ADOPT-ALL study is a prospective, randomized, single-blinded cross-over, study of 250 patients with history of PAF. The objective was to investigate whether DDDR pacing with the AF Suppression™ algorithm could reduce episodes of atrial fibrillation more effectively than DDDR pacing alone (as Auto-Mode-Switch (AMS) burden and AF burden).
Results: Presently 230 patients are enrolled internationally, 75 patients in the Austrian centers, 44 Austrian patients with a stable anti-arrhythmic drug regimen have finished the 6 month follow-up. The reduction of mean AMS burden and mean AF burden has been calculated (Table 1) as well as the percentage of atrial pacing and the mean heart rate (Table 2).

Table 1. Mean AMS and AF burden in % of total follow-up time

	AF Suppression OFF	AF Suppression ON	Reduction in %	p-Value
Mean AMS burden (n=44)	6,9	3,5	49,4	<0,04
Mean AF burden (N=44)	6,6	3,0	54,0	<0,04

Table 2. Mean heart rate in /min

	AF Suppression OFF	AF Suppression ON	p-Value
% of atrial stimulation	68,15 ± 28,0	95,03 ± 11,7	<0,00001
Mean heart rate	68,74 ± 7,0	70,68 ± 7,6	n.s.

Conclusion: These results show that the AF Suppression™ algorithm reduces significantly mean AMS burden and mean AF burden in patients with sinus node dysfunction and paroxysmal or persistent atrial fibrillation. The percentage of atrial stimulation was highly increased (by about 40%) nevertheless the mean heart rate did only slightly increase (2.8%). The AF Suppression™ algorithm was very well tolerated by all patients and has not been turned off in any patient.

824 Effect of pacing for prevention and termination of atrial tachyarrhythmias on arrhythmia burden over a 12 month period

C.W. Israel, G. Grönefeld, J.R. Ehrlich, Y.G. Li, S.H. Hohnloser. *J. W. Goethe University Hospital, Cardiology, Frankfurt, Germany*

Atrial pacing techniques are being used for prevention and termination of atrial tachyarrhythmias (ATs). The present study analyzed the effect of 3 combined algorithms for AT prevention together with atrial antitachycardia pacing (ATP) on the time that the patient (pt) spends in AT (AT burden).
Methods: In pts with a conventional pacing indication and ATs, a DDDRP pacemaker (AT500, Medtronic Inc, MN) was implanted. Memory functions for AT episodes (atrial electrograms, marker annotations) and AT burden were activated after implantation. After 1 month, reliability of AT detection was assessed on the basis of stored annotated atrial electrograms, and algorithms for AT prevention (continuous overdrive, atrial rate stabilization, post mode switching overdrive) and atrial antitachycardia pacing modes (burst, ramp) were activated. Devices were interrogated after 1, 3, 6 and 12 months. At 12 months, AT burden was classified into 6 groups: 1. 0% (no AT episodes after activation of preventive pacing), 2. less or equal to 1%, 3. 1-99% with constant decrease, 4. 1-99% with no change, 5. 1-99% with constant increase, 6. 100% (persistent for the final 6 months).
Results: In 60 pts (sick sinus syndrome 39, AV block 12, binodal disease 2, planned AV node ablation 7, carotid sinus syndrome 1) and ATs (atrial fibrillation 54, atrial flutter 22, ectopic AT 3) which were persistent in 27 pts, mean AT burden was 12 ± 24% after 1 month (no preventive pacing) and 14 ± 29% after 12 months. Twenty pts (33%) had no AT episode, in 10 pts (17%) AT burden was less or equal to 1%. In 9 pts (15%), the AT burden was 1-99% and showed a constant decrease, in 7 pts (12%) it remained unchanged, and in 10 pts (17%) it increased continuously. Four pts (7%) had a progression to permanent AT.
Conclusion: In approximately 1/3 of pts, pacing for prevention of AT completely suppressed AT. Another 1/3 responded well to pacing with an AT burden less or equal to 1% or a constant decrease of AT burden. In 1/3 of pts, AT burden was unchanged or even increased despite these pacing techniques.

WE ARE STILL ON THE WAY: DRUG ELUTING AND COATED STENTS

861 Oral rapamycin to inhibit restenosis in de novo coronary lesions requiring stenting: the ORBIT study

R. Waksman, A.E. ajani, E. Cheneau, L. Leborgne, E. Stabile, A.D. Pichard, L.F. Satler, K.K. Kent. *Washington Hospital Center, Cardiology 4B-1, WASHINGTON, United States of America*

Background: Drug-eluting stents (utilizing antiproliferative agents such as Rapamycin) have shown the ability to limit restenosis. Oral Rapamycin(R)is an alternative delivery strategy that can target all stenosed coronary segments and is potentially more cost effective. Methods: The Oral Rapamycin to inhiBIT restenosis (ORBIT) study consists of a 50 patient (pt) registry for de novo coronary artery stenosis treated with stent implantation in up to 2 vessels. The first 30 pts receive R 2 mg/day for 30 days, then 20 pts R 5mg/day for 30 days, after all pts receive a 5mg oral bolus on day of the procedure. Results: We report an interim analysis of the first 30 pts (age 60 ± 10 years, 14% diabetes) enrolled (R 2mg/d). The mean number of treated lesions per pt was 1.3 ± 0.5, with reference vessel diameter 3.2 ± 0.4 mm and mean lesion length of 21.3 ± 10.5 mm. Angiographic success was achieved in all pts. Mean pre-discharge serum R levels is 3.4 ± 2.4 ng/ml (range 1.0- 8.4). No in-hospital events were noted apart from one patient with post-procedural CKMB rise > 3x normal. One patient was dropped after the initial loading dose of R. One pt ceased R after 7 days due to gingival bleeding and 5 pts have had diarrhea, which has resolved on discontinuing the treatment. To date, 24 pts (83%) have completed 30-day treatment with no reported sepsis at a mean follow-up of 56.6 ± 30.7 days. No patient has required repeat PCI since study enrollment. Conclusions: Oral Rapamycin administration for prevention of restenosis is safe and feasible. Complete 6-month clinical and angiographic outcomes will be available at presentation.

862 Persistent inhibition of neointimal hyperplasia after sirolimus eluting stent implantation: long-term (18 months) clinical and 3D-IVUS follow-up

M. Degertekin, K. Tanabe, J. Vos, D. Foley, P. Smits, W J. Giessen, P J. Feyter, P W. Serruys. *Erasmus University-Thoraxcenter, Interventional Cardiology, Rotterdam, Netherlands*

Background: The early results (4-12 months) of sirolimus eluting stent implantation showed a near complete abolition of neointimal hyperplasia. However the question remains whether the early promising results will persist at long term follow-up. The objective of our study was to evaluate the safety and efficiency of sirolimus eluting stent implantation at 18 months follow-up.
Methods: Fifteen patients with de-novo coronary artery disease were treated with 18mm sirolimus-eluting Bx VELOCITY stents (Cordis Waterloo, BL), loaded with 140 μg sirolimus/cm^2 metal surface area in a slow release formulation (>28 days drug release). Motorized pullback IVUS was performed post procedure and at 6M and 18M FU. Vessel volume, stent volume, neointimal hyperplasia (NIH), and % obstruction volume was calculated.
Results: Sirolimus eluting stent implantation was successful in all 15 patients. During the in-hospital course, 1 patient died of cerebral haemorrhage. At 18 month repeat catheterization performed in 8 of 14 eligible patients (6 asymptomatic patients refused). Through 6 months follow up and up to 18 months no restenosis and additional event occurred. In 2 patients, additional stenting was performed at 18 M FU due to significant lesion progression remote from the Sirolimus stent. 3-D IVUS showed no significant deterioration in lumen volume (see table). No edge effect was observed. Proximal and distal edge lumen volumes were calculated 44.0 ±17.6 mm^3 and 34.9±12.2 mm^3, at 6 month versus 42.7 ±19.9 mm^3 and 33.3±16.4 mm^3 at 18 M follow-up, respectively P=NS).

3D IVUS results

	Post	6M	18M
Vessel Vol. (mm^3)	280.9±74.4	287.4±64.4	283.5± 70.2
Stent Vol. (mm^3)	130.7±32.5	132.6±32.2	130.7±30.1
Lumen Vol. (mm^3)	130.7 ±32.5	130.9±32.1	124.2±27.5
NIH Vol. (mm^3)		1.7±1.6	6.5± 5.2*
% Obstruction Vol		1.4±1.2	4.8±2.8*

*p<0.05 6M FU vs 18M FU (paired t-test)

Conclusion: Sirolimus eluting stents are safe and effective in single de-novo coronary lesions in preventing neointimal hyperplasia up to 18 months after stent implantation.The modest but significant increase in the NIH warranted further careful quantitative IVUS assessment at 24, 36, 48 month follow ups.

863 First clinical experience with a paclitaxel-derivate eluting polymer-stent system implantation for ISR: immediate and long-term outcome

F. Liistro[1], G. Stankovic[2], A. Chieffo[1], C. Di Mario[2], M. Montorfano[1], M. Carlino[1], P. Pagnotta[1], A. Colombo[2]. [1]*San Raffaele, emodinamica, milan, Italy;* [2]*Columbus Hospital, Emo Centro Cuore, Milan, Italy*

Background: It has been shown that antiproliferative drugs, such as paclitaxel, lower the amount of intimal hyperplasia following stent implantation. We report the first clinical experience of 7-hexanoyltaxol (QP2) eluting polymer stent system (QuaDS) implantation for in-stent restenosis.
Methods and Results: Fifteen consecutive patients with elective indication to percutaneous coronary intervention (PCI) for in-stent restenosis were treated with the QuaDS-QP2 stent implantation. Sixty percent of lesions had an ostial-proximal location and diffuse ISR pattern was present in 46.6% of target lesions. 30% of the patients had three-vessel disease and multivessel intervention was performed in 5 patients. Among these patients, the QuaDS-QP2 stent was implanted only in one of the treated vessels. The QuaDS-QP2 stent was successfully implanted in all target lesions except for two lesions where the restenotic segment could not be completely covered by the stent. One patient suffered from post-procedure non-Q wave myocardial infarction (NQWMI). No other adverse events were observed during hospital stay. Six and twelve months angiographic and clinical follow-up was scheduled for all patients. At 6 months three patients had target lesion revascularization (20%). Two patients had restenosis (13.3%). One of them in a gap between two drug-eluting stents, and the other one had stent occlusion leading to NQWMI two months after the procedure. Minimal intimal hyperplasia was observed in all the segments covered by drug-eluting stents (late loss = 0.47±1.01 mm with a loss index = 0.17±0.39). At 12 months, one patient suffered from NQWMI and 8 out of 13 patients (61.5%) had angiographic restenosis (late loss = 1.36±0.94mm with a loss index = 0.62±0.44).
Conclusion: This first experience with QuaDS-QP2 stent implantation for in-stent restenosis revealed minimal intimal hyperplasia at 6-month follow-up. However, the antiproliferative effect was not maintained at 12-month follow-up resulting in delayed occurrence of angiographic restenosis. We cannot exclude a possible late inflammatory reaction to the polymer carrier as an explanation for these failures.

864 Sirolimus-eluting stent for treatment of in-stent restenosis: the first European clinical experience

M. Degertekin, E. Regar, P C. Smits, J. Vos, D P. Foley, W J. Giessen, P J. Feyter, P W. Serruys. *Erasmus University-Thoraxcenter, Interventional Cardiology, Rotterdam, Netherlands*

Background: Recent trials indicated that the use of Sirolimus eluting stents(SES)was safe and effective in inhibiting in stent neointimal hyperplasia in de-novo lesions.The aim of our study is to evaluate the safety, feasibility and clinical outcome (280days) of SES in patients with ISR.
Methods: Pts with recurrent ISR (>50%DS)in a native coronary artery and objective evidence of ischemia were included to receive an 18 mm sirolimus-eluting Bx VELOCITY stent(Cordis). QCA and 3D-IVUS follow-up was performed at 4M. Vessel volume,lumen volume, stent volume, % in-stent volume obstruction(PIVO)(SV-LV/SV*100)were calculated. Late lumen loss was defined as MLD post procedure-MLD FU.All pts received Clopidogrel 75 mg for 2M and Aspirin >75 mg indefinitely.
Results: SES implantation(n=24) was successful in all 15 patients. Baseline characteristics; DM 4/15,previous PCI per lesion 1.5± 0.9(range1-4),previous brachytherapy 4/15. Types of ISR; 8pts type I-II and 7pts type III-IV.In hospital course was uneventful. One pt died (sudden death) 3.5M after stent implantation. Only 1 pt showed repeat restenosis with silent total re-occlusion at 4M FU angiography.In the remaining pts (n=13),late lumen loss was 0.09 mm.IVUS FU were obtained in 12 pts. One patient with 5 eluting stents shows no sign of stenosis (3.4 PIVO) at 4m FU IVUS, developed acute occlusion 3 weeks after discontinuing clopidogrel.The pt was successfully treated by thrombus aspiration and re-PTCA. In addition, 1pt who had undergone two bypass surgery, 3 times repetitive in stent re-stenosis and no NIH (2.2PIVO)in the SES at 4M FU IVUS,died due to congestive heart failure 9.5M after the index procedure.

4M Follow-up 3D-IVUS results

N=12	POST	4M FU
Vessel Volume (mm^3)	370.9 ± 130.2	371.2 ± 134.7
Stent Volume (mm^3)	156.1 ± 58.4	157.6 ± 64.3
Lumen Volume (mm^3)	156.1± 58.4	151.4 ± 62.5
% Obstruction Volume		3.9 ± 3.4

Conclusion: Sirolimus eluting stent implantation in ISR lesions is feasible, safe and effectively prevents neointima formation even a patient population with highly complex lesions.

865 Can sirolimus-eluting stents prevent restenosis in diabetic patients? A subanalysis of the randomized, multi-center RAVEL trial

E. Regar[1], M.C. Morice[2], J. Sousa[3], J. Fajadet[4], M. Perin[5], E. Ban Hayashi[6], A. Colombo[7], P.W. Serruys[8] on behalf of the RAVEL Investigators. *[1]Thoraxcenter, Z 120, Cardiology, Rotterdam, Netherlands; [2]L Institut Cardiovasculaire Paris Sud, Massy, France; [3]Instituto Dante Pazzaneze de Cardiolog, Sao Paulo, Brazil; [4]Clinique Pasteur, Toulouse, France; [5]Incor Hospital, Sao Paulo, Brazil; [6]Instituto Nacional de Cardiologia, Mexico, Mexico; [7]Centro Cuore Columbus, Milan, Italy; [8]Thoraxcenter, Rotterdam, Netherlands*

Diabetic patients (pts) are prone to procedural complications and to a less favorable outcome after percutaneous coronary intervention (PCI) in comparison to non-diabetic pts.
We investigated the outcome of diabetics after implantation of sirolimus eluting stents.
We performed a subgroup-analysis of pts with diabetes mellitus who were prospectively included into the multicenter RAVEL trial. Pts with single de novo lesions were randomized to receive a 18mm sirolimus eluting (SES) Bx velocity™ stent (Cordis, Waterloo, Belgium) or a bare (BS) Bx velocity™ stent (Cordis, Waterloo, Belgium). Major adverse cardiac events (MACE) at 6 month follow up were defined as death, myocardial infarction (MI), target vessel PTCA and CABG.
QCA was performed by using the CAAS system.
Results: 44 Patients with diabetes mellitus were randomized into the RAVEL trial.

QCA

		SES (n=19)	BS (n=25)	p-value
Baseline	Lesion length (mm)	9,4 (3,2)	9,4 (2,4)	ns
	RD (mm)	2,52 (0,51)	2,51 (0,47)	ns
	MLD (mm)	0,99 (0,24)	0,93 (0,33)	ns
	DS (%)	60 (9)	63 (10)	ns
Post	MLD (mm)	2,37 (0,43)	2,36 (0,45)	ns
	DS (%)	13 (6)	14 (9)	ns
6m FUP	MLD (mm)	2,31 (0,40)	1,56 (0,64)	< 0.001
	DS (%)	16 (5)	38 (21)	< 0.001
	Late loss (mm)	0,08 (0,20)	0,82 (0,53)	< 0.001
	Restenosis rate (%)	0	42	< 0.001

Mean (1 SD)

In the follow-up period, no pt (0%) of the SES group experienced a MACE, while 3 pts (12%) of the BS group had MACE (1 death, 1 MI, 1 PTCA).
Conclusion: Sirolimus eluting stents seem to favorably affect the outcome of diabetic patients. No MACE, no restenosis and only minimal late lumen loss was seen in our pts at 6 months follow-up. This might support the use of sirolimus eluting stents as first-line PCI strategy in diabetics.

866 Influence of stent coatings on acute and six-month clinical and angiographic outcomes in real world patients

F. Fabbiocchi, S. Galli, D. Trabattoni, S. De Martini, G. Calligaris, P. Montorsi, A.L. Bartorelli. *Centro Cardiologico Monzino, Institute of Cardiology, Milan, Italy*

Purpose: To compare acute and six-month clinical and angiographic results of coated (C) (Carbostent and PC Biodivysio) and uncoated (UC) stents in a real world population.
Methods: From January 1999 to December 2000, 1544 pts underwent PCI with stent implantation: 590 pts had C stents and 954 pts had UC stainless steel stents according to operator preference. The two groups were matched in gender, age and major cardiovascular risk factors. Clinical indication for PCI were stable angina (68.8% C vs. 66.3% UC, ns) unstable angina (18.6% C vs 18.4% UC, ns) and AMI (8.8% C vs 12.3 UC, $p<0.001$). Multiple stents were implanted in 20% C vs 22.5% UC (mean stent/pt 1.4 ± 0.5 C vs 1.3 ± 0.6 UC, ns) respectively, while stent length was 21.6 ± 11.5 C vs 19.9 ± 8.3 UC (p=ns), and stent diameter was 3.6 ± 0.6 C vs 3.6 ± 0.58 UC.
Results: Angiographic success was obtained in 98% C vs 97% UC, death occurred in 0% C vs 1.2% UC, AMI in 2.8% C vs 2.5% UC, subacute stent thrombosis was 0% in C vs 0.6% in UC (all p=ns). Six-month follow-up clinical and angiographic data are shown in Table 1
Conclusions: Similarly high clinical and angiographic acute success was obtained with C and UC stents. No late thrombosis occurred in C pts, suggesting thromboresistant properties of C stents. Carbofilm and phosphorylcoline coated stents were associated with significantly lower restenosis rate in unselected real world patients, which likely resulted from reduced neointimal proliferation, as suggested by a lower loss index.

Table 1

	Coated	Uncoated	p value
N° pts	282	418	-
Death	0.3%	0%	ns
MI	0.3%	1.1%	ns
Angina/Ischemia	17.7%	20%	ns
Re-PTCA	14%	21%	ns
CABG	2.5%	2.4%	ns
Late Loss	0.88	1.10	0.02
Loss Index	0.38	0.55	0.002
Restenosis Rate	21%	32%	0.002

DRUG ELUTING STENTS: OPTIONS BEYOND SIROLIMUS?

867 A polymer-based copper coating can generate nitric oxide from S-nitrosoglutathione but does not induce significant neointimal formation

G. Richardson[1], J. Gunn[2], A.C. Morton[2], S.E. Greenwald[3], N. Benjamin[4], M.T. Rothman[5]. *[1]St Bartholomew's Hospital, Cardiology Department, London, United Kingdom; [2]Sheffield University, Cardiovascular Research Group, Sheffield, United Kingdom; [3]St Bartholomew's Medical College, Department of Morbid Anantomy, London, United Kingdom; [4]St Bartholomew's Medical College, Department of Clinical Pharmacology, London, United Kingdom; [5]London Chest Hospital, Cardiology Department, London, United Kingdom*

Background: Current research is directed towards finding an agent that can be coated onto a stent to inhibit in-stent restenosis, a process which involves platelet, inflammatory cell and vascular smooth muscle cell responses. Nitric oxide (NO) is a potential candidate for this role, as it can theoretically inhibit all aspects of the vascular response to stent deployment, whilst enhancing endothelial cell regrowth.
S-nitrosothiols (RSNOs) are endogenous circulating NO donors. We have previously shown that NO can be generated from RSNOs by copper in a dose-dependent manner, to inhibit platelet aggregation in vitro.
However, copper-coated stents have been shown by others to induce severe inflammatory responses in the vessel wall. In order to coat stainless steel with small quantities of copper we have developed a novel polymer-based method. The coating, containing 5% or 20% copper (w/w), can be used to generate NO from RSNOs to inhibit platelet aggregation in vitro in a dose-response manner.
Methods and Results: Stainless steel discs were implanted into subcutaneous tissues in mice and inflammatory responses were assed by measuring histological tissue changes and macrophage acid phosphatase activity on the surface of the disc 7 days after implantation. The 20% copper coating induced significantly more inflammation than both the 5% copper and the polymer coating alone. There was no difference between the effects of 5% copper and the polymer itself.
The effect of the coating on the development of neointima was then tested in the porcine coronary artery model. Stents coated with the polymer-copper coating (1% and 5% copper (w/w); n = 6 per group) were deployed at a balloon artery ratio of 1.25:1. The vessels were harvested at 28 days and the resulting neointimal thickness compared with that seen following implantation of stents coated with polymer alone. Neointimal thicknesses (arbitrary units), corrected for vessel size and injury score, were 0.019 + 0.001, 0.032 + 0.009 and 0.021 + 0.001 for 1% copper, 5% copper and polymer alone respectively (mean + sem; p = 0.152, 1-way ANOVA).
Conclusions: NO can theoretically inhibit the process of in-stent restenosis. Copper can generate NO from RSNOs, but is inflammatory and pro-thrombotic. Stents coated with a polymer-copper mixture, at concentrations of copper that will inhibit platelet aggregation in vitro, do not induce significantly more neointimal formation in porcine coronary arteries than those coated with polymer alone. Thus it may be possible to use a polymer-copper-coated stent to generate NO within the coronary artery.

868 Latrunculin A inhibits smooth muscle cell proliferation and neointimal formation in a porcine coronary stent model

K J. Salu[1], J M. Bosmans[1], H. Bult[2], Y. Huang[3], X. Liu[3], I K. De Scheerder[3], C J. Vrints[1]. [1]*University Hospital Antwerp, Cardiology, Edegem, Belgium;* [2]*University of Antwerp, Pharmacology, Wilrijk, Belgium;* [3]*University Hospital Gasthuisberg, Interventional Cardiology, Leuven, Belgium*

Background: In-stent neointimal formation, predominantly due to smooth muscle cell (SMC) migration and proliferation, remains a significant limitation of coronary stenting. Latrunculin A (LA) is an inhibitor of the actin microfilament formation, thereby theoretically interfering with SMC migration and proliferation. This study evaluated the in-vitro and in-vivo effects of direct LA stent coating on in-stent neointimal formation in a porcine coronary model. Methods: In-vitro cell proliferation was assessed by means of a coulter counter after LA incubation (10^{-8} - 10^{-5} M) for 7 days with SMCs isolated from the rabbit aorta. Coronary stents (13 mm, Multi-Link Tristar ®, Guidant) were dipped in pure ethanol (control) or in a 1 mg LA/ml ethanol solution (treatment) and air-dried. Loading capacity and release in NaCl at 37°C were performed using UV spectrophotometry. Stents (12 control and 12 treatment) were then randomly deployed (oversize 1.1:1 to 1.2:1) in the right or left coronary artery of 12 crossbred pigs (weight 20 - 25 kg). The pigs were sacrificed after 6 weeks. Blinded quantitative coronary analysis (QCA) was performed before, immediately after stent implantation and at follow-up using the CAAS-II®-QCA-system. Blinded morphometry was performed on 5 μm cross-sections using stereological point counting. Results: LA inhibited SMC proliferation in a dose-dependent way (control: 1.82±0.21, 10^{-8} M: 1.84±0.07*, 10^{-7} M: 1.25±0.09*, 10^{-6} M: 0.35±0.10*, 10^{-5} M: 0.31±0.13*; data are x 10^5 cells/well; n=4; *p<0.01). Coated stents contained 1.53±0.12 μg LA (n=3). Complete release in-vitro was already achieved after 4 hours. QCA analysis at 6 weeks revealed a decreased late lumen loss (-0.03±0.20 vs 0.23±0.29: p<0.05) and percentage stenosis (15±5 vs 30±14: p<0.005) in the LA-coated stents. Morphometry showed a decreased intima/injury value (1.0±0.4 vs 1.3±0.8: p=0.08) in the LA-group. No thrombosis was found in either group. vWF immunostaining showed complete re-endothelisation at 6 weeks in both groups. Conclusion: In-vitro, latrunculin A inhibits SMC proliferation in a dose-dependent way. Direct latrunculin A stent coating reduces neointimal hyperplasia after implantation in healthy porcine coronary arteries in-vivo. These results warrant further studies of latrunculin A stent coatings.

869 Tacrolimus, but not sirolimus targets human vascular smooth muscle cells, but spares endothelial cells – Implications for drug-eluting stents

C M. Matter[1], S. Wnendt[2], D J. Kurz[1], T. Kozai[1], J. Grünenfelder[3], G. Zünd[3], A. Jaschko[1], T F. Lüscher[1]. [1]*Cardiovascular Research, Institute of Physiology/Cardiology, Zurich, Switzerland;* [2]*Jomed, Rangendingen, Germany;* [3]*Surgery/University Hospital, Cardiac Surgery Research, Zurich, Switzerland*

Background: Excessive proliferation and migration of vascular smooth muscle cells (VSMC) plays a major role in the development of in-stent restenosis. Indeed, local antiproliferative strategies such as brachytherapy and, most recently, rapamycin-eluting stents have been shown to reduce the occurrence of restenosis. However, late thrombosis has emerged as a side effect in both clinical applications suggesting insufficient reendothelialisation. The ideal agent used for local drug delivery would exert strong antiproliferative action on VSMC while sparing endothelial cells (EC). Sirolimus (FK506) and tacrolimus (rapamycin) are potent antiproliferative and immunosuppressive agents that both bind to FK binding protein 12, but have different downstream targets. We investigated whether these drugs differ with regard to their effects on VSMC and EC.

Methods and Results: DNA synthesis using thymidine incorporation was determined after stimulating cultured human saphenous VSMC with PDGF-BB 5 ng/ml and EC with fetal calf serum 2% for 24 hours. A dose-response curve was characterized in the presence and absence of tacrolimus and sirolimus using drug concentrations ranging from 10E-12 to 10E-6 M (n>3 for each condition). The half maximal inhibitory concentration for VSMC (IC50) for tacrolimus was 5.1 x 10E-7 ± 4.3 x 10E-7 M and for sirolimus 4.1 x 10E-9 ± 2.9 x 10E-9 M. Compared to the IC50 in VSMC, the IC50 in EC was met only at higher concentrations for tacrolimus (3.3 x 10E-6 ± 2.5 x 10E-6 M), but at lower concentrations for sirolimus (7.1 x 10E-10 ± 1.7 x 10E-10 M).

Conclusions: Sirolimus is a more potent antiproliferative drug in VSMC than tacrolimus. Anticipating that the effective dose for targeting VSMC proliferation of tacrolimus can be achieved on a drug-eluting stent, the unwanted side effects on EC proliferation might be less with tacrolimus than with sirolimus. These findings suggest that on a drug-eluting stent, tacrolimus allows earlier endothelial regeneration than sirolimus and make it a promising candidate for local drug delivery.

870 Stent-based delivery of combined chemotherapy with cis-platinum and mitoxandrone in a porcine coronary model to prevent restenosis

C. Stefanadis, E. Tsiamis, S. Vaina, E. Stefanadi, D. Tsekoura, K. Toutouzas, D. Poulis, P. Toutouzas. *Hippokration Hospital, Dept of Cardiology, Athens, Greece*

Background: Prevention of neointimal hyperplasia after stent implantation is a target for current cardiology. Drug-eluting stents, such as rapamycin-eluting stents have been proposed as means of preventing restenosis. However, combination of cytotoxic agents hasn't been used. The purpose of the present study was to compare the angiographic and histologic results of stent-based delivery of cis-platinum in combination with mitoxandrone, and conventional stent implantation in the coronary arteries of 13 pigs (20-26Kg).

Methods: A BiodivYsioTMDD stent, was completely embedded for 5 minutes in a 5 ml solution of cis-platinum (1mg/0.5ml) and mitoxandrone (4.75mg/4.5ml). Thereafter, the stent was allowed for 5 minutes to dry ensuring no contact with any surface. Seven BiodivYsioTMDD stents were implanted to LAD and 6 to LCx. Thirteen conventional stents were placed in the other branch of the left coronary artery serving as control. Balloon to artery ratio was 1.17 ± 0.1. Maximum balloon pressure was 15 atm. At 5 weeks, the animals were sacrificed after completion of coronary angiography and morphometric studies were performed.

Results: All vessels were patent after the implantation except of one 1 case of subacute thrombosis in the control group. Restenosis was observed in one vessel of the control group. Histologically, endothelialization was similar between the two groups. The arterial middle layer was thinner in the drug delivery stent compared to the control group.

Conclusions: The results of the present study show that stent-based delivery of cis-platinum combined with mitoxandrone is feasible and reduces restenosis. These positive results encourage further clinical investigations.

871 VEGF-eluting stents reduce stent thrombosis, but not restenosis, in vivo

N. Swanson[1], K. Hogrefe[1], Q. Javed[1], N. Malik[2], A.H. Gershlick[1]. [1]*Glenfield Hospital, Cardiology Clinical Sciences, Leicester, United Kingdom;* [2]*University of Manchester, Cardiology, Manchester, United Kingdom*

Local drug delivery by stent has been shown to reduce in-stent restenosis in recent encouraging trials (e.g. ELUTES, RAVEL, TAXUS). We report the use of VEGF delivered by polymer-coated stents.

VEGF is an endothelial-cell specific mitogen. After stenting, the arterial endothelium is almost entirely denuded. This loss of endothelium contributes to the smooth muscle cell (SMC) proliferation seen in restenosis, since SMCs become exposed to mitogens in the blood. Furthermore, endothelium actively inhibits SMC hyperplasia, by producing NO and heparans. Over time, the endothelium recovers, "passivating" the stent and SMC hyperplasia is arrested.

We aimed to speed the re-endothelialisation process by delivering VEGF absorbed into the polymer coating of a stent. We also tested whether VEGF - which stimulates NO - reduces stent thrombosis. Both effects might reduce intimal hyperplasia.

Work in vitro confirmed that Cook polymer-coated stents absorbed and then gradually released VEGF. This released VEGF stimulated the growth of endothelial cells adjacent to the stent.

VEGF-loaded or control stents were then tested in a New Zealand White rabbit iliac artery model. Acute thrombosis was measured in the vessels using Indium-labelled platelet deposition. The extent of endothelialisation (using scanning electron microscopy) and subacute thrombosis was measured at 7 days. At 28 days the amount of intimal hyperplasia was determined from morphometric analysis of H&E stained, resin-embedded cross sections of stented vessels.

Acute thrombosis was less on the VEGF coated stents, but this did not achieve significant levels (P=0.2). At 7 days, thrombus formation was significantly reduced -median weight of thrombus 12.5mg (controls) v. 0mg (VEGF), p=0.014. However, no beneficial effect was seen on endothelialisation, which was minimal and unquantifiable in both groups, or intimal hyperplasia. Luminal area was 4.4±1.0mm^2 (control) v. 4.7±0.5mm^2 (VEGF), p=0.45. Neointimal area was 2.2±0.9mm^2 v 2.4±1.8mm^2 (p=0.8).

Conclusions Vascular endothelial growth factor delivery by stent in this model does not seem to alter re-endothelialisation. No beneficial results were seen on restenosis. A beneficial effect on thrombus formation early after stent implantation was seen. Such an effect, which may be mediated by NO production, would make these stents less thrombogenic than current clinically used stents.

872 The effect of local simvastatin delivery on neointimal formation in vivo after vascular injury: comparison with rapamycin

K. Tanabe[1], H. Ishiyama[2], W.J. van der Giessen[1], P.W. Serruys[1].
[1]Rotterdam, Netherlands; [2]Kanagawa, Japan

Background: Although statins have been shown to exert anti-proliferative effects on smooth muscle cells in vitro, the previous major prospective human clinical trials failed to corroborate the beneficial effect of statin therapy on restenosis after conventional coronary balloon angioplasty. However, systemic administration for a local problem such as restenosis does not seem the most logical approach. The aim of this study was to investigate the effect of local simvastatin delivery on neointimal formation in vivo.
Methods: 15 Wister rats were randomized in the simvastatin group (SIM, n = 6), the rapamycin group (RAP, n = 6) or the control group (CON, n = 3). After angioplasty, an osmotic pump (ALZET, USA) was placed outside the injured carotid artery and then the rats were allowed to recover. The pump was filled with 50iM simvastatin in the SIM group, 50iM rapamycin in the RAP group and vehicle only in the CON group. The infusion was continued for 14 days. The sections of the injured arteries were examined in 3 rats in each group at 14 days and those of remaining 3 rats in the SIM group and the RAP group were examined at 28 days.
Results: A significant reduction of neointimal thickness was observed in the SIM group (32.0±23.5 mm, p = 0.03) and the RAP group (33.0±11.0 mm, p = 0.02) at 14 days when compared with the CON group (106.0±30.8 mm). In the SIM group, the neointimal thickness observed at 28 days (45.0±24.4 mm) was similar to that at 14 days (p = 0.53). In the RAP group, the neointimal thickness at 28 days (87.0±36.7 mm) increased compared with that at 14 days. However, this trend (p = 0.07) failed to be statistically significant. The histologic sections stained with a polyclonal antibody against von Willebrand factor demonstrated that regenerated endothelium was present in the balloon-injured areas in the SIM group at 14 days, whereas the RAP group showed incomplete re-endothelialization at 14 days.
Conclusion: The local simvastatin delivery shows sustained reduction of neointimal hyperplasia in a balloon-injury model, while it has a favorable effect on re-endothelialization. Simvastatin is a good candidate for local delivery from a drug-eluting stent.

CARDIAC COMPUTED TOMOGRAPHY: SOMETHING NEW ON THE HORIZON?

873 The MUNICH registry: "normal" distribution of coronary artery calcium measured by 4-slice computed tomography in over 2000 asymptomatic individuals

S. Silber[1], A. Schmermund[2], R. Erbel[2] on behalf of the MUNICH registry.
[1]Müller Hospital, Cathlab, Munich, Germany; [2]University Clinic, Essen, Germany

Accurate quantification of coronary calcium, usually by means of the Agatston calcium score, is a prerequisite for assessing calcified atherosclerotic plaque burden. For this purpose, electron-beam computed tomography (EBCT) is currently being regarded as the "gold standard". Recently, four-slice (4-S)-CT has become an alternative, new modality. However, neither a standard image acquisition protocol nor the normal distribution pattern of the calcium score in asymptomatic individuals have been established for 4-S-CT. The MUNICH registry (MUltislice Normal Incidence of Coronary Health) consecutively collects these data using 4-S-CT and prospective ECG-triggering in analogy to the MESA protocol (4x2.5 mm).
Results: Calcium was detected in 990 (65%) men and 248 (48%) women (p < 0.001). Age, gender and all of the established causal risk factors (systemic hypertension, active smoking, hypercholesterolemia, diabetes but not BMI) were independently associated with the Agatston calcium score. Age and gender specific 10th, 25th, 50 th, 75 th and 90 th percentiles of the Agatston score distribution were established and will be presented. There was a good correlation to previously reported percentile values derived from studies using EBCT.
Conclusions: The current data from the MUNICH registry establish a database for the calcium scores determined by 4-S-CT and prospective ECG-triggering in apparently healthy subjects. The similarity with percentile values previously reported in EBCT-studies suggest that 4-S-CT provides useful information about the presence and extent of coronary atherosclerosis. Since the data acquisition of the current study is comparable to the method used for the MESA study currently performed in the USA, the data from the MUNICH registry will be comparable to the 4-S-CT data from the MESA-study. There was a surprisingly good agreement between the MUNICH "normal distribution" and the published EBT data.

874 Calcium score as assessed by multislice computed tomography does not predict maximal coronary artery stenosis: an in-vitro study

M. Frick[1], F. Karakolcu[1], H. Gschnitzer[1], A. Stoeger[2], G. Friedrich[1], F. Weidinger[1], O. Pachinger[1], S.P. Schwarzacher[1]. [1]Division of Cardiology, Department of Medicine, University of, Innsbruck, Austria; [2]University of Innsbruck, Department of Radiology, Innsbruck, Austria

Background: Electron beam computed tomography and multi-slice computed tomography (MSCT) have been shown to accurately detect coronary calcification. However, the association of MSCT detected calcium score and percent area stenosis as assessed by intravascular ultrasound (IVUS) is unknown.
Methods: 32 human coronary arteries were fixed in a flow model and perfused with saline. After setting landmarks, an automated pull back (0.5 mm/sec) with an IVUS catheter (40 MHz) was performed through all coronary arteries. Total vessel (VA) and lumen area (LA) were measured. In addition, plaque area (PA; VA-LA) and percent area stenosis [PS=(PA/VA)x100] were calculated for each vessel (n=32) and each segment (n=599). Calcifications were identified by bright dense echo and quantified by circumferential degrees (IVUS Ca; 0-360 degrees). Following IVUS, a MSCT (Somatom Plus Volume Zoom 4, Siemens) was performed for each vessel and the results were quantified using Agatston Score.
Results: In 21 coronary arteries MSCT was able to detect calcium, whereas in 11 coronaries no calcium was found. Interestingly, average PS (62.1±7.3 vs. 57.3±5.2; p=0.06) and maximal PS (73.4±7.0 vs. 74.7±10.1; p=0.33) as assessed by IVUS were not significantly different between MSCT calcium positive and negative vessels. MSCT analyses for the single segments revealed calcium in 141 segments. However, PS was significantly higher in these MSCT calcium positive compared to the calcium negative segments (66.0±9.5 vs. 59.6±9.1, p<0.01). Also, MSCT calcium score showed a close correlation with calcium identified by IVUS (r=0.83, p<0.01), but only a weak correlation with PS (r=0.30; p<0.01).
Conclusion: Although MSCT detected coronary calcification accurately it is not necessarily associated with percent area stenosis. As maximal percent area stenosis was not different between MSCT calcium positive and negative vessels, our data do not support MSCT as a reliable means for the discrimination of patients with or without significant coronary artery stenosis.

875 Impact of the heart rate on multislice computed tomography coronary angiography

K. Nieman[1], B.J. Rensing[1], R.J.M. van Geuns[1], P.M.T. Pattynama[2], P.J. de Feyter[1]. [1]Rotterdam University Hospital, Cardiology, Rotterdam, Netherlands; [2]Rotterdam University Hospital, Radiology, Rotterdam, Netherlands

Introduction: Multislice spiral computed tomography (MSCT) has emerged as a promising non-invasive tool to assess the coronary arteries. However, due to a limited temporal resolution the technique is vulnerable to motion artifacts caused by residual cardiac motion. We evaluated the impact of the mean heart rate (HR) on the diagnostic accuracy of MSCT coronary angiography.
Methods: IV contrast-enhanced MSCT angiography (4 x 1 mm protocol, 500 ms rotation time, Siemens VolumeZoom, Forchheim, Germany) was performed in 78 patients, who were suspected of obstructive coronary artery disease. No additional beta-blocking medication was used prior to the scan. Using retrospective ECG gating, sets of slices were reconstructed at different positions within the cardiac cycle. The data set with the least motion artifacts was selected for further analysis. All coronary segments, with a diameter >2 mm and without stents (N=25), were evaluated for >50% stenosis by two investigators and compared to conventional X-ray angiography. Stratified according to average HR during the scan, patients were divided in three equally sized groups.
Results: in the group with the lowest heart rates only few motion artifacts were encountered. The segment assessability and overall sensitivity (stenotic lesions in non-assessable segments regarded as false-negative scores) were significantly better in low heart rates (P<0.01). The coronary segment assessability, diagnostic parameters and accuracy to classify patients as no-, one- or multivessel disease, are summarized in the table.

Groups	All (n=78)	I (n=26)	II (n=26)	III (n=26)
Mean heart rate	68.0 ± 12.1	55.8 ± 4.1	66.6±2.8	81.7 ± 8.8
Assessable	68%	78%	73%	54%
Sensitivity*	84%	97%	74%	67%
Specificity*	95%	96%	94%	94%
Positive PV*	67%	82%	58%	43%
Negative PV*	98%	99%	97%	97%
Overal sensitivity	63%	82%	61%	32%
Patient accuracy	56%	73%	54%	42%

*For assessable segments; PV = predictive value.

Conclusions: the diagnostic accuracy of MSCT is significantly better in patients with low heart rates. This supports the argument for routine use of beta-receptor blocking in patients with higher heart rates.MSCT diagnostic accuracy

876 Conventional risk factor analysis versus coronary calcification scanning in patients presenting in the emergency department with chest pain

D.A. Laudon[1], K.V. Ballman[2], L.F. Vukov[1], J.F. Breen[3], A.S. Terry[2], P.F. Sheedy[3], T. Behrenbeck[4]. [1]*Mayo Clinic, Emergency Medicine, Rochester, MN, United States of America;* [2]*Mayo Clinic, Department of Biostatistics, Rochester, MN, United States of America;* [3]*Mayo Clinic, Department of Radiology, Rochester, MN, United States of America;* [4]*Mayo Clinic, Cardiovascular Diseases, Rochester, MN, 55905, United States of America*

Coronary risk factor (RF) analysis has been used to risk stratify patients. We studied if a similar analysis identifies patients at high risk of coronary artery disease (CAD) presenting to the emergency department with chest pain. Prospective enrollment criteria of the 262 patients consisted of an intermediate probability of CAD, a negative or indeterminate EKG and negative cardiac markers. All patients underwent conventional cardiac testing (serial enzyme determination, stress testing, or angiography) and determination of coronary risk factors. Coronary calcification scans (CAC) were performed using a GE-Imatron 150®. The attending physician was blinded to the result. 43 patients had a positive event, defined as an MI (by enzyme determination, n=9), or conventional testing. Lipid profiles in patients with MI were drawn at least 6 weeks from the event. Results are listed in the table below:

Risk factor analysis

Variable	Odds ratio (95% CI)	p-value
Age at enrollment	1.054 (1.005 - 1.105)	0.030
Gender; female	0.504 (0.225 - 1.129)	0.10
Diabetes	3.355 (1.088 - 10.343)	0.035
BMI	1.044 (0.982 - 1.109)	0.17
LDL - cholesterol	1.000 (0.991 - 1.010)	0.95
HDL - cholesterol	0.992 (0.967 - 1.017)	0.51
Total cholesterol	1.001 (0.994 - 1.009)	0.72
Triglycerides	1.001 (0.998 - 1.004)	0.55
Hypertension	1.661 (0.792 - 3.483)	0.18
Tobacco	1.492 (0.713 - 3.124)	0.29
Family history of MI	1.733 (0.882 - 3.406)	0.11
Framingham Risk Score	1.115 (1.012 - 1.229)	0.028
Duke Score <5	12.566 (4.673 - 33.793)	<0.0001
CAC score <0	21.224 (4.967 - 90.699)	<0.0001
CAC score <10	21.483 (7.262 - 63.549)	<0.0001

CI = confidence interval, BMI = body mass index, CAC = coronary artery calcification

Conclusions: 1) Conventional RF analysis is only marginally helpful to establish the origin of chest pain. 2) The Duke score is an independent predictor. 3) CAC is the most powerful predictor of cardiac chest pain.

877 Changes in both left- and right ventricular volumes and function after passive cardiomyoplasty assessed by electron beam computed tomography

A. Lembcke[1], T.H. Wiese[1], S. Dushe[2], H. Hotz[2], C.N.H. Enzweiler[1], B. Hamm[1], W.F. Konertz[2]. [1]*Department of Radiology,* [2] *Department of Cardiovascular Surgery, Charité, Humboldt-University, Berlin, Germany*

Purpose: To demonstrate changes in both left- and right ventricular (LV, RV) volumes and function as well as LV myocardial mass after implantation of a cardiac support device (CSD, Acorn®), a preformed knitted polyester mesh-graft placed around the ventricles to prevent further dilatation in congestive heart failure.

Material and Methods: Thirteen consecutive patients (12 males, 1 female; age 59 ± 8 years) with ischemic or primary dilated cardiomyopathy underwent electron-beam CT 2 weeks before and 6 - 9 months after CSD implantation. Standardized contrast enhanced studies were performed along the short heart axis and following parameters were calculated using the slice summation method: end-diastolic and end-systolic volume (EDV, ESV), ejection fraction (EF) and myocardial mass (MM). Additionally, the forward cardiac output (CO) was measured in the aorta using the indicator dilution method.

Results: Morphologic and morphometric assessment of the heart was feasible in all patients. Significant decreases of enddiastolic and endsystolic volumes as well as an improved function were found for both left and right ventricle (table). After CSD implantation a small hyperdense thickening along the pericardium was observed in all cases, but no patient had pericardial effusion or an intracardiac thrombus.

LV and RV changes after CSD implantation

	preoperative	postoperative
LV-EDV (ml)	406 ± 134	323 ± 133 *
LV-ESV (ml)	331 ± 127	247 ± 128 *
LV-EF (%)	19.6 ± 6.3	26.2 ± 13.5 *
CO (l/min)	3.8 ± 1.0	4.5 ± 1.6 *
LV-MM (g)	314 ± 94.6	284 ± 73.5 *
RV-EDV (ml)	216 ± 100	163 ± 78.8 *
RV-ESV (ml)	156 ± 91.8	91.5 ± 75.6 *
RV-EF (%)	35.7 ± 15.7	48.9 ± 15.4 *

* significance (paired t-test; $p<0.05$) for preoperative vs. postoperative value (mean ± standard deviation)

Conclusion: Electron-beam CT measurements yields useful additional three-dimensional information on postoperative changes in both LV and RV morphology and function. These findings supplement initial reports on the safety and the efficacy of CSD implantation.

878 Multislice computed tomography contrast enhanced imaging of arterial and venous coronary artery bypass grafts

R. Raipancholia[1], M. AlBustami[2], R.J. Chambers[2], J. Partridge[2], A.G. Mitchell[2], M. Amrani[2], C. Ilsley[2]. [1]*Harefield Hospital, Cardiology, HAREFIELD, United Kingdom;* [2]*Harefield Hospital, Cardiology, Middlesex, United Kingdom*

Background: Contrast enhanced Multislice CT (MSCT) with retrospective ECG- gated image reconstruction has been shown to provide non-invasive visualization of the coronary artery lumen. We investigated the potential value of MSCT angiography in evaluation of both arterial and venous coronary artery bypass grafts.

Methods: We studied 40 symptomatic patients (31 men, 9 women, mean age 61 years, range 44-82 years) by both MSCT (SOMATOM Volume Zoom, Siemens) and conventional coronary angiography. The mean time interval between conventional angiography and MSCT was 5 days, range 2-10 days. A total of 131 grafts (40 left internal mammary artery, 5 right internal mammary artery,9 radial artery grafts and 77 venous grafts) were studied. After intravenous injection of a non ionic contrast medium the heart was scanned from level of carina within a single breath hold. The retrospective electrocardiographically gated reconstruction sources images and three dimensional reconstructed volumes were analysed by two investigators, unaware of the results of conventional angiography. The Multislice CT images of coronary bypass grafts were compared with selective coronary bypass angiography as the control.

Results: Multislice CT defined 39 of 42 arterial grafts as patent with 93% sensitivity and 100% specificity (12/12). MSCT defined patency of 29 of 31 left internal mammary artery (sensitivity 94%, specificity 100%). MSCT visualized the anastomotic site of left internal mammary artery graft in 71% of cases (22/31). 35 of 36 venous grafts were identified as patent with a sensitivity of 97% and specificity of 97%. In venous grafts 8 of 10 high grade stenoses were correctly detected by MSCT (sensitivity 80%).

Conclusions: Our preliminary results suggest that MSCT is a promising modality for non-invasive imaging of both arterial and venous coronary artery bypass grafts and will develop into a reliable clinical technique.

STRATIFICATION IN CORONARY ARTERY DISEASE: USE OF MYOCARDIAL IMAGING

879 Magnetic resonance flow mapping for non-invasive evaluation of vein grafts after percutaneous intervention

S.E. Langerak[1], L.P. Salm[1], H.W. Vliegen[1], J.W. Jukema[1], A.H. Zwinderman[2], H.J. Lamb[3], A. de Roos[3], E.E. van der Wall[1]. [1]*Dept. of Cardiology,* [2]*Dept. of Medical Statistics, Leiden, Netherlands;* [3]*Dept. of Radiology, Leiden University Medical Center, Leiden, Netherlands*

Background: MR flow mapping is a potential non-invasive diagnostic tool for evaluation and follow-up of grafts after PCI. However, MR reference values for function in different graft types are limited and studies focusing on the feasibility of MRI to study the effect of PCI are lacking.

Methods: Fast MR flow mapping at baseline and during adenosine-induced stress was performed in 39 non-stenotic single vein grafts and 20 non-stenotic sequential vein grafts, as well as in 15 stenotic vein grafts before and 7.3±1.5 weeks after successful PCI.

Results: Reference values in single vein grafts for baseline average peak velocity (APV), stress APV and velocity reserve were 8.6±3.4 cm/s, 20.2±9.5 cm/s, and 2.4±0.8, respectively. In sequential vein grafts, significantly higher values for baseline APV (12.2±5.0 cm/s) and stress APV (27.2±10.6 cm/s) but a similar velocity reserve (2.3±0.7) were found. After PCI significant improvements in baseline APV (pre-PCI: 9.2±6.6; post-PCI: 12.9±7.9 cm/s, $P=0.008$) and stress APV (pre-PCI: 12.9±6.3; post-PCI 27.1±13.9, $P<0.001$) were demonstrated. No improvement in velocity reserve was observed, since both baseline and stress APV improved.

Conclusions: In sequential vein grafts absolute velocity and flow values are significantly higher than in single vein grafts, underscoring the need for separate functional reference values in different graft types. Velocity reserve appears not useful to discriminate between stenotic and non-stenotic grafts. Graft function significantly improved after PCI to reference values. MR flow mapping offers perspective for non-invasive follow-up of graft function and long-term monitoring after intervention.

880 MRI predicts myocardial and vascular remodelling in patients with acute revascularized myocardial infarction

I. Paetsch, A. Wahl, A. Gollesch, S. Hettwer, H. Langreck, E. Fleck, E. Nagel.
German Heart Institute, Internal Medicine/Cardiology, Berlin, Germany

Background: Microvascular obstruction (MO) in acute myocardial infarction (MI) is associated with a higher rate of cardiovascular complications. Purpose was to determine whether quantitatively assessed infarct volumes and presence of MO determine infarct expansion and ventricular or vascular remodeling.
Methods: 23 pts with first acute MI (57±9 years; CKmax 857±707 U/l) underwent primary PTCA (n=14), or lysis (n=5) or initial conservative management (n=4) followed by elective PTCA. In addition, all pts received maximal medical treatment as defined by guidelines, and underwent invasive coronary angiography at 3 months follow-up to ensure patency of infarct related artery (IRA).Significant restenosis was defined as > 50% diameter stenosis as assessed by quantitative coronary angiography (QCA). Cardiac MRI was performed at baseline (<5 d after MI) and follow-up (1.5 T MR tomograph, ACS NT, Philips, The Netherlands). The complete heart was imaged with multiple cine short-axis views (balancedFFE-sequence, (TE/TR/flip 1.9/4.0/60)). 15min after administration of Gd-DTPA (0.02 mmol/kg) a 3-D, navigator corrected inversion-recovery sequence (5.3/3.2/15, slice thickness 5mm, PP-delay 225-250ms) covering the complete heart was used for determination of hyperenhanced (HYPER) and hypoenhanced myocardium within the hyperenhancement (MO). Left ventricular volumes/mass, volume of HYPER and MO as well as transmural extent of MI were calculated. %Infarcted volume was defined as (HYPER+MO)/total myocardial volume.
Results: At initial MRI all pts presented with a regional hyperenhancement, 10 had MO. %Infarcted volume, but not transmural extent, correlated with CK-max (r=0.86) and LVEF at follow-up (r=-0.80). In the absence of MO, LVEDV remained unchanged (137±28 vs 136±18 ml; p=ns), while LVEF increased at follow-up (41±4 vs 47±6%; p<0.05). If MO was present, LVEF did not improve (37±11 vs 37±12%; p=ns) and there was a significant increase in LVEDV (150±37 vs 168±20 ml; p<0.05). In the acute setting 7 out of 10 pts with MO had an occluded IRA and 8 had a significant restenosis at follow up (80%), whereas only 2 out of 13 pts (15%) without MO developed a significant restenosis (p<0.01).
Conclusions: Infarct volume 3 months after revascularization can be predicted using contrast enhanced MR in the acute setting. The presence of MO predicts 1)an increase of LVEDV, 2)no improvement of LVEF and 3)development of early restenosis of IRA. Maximal medical therapy prevents myocardial remodeling in pts with MI but without MO.

881 Seven-year follow-up after a normal exercise stress sestamibi study

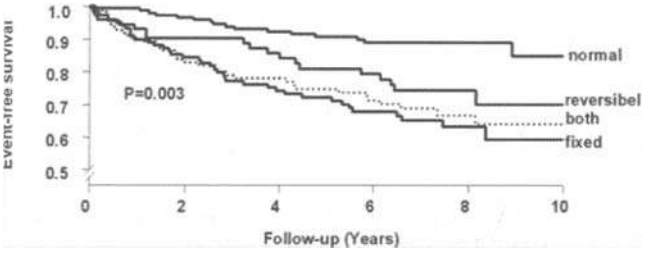
A. Elhendy[1], A. Schinkel[2], R. van Domburg[2], D. Poldermans[2], J. Bax[2], J. Roelandt[2]. [1]*Mayo Clinic, Cardiovascular Division, Rochester, United States of America;* [2]*Dijkzigt Hospital - ThoraxCenter, Cardiology Dept., Rotterdam, Netherlands*

Rationale. The aim of this study was to evaluate the incidence and predictors of mortality and cardiac events at long term follow up after a normal exercise stress 99m-technetium sestamibi SPECT study.
Background: A normal exercise sestamibi study identifies patients with a low event rate at an intermediate term follow up. However, the longer-term outcome has not been evaluated.
Methods: Follow up was performed in 218 patients who underwent symptom limited bicycle exercise stress test in conjunction with 99m technetium sestamibi SPECT and demonstrated normal stress and resting perfusion. Endpoints were all cause mortality and hard cardiac events (cardiac death and non-fatal myocardial infarction).
Results: Mean age was 53 ± 10 years. There were 108 men and 110 women. Forty-seven patients (22%) were known to have coronary artery disease (previous coronary angioplasty or myocardial infarction). The pretest probability of coronary artery disease in the remaining patients was low in 57 and intermediate or high in 107 patients. Mean follow up duration was 7.4 ± 1.8 (maximal = 11.7) years. The minimum follow up duration (in patients without events) was 6 years. During follow up, 13 patients died of different causes (cardiac death in one patient) and 10 patients had non-fatal myocardial infarction. The annual hard cardiac event rate was 0.7% per year during the 6 years and 2% per year during the seventh and eighth year following the test. Overall mortality rate was 0.6% during the 5 years and 1.8 between the sixth and eighth years following the test. In a Cox multivariate analysis model, exercise heart rate was the only independent predictor of hard cardiac events (Chi^2 = 12, risk ration (RR) =0.95, CI 0.92-0.98). Independent predictors of all cause mortality were age (Chi^2 = 4, RR = 1.08, CI 1-1.17) and exercise heart rate (Chi^2 = 5, RR =0.97, CI 0.95-1). By using receiver operator curves, exercise heart rate <130 beats/minutes was the best cutoff that identified patients with higher event rate.
Conclusion: Patients with normal exercise 99m-technetium sestamibi SPECT have a very low mortality and cardiac event rate at a longer-term follow up. Events occur more frequently in patients with low exercise heart rate. These patients should be closely followed and may require pharmacologic stress testing subsequently, due to the possible impact of heart rate on the sensitivity of exercise stress test.

882 Long-term prognostic value of dobutamine-atropine stress ^{99m}Tc-sestamibi SPECT: a single-center experience with 8-year follow-up

A.F.L. Schinkel, A. Elhendy, R.T. van Domburg, J.J. Bax, E.C. Vourvouri, F.B. Sozzi, J.R.T.C. Roelandt, D. Poldermans. *Erasmus Medical Center Rotterdam, Cardiology Dept., Rotterdam, Netherlands*

Objectives: The aim of this study was to determine the long-term prognostic value of dobutamine-atropine 99mTc-sestamibi SPECT in patients with limited exercise capacity.
Background: The prognostic value of 99mTc-sestamibi SPECT has been assessed for short- and intermediate-term follow-up. However, the long-term prognostic value is ill defined.
Methods: Clinical data and SPECT results were analyzed in 531 consecutive patients. Follow-up was successful in 528 (99.4%) patients, 55 underwent early revascularization (<3 months) and were excluded. A normal/abnormal study was considered in the absence/presence of fixed and/or reversible perfusion defects. A summed stress score (SSS) was obtained to estimate the extent and severity of perfusion defects.
Results: An abnormal scan was detected in 312 patients. During the 8±1.5 year follow-up (4.5-10.6), cardiac death occurred in 67 patients (total death 165), nonfatal infarction in 34, and late revascularization in 49. The annual event rates for cardiac death, cardiac death or infarction, and all events were 0.9%, 1.2%, and 1.5% respectively after a normal scan, and 2.7%, 3.4%, and 4.4% after an abnormal scan (P<0.05). In a multivariable Cox proportional-hazards model, not merely the presence of an abnormal scan but also the SSS provided incremental prognostic information over clinical data (P<0.0001). The hazard ratio for cardiac death was 1.09 (95% CI 1.01 to 1.18) per 1 unit increment of the SSS.



Cardiac death/infarction free survival.

Conclusions: The incremental prognostic value of dobutamine-atropine stress 99mTc-sestamibi SPECT over clinical data is maintained over an 8-year follow-up period in patients with limited exercise capacity.

883 Incremental prognostic power of the Duke treadmill score, exercise EF and SPECT imaging in high-risk patients for coronary artery disease

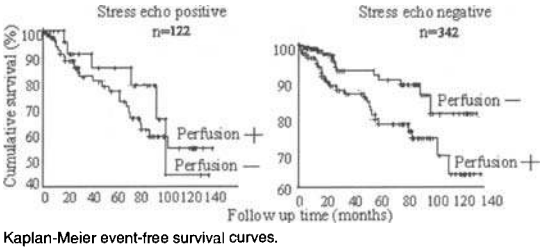
S. Borges-Neto, W.T. Smith. *Duke University Medical Center, Radiology/Nuclear Medicine, Durham, United States of America*

Background: Non-invasive exercise testing has been shown to provide prognostic information and risk stratification mostly in patients with suspected coronary artery disease (CAD). However, the incremental contribution of the Duke treadmill score (DTS), exercise first pass radionuclide angiography (RNA-EF) and exercise perfusion SPECT imaging, has not been assessed in a high-risk population undergoing all three test modalities.
Methods: 895 patients were identified who underwent Bruce protocol exercise treadmill testing with RNA-EF and SPECT perfusion imaging as a single test between 1993 and 2000. Patients were followed for the outcomes of all-cause death, cardiovascular death (CVD), and non-fatal MI. Relative prognostic power of each test was evaluated unadjusted and adjusted for baseline characteristics using Cox proportional hazards models.
Results: During follow-up (median = 3.9 years), outcome events occurred in 163 patients. Without adjustment, each of the risk stratification modalities proved highly predictive of the combined endpoint of cardiovascular death or non-fatal MI (DTS Chi^2=13.8, p=0.0002; RNA-EF Chi^2=24.3, p=0.0001; SPECT Chi^2 = 15.5, p=0.0001). Perfusion and function imaging provided significantly more prognostic power than DTS alone. In clinically risk-adjusted models, exercise RNA-EF provided incremental prognostic information above that provided by SPECT for the end-point of CVD. Once RNA EF was known, no additional information was provided by SPECT. Conversely, exercise SPECT perfusion was a better predictor of non-fatal MI and added incremental prognostic information above that provided by RNA-EF (Incremental Chi^2 = 13.4, and 5.5, respectively, p< 0.05).
Conclusion: Exercise DTS, perfusion SPECT and exercise RNA-EF are each significant predictors of cardiovascular events in high-risk patients. SPECT imaging predicted non-fatal MI most powerfully, while RNA-EF is the strongest predictor of cardiovascular and all-cause mortality. The optimal risk stratification of high-risk patients for CAD may consist of the combined assessment of LV function and myocardial perfusion.

884 The relative prognostic value of stress nuclear perfusion versus stress echocardiography

A. Varga[1], P. Marzullo[2], N. Gruber[1], A. Gimelli[2], T. Forster[1], L. Csernay[1], M. Csanady[1], E. Picano[2]. [1]*Szeged University, 2nd Dept. of Medicine, Szeged, Hungary;* [2]*Institute of Clinical Physiology, PISA, Italy*

Background: Stress echocardiography and radionuclide perfusion imaging are useful imaging modalities for the diagnosis of coronary artery disease. Aim: To evaluate the long term prognostic value of the 2 imaging modalities (nuclear and echo) in patients with known or suspected coronary artery disease.
Methods: We studied 464 patients (320 males, mean age 56±10 years) who underwent on different days and in random order within one week pharmacological stress echocardiography (dobutamine; n=249, or dipyridamole; n=215) and perfusion scintigraphy (Thallium; n=122 or MIBI; n=342) with either dipyridamole (n=225) or dobutamine (n=239). All patients were followed up for 48±39 months. Patients with revascularization <12 months after testing were not included in the analysis.
Results: Seventy-two patients experienced events: 21 non fatal myocardial infarctions, 13 cardiac deaths, and 38 patients had a late (> 12 months) revascularization procedure either by PTCA (n=21) or CABG (n=17). The cumulative event free survival was 91% in patients with negative and 78% in patients with positive perfusion scintigraphy (p<0.01); 88% and 75% in patients with negative and positive stress echocardiography, respectively (p<0.01). When stress echocardiography was first incorporated in the prognostic model, scintigraphy added significant information only in patients with negative stress echo results (figure).



Kaplan-Meier event-free survival curves.

Conclusion: Stress echocardiography and perfusion scintigraphy are useful predictors, with comparable prognostic value, of late cardiac events in patients with known or suspected coronary artery disease. The incremental prognostic value of perfusion scintigraphy over stress echo is detectable in patients with negative, not with positive echo.

MYOCARDITIS: DIAGNOSTIC ASPECTS

885 Polymorphic presentation and prognostic factors in biopsy-proven myocarditis: a single centre experience in 100 cases

A.L.P. Caforio[1], F. Tona[1], A. Angelini[2], L. Daliento[1], M. Bontorin[1], S. Piaserico[3], S. Iliceto[1], G. Thiene[2]. [1]*University of Padua, Cardiology, Dept Exp Clin Med, Padua, Italy;* [2]*University of Padua, Pathology Dept., Padua, Italy;* [3]*University of Padua, Dermatology Dept., Padua, Italy*

The clinical spectrum of acute myocarditis (My) ranges from subtle ECG abnormalities to fulminant heart failure and sudden death. The prognostic significance of features at diagnosis (dgn) is controversial.
Methods: We studied 100 patients (pts), 62 males, aged 32 ± 19 years, mean follow-up (f-u) 30 ± 39 months. Presentation was in 18 pts with arrhythmia and/or syncope (group I), in 62 left ventricular (LV) dysfunction (group II), in 20 rest angina with abnormal troponin I (group III). 69 pts were in I/II NYHA class, 24 in III and 7 in IV; 4 pts were in atrial fibrillation, 10 had an atrioventricular block, 10 a LV bundle branch block and 14 ST-T ischemic changes. LV end-diastolic volume (LVEDV) and ejection fraction (LVEF) by 2-dimensional echocardiography (2-D echo) were 104 ± 49 ml/m^2 and 41 ± 14% respectively. Cardiac catheterization (CC) showed a mean right atrium pressure (mRAP) of 5 ± 5 mmHg and a LVEF of 43 ± 18%. Coronary angiogram was normal in all pts. Histology on endomyocardial biopsy (EMB) was of My (Dallas criteria) (91 lymphocytic, 3 polymorphic, 4 giant cell, 1 eosinophil and 1 sarcoid). Features at dgn in alive vs dead/transplanted pts as well as among groups were compared by analysis of variance; the prognostic effect of LVEF at dgn was confirmed by logistic regression in terms of odds ratio (OR) and 95% confidence intervals (CI).
Results: At f-u 61 pts were alive, 21 dead or transplanted, 18 lost; 60 pts were in NYHA I/II, 1 patient in III, with a LVEF of 51 ± 13%. Actuarial survival (Kaplan Meier) was of 69% at 3 years. Univariate predictors of death or transplantation were: NYHA II to IV (p=0.02), presentation with LV dysfunction (p=0.01), higher mRAP (10 ± 7 vs 4 ± 3 mmHg, p=0.005), lower LVEF at CC (27 ± 16 vs 47 ± 17%, p=0.004) and on 2-D echo (30 ± 10 vs 44 ± 14%, p=0.001). Group II pts had lower LVEF (p=0.0001) and greater LVEDV (p=0.0001); at f-u there were more dead/transplanted pts in Group II (38.5%, p=0.008) than in the other groups. By logistic regression, pts with LVEF at dgn between 34% and 46% had increased mortality risk (OR 10, CI 1.5-58.8, p=0.01) as well as pts with LVEF <33% (OR 16.6, CI 1.37-200,p=0.01) compared to pts with LVEF> 46%.
Conclusions: Biopsy-proven My has a high mortality rate (31% at 3 years). Clinical presentation with LV dysfunction is common; this underlines the diagnostic value of EMB in pts with LV dysfunction and normal coronary angiograms. The main independent negative predictor is the degree of reduced LVEF at dgn. The prognostic relevance of etiology (e.g. infective vs immune) remains to be clarified.

886 Endothelial dysfunction in myocardial inflammation correlates in patients' epicardial arteries, systemic arteries and coronary microcirculation

K.B. Vallbracht, U. Kühl, P.L. Schwimmbeck, S. Behrens, A. Morguet, B. Seeberg, H.P. Schultheiss. *University Hospital Benjamin Franklin, Cardiology, Berlin, Germany*

Background: In patients with inflammatory cardiomyopathy (InfCM), immunohistological evaluation of myocardial biopsies demonstrates an inflammatory immune response in myocardium and vessels, which is associated with endothelial dysfunction of systemic arteries. Aim of this study was to investigate endothelial function (ENF)of epicardial and systemic arteries and coronary microcirculation in correlation.
Methods: ENF of epicardial arteries, coronary microcirculation and systemic arteries was tested in 51 consecutive patients with suspected myocardial inflammation. In 40 patients, InfCM was confirmed by immunohistology, 11 patients had normal myocardial biopsies. ENF of the epicardial arteries was measured during the heart catheterization, by diameter changes of the LAD in response to locally administered acetylcholine (muscarinic receptor mediated ENF (ACh3MD)) and adenosine (shear stress mediated ENF (FMDc)). ENF of the coronary microcirculation was tested via flow-wire, measuring velocity changes in the LAD during local infusion of the above vasoactive substances (CBF). ENF of the radial artery was examined by means of high resolution ultrasound, measuring flow mediated vasodilation (FMDp). ENF was compared to endothelium independent vasoreactivity to glyceroltrinitrate.
Results: Mean age of the 51 patients was 43±13 years, 29 were male, 22 female. Mean left ventricular ejection fraction was 60±15%. ENF was impaired in patients with InfCM as compared to controls. Endothelial dysfunction was demonstrated in epicardial arteries (shear stress mediated (FMDc (%) 2.90±4.83 vs. 15.05±11.08) and ACh-mediated (ACh3MD (%) -22.95 ±23.95 vs. 2.89±19.88)), in the coronary microcirculation (CBF (%) 35.62±102.07 vs. 135.81±186.9) and in systemic arteries (FMDp 3.67±2.38 vs. 6.59±4.54). The severity of endothelial dysfunction in the different vascular beds correlated: FMDc-FMDp r=0.461 (p=0.001), FMDp-ACh3MD r=0.361 (p=0.011), FMDc-ACh3MD r=0.374 (p=0.008), CBF-FMDc r=0.295 (p=0.04), CBF-ACh3MD r=0.461 (p=0.001). Endothelium independent vasodilation in patients with InfCM was only mildly impaired, as compared to controls.
Conclusions: InfCM is associated with endothelial dysfunction, which involves epicardial and systemic arteries, as well as coronary microcirculation. The extent of endothelial dysfunction in these vascular regions correlates. ENF mediated by shear stress and by muscarinic receptors is impaired. Non-invasive measurement of ENF in systemic arteries may reflect coronary endothelial function.

887 Comparison of virus serology with endomyocardial biopsy findings in patients with viral myocarditis focusing on parvovirus B19

I. Janzen[1], B. Schwaab[2], B. Gärtner[3], R. Kandolf[4], B. Hennen[1], M. Böhm[1]. [1]*Universitätskliniken des Saarlandes, Innere Medizin III, Homburg/Saar;* [2]*Curschmann-Klinik, Timmendorfer Strand;* [3]*Universitätskliniken des Saarlandes, Abteilung für Virologie, Homburg/Saar;* [4]*Universitätsklinikum, Abteilung für Molekulare Pathologie, Tübingen, Germany*

Purpose: Guidelines for the diagnosis of myocarditis still recommend virus serology. The present study prospectively compared results of virus serology in serum with results of viral genome detection in endomyocardial biopsies.
Method: In 92 patient with clinical suspected myocarditis at least 4 left ventricular endomyocardial biopsies were taken after invasive exclusion of coronary heart disease or valve disease by coronary angiography and left heart catheterisation. Myocardial viral genome was detected by PCR and in situ-hybridisation. Before this procedure biopsy blood samples of all patients were taken for serological analysis of infection with cardiotropic viruses (Coxsackie-, Entero-, Echo-, Adeno-, Herpes-, Influenza-, Parainfluenza-Virus as well as Parvovirus B19).
Results: In 24 of 92 patients (26%) viral genome was detected in myocardial biopsies: Entero- (n=6), Epstein-Barr- (n=3), human Herpes-6 (n=1), Coxsackie-B3-Virus (n=1) and Parvovirus B19 (n=13). In serological testing no patient revealed an acute infection with the same virus that was detected in endomyocardial biopsy. However, 23 patients showed serological signs of an infection in the past with the same virus that was detected in the myocard. In patients exhibiting myocardial virus persistence an acute myocarditis was documented once by histology and immunhistology; chronic myocarditis was observed in 15 patients and dilated cardiomyopathy in 8 cases.
Conclusion: The detection of myocardial viral genome does not correlate with the serological findings of an acute virus infection. Because of the high prevalence of these viruses in the general population virus serology does not show any benefit for the diagnostic of myocarditis. In view of the considerable costs for virus serology in serum this technique should be abandoned from the diagnostic tools in suspected myocarditis. As 54% of detected viral genome in this cohort of patients was Parvovirus B19 this virus seems to be considered as a new cardiotropic virus.

888 Enteroviral persistence and elimination are associated with the course of lymphocytic infiltration in human myocarditis

M. Noutsias, U. Kuhl, S. Jaskolla, P.L. Schwimmbeck, M. Pauschinger, H.P. Schultheiss. *University Hospital Benjamin Franklin, Cardiology Dept., Berlin, Germany*

The mechanisms responsible for viral elimination (VE) or viral persistence (VP) in enteroviral myocarditis have not been elucidated, yet.
We investigated immunohistochemically detected T-lymphocytic infiltrates (CD2+, CD3+ cells; unit: cells/high power field at 400xfold magnification) in endomyocardial biopsies (EMBs) from myocarditis patients (n=15; 4 females; age: 49±12 years; LVEF: 54±15%) with molecular biological (PCR) prove of enteroviral genome in the initial EMB. Intramyocardial infiltration and the presence of enteroviral genome were evaluated also in follow-up EMBs (2nd EMB at 6 months, 3rd EMB at 12 months after the initial presentation). At the 2nd EMB, 3 cases (20%) did not present any enteroviral genome, and at the 3rd EMB, 8 cases (53%) presented viral elimination (VE), the 3 patients showing VE at the 2nd EMB persisting negative for viral genome at the time of the 3rd EMB. Whereas T-lymphocytic infiltrates increased in VE-patients over time, T-lymphocytic infiltrates decreased significantly ($p<0.05$) in VP-patients at follow-up (MANOVA, mode: repeated measures, variable: time; table values: mean±SD). This tendency was already perceived at the 2nd EMB and pursued at the 3rd EMB (table).

	1st EMB	2nd EMB	3rd EMB
CD2-VP	5.2±6.7	4.7±4.7	2.3±2.2
CD2-VE	2.0±1.7	3.8±5.6	3.9±6.8
CD3-VP	5.2±7.4	4.9±5.3	2.3±2.6
CD3-VE	2.1±1.2	3.8±5.6	3.6±5.7

The natural course of enteroviral myocarditis significantly depends on the course of T-lymphocytic infiltration: Whereas significant increment of intramyocardial infiltration over time leads to elimination of the viral genome, decrement of lymphocytic infiltration is associated with viral persistence. Our data suggest antiviral-immunomodulatory regimens in myocarditis patients with viral persistence.

889 Significance of human parvovirus B19 in human myocarditis of the adult

S. Düx[1], S. Lentini[1], D. Skowasch[1], K. Klingel[2], R. Kandolf[2], B. Lüderitz[1], G. Bauriedel[1]. [1]*University of Bonn, Med. Univ. Klinik und Poliklinik II, Bonn;* [2]*University of Tübingen, Institute for Molecular Pathology, Tübingen, Germany*

Purpose: Human Parvovirus B19 (PVB19) is an important pathogen in fetal development to childhood, e.g. causing hydrops fetalis, erythema infectiosum and myocarditis. Clinical manifestations of PVB19 infection in adults are unspecific devoid a few cases reported that showed a relationship between PVB19 and myocarditis. The aim of this study was to determine the role of human PVB19 in adult myocarditis versus specific cardiomyopathies.
Methods: A total of 86 left ventricular endomyocardial biopsies was retrieved from patients that presented with cardiac dysfunction. Myocardial specimens were analyzed by histochemistry, PCR and in-situ-hybridization for PVB19, Epstein-Barr (EBV), Enterovirus (EV) and Human Herpes Virus 6 (HHV6). Apoptosis was detected by TUNEL labeling. Enddiastolic volume (EDV), its index (EDVI) and ejection fraction (EF) were assessed by ventriculography.
Results: In 37 of 86 cases (43%), myocarditis was grouped into acute myocarditis (n=4), chronic myocarditis (n=7), with (n=11) or without (n=15) tissue defects, and into dilated cardiomyopathy (DCM, n=24), and hypertrophic CM (HCM, n=15) by histochemistry. No histopathologic abnormalities were found in 10 cases. As to myocarditis, PVB19 DNA was found in 46% of all patients (acute 50%, chronic 71%, without defect 60%, with defect 36%), EV DNA in 5%, EBV DNA in 5%, HHV6 and PVB19 DNA in 5%, EBV and PVB19 DNA in 3% positive, whereas in 35% no virus was detected by PCR (see table, figures in per cent). Comparing hemodynamic data, PVB19(+) myocarditis was associated with a lower EF than virus(-) myocarditis (39±16% vs 54±14%, p=0,012), while there were no differences in EDV or EDVI. Also, hemodynamic data and apoptosis did not correlate.

	n=86	PVB19	EV	EBV	HHV6	no virus
Myocarditis	43	46	5	5	0	35
DCM	28	4	0	0	4	92
HCM	17	13	0	0	0	87
Controlls	12	10	0	0	0	90

Conclusions: PVB19 is by far the predominant virus in adult myocarditis and mainly associated with chronic myocarditis and myocarditis without documented tissue defect. The specific pathomechanisms induced by PVB19 are still unclear and merit further consideration.

890 Active lymphocytic myocarditis: virologic and immunologic profile of responders versus non-responders to immunosuppressive therapy

C. Chimenti[1], M. Pieroni[1], F. Calabrese[2], R. Verardo[1], G. Thiene[2], A. Maseri[3], A. Frustaci[1]. [1]*Catholic University, Department of Cardiology, Rome, Italy;* [2]*University of Padua, Department of Pathology, Padua, Italy;* [3]*Istituto San Raffaele, Department of cardiology, Milan, Italy*

Background: The beneficial effect of immunosuppressive treatment on myocarditis is still controversial possibly because the immunologic and virologic profile of potential candidates is largely unknown.
Methods: Among 112 consecutive patients with a histological diagnosis of active lymphocytic myocarditis, 41 (29M, 12 F, mean age 42.9±13.5 years) characterized by progressive heart failure in spite of conventional supportive therapy were treated with prednisone and azathioprine for 6 months. All were re-submitted to cardiac catheterization, angiography and endomyocardial biopsy at 1 and 6 months of follow-up. 21 patients responded with prompt improvement in left ventricular ejection fraction (EF) from 25.7±4.1% to 47.1±4.4% and showed evidence of healed myocarditis at control biopsy. Conversely, 20 patients failed to respond and remained stationary (12), underwent cardiac transplantation (3) or died (5), showing a histological evolution toward dilated cardiomyopathy. We retrospectively performed a polymerase chain reaction on frozen endomyocardial tissue for the most common cardiotropic viruses and evaluation of circulating cardiac autoantibodies on pts sera.
Results: Viral genomes were present in 17 of non-responders (85%), including enterovirus (5), Epstein-Barr virus (5), adenovirus (4), both adenovirus and enterovirus (1), influenza A virus (1), parvovirus-B19 (1) and in 3 of responders, all positive for hepatitis C virus. Cardiac autoantibodies were present in 19 responders (90%) and in none of non-responders.
Conclusions: Patients with active lymphocytic myocarditis, circulating cardiac autoantibodies and no viral genome in the myocardium are most likely to benefit from immunosuppression. The beneficial effect of immunosuppression observed in HCV myocarditis suggests a relevant immunomediated component of damage.

NEW ISSUES IN HYPERTROPHIC CARDIOMYOPATHY

891 Implanteble cardioverter defibrillator utilization among device recipients with hypertrophic cardiomyopathy – The Israeli experience

A. Militianu, B. Zafrir on behalf of The Israeli group of pacing and electrophysiology. *Lady Davis Carmel Medical Center, Cardiology, HAIFA, Israel*

Little is known about implantable cardioverter defibrillator (ICD) discharges in recipients of devices with hypertrophic cardiomyopathy (HCM). We retrospectively analyzed ICD utilization in all ICD recipients with HCM ever implanted in Israel. Among approximately 2000 ICD implanted, 51 were high-risk patients (pts) with HCM. Thirty six (71%) were males and the mean age was 42.5 (range 13-77). The indication for the ICD implantation (imp) were:1)Secondary prevention (SP)- in 24 pts after aborted sudden cardiac death (SCD) or spontaneous sustained ventricular tachyarrhythmia (VTA). 2) Primary prevention (PP)-in 27 (53%) high-risk pts for SCD, who had at least one risk factor (family history of SCD, syncope or inducible VTA at EPS).All the ICD's had stored electrogram capability.
Results: During mean follow-up of 36.7 mos (range 3-127) [41.6 mos (range 4-127) in the SP group and 32.4 mos (range 3-110) in the PP group (p=0.24)], 16 pts (31%) had at least 1 appropriate (app) ICD discharge and 9 pts (18%) only inappropriate discharges. First app discharge occurred at a mean of 17.4 mos (range 1-73), [16.9 mos (range 1-73) in the SP group and 19.7 mos (range 14-24) in the PP group (p=0.82)], due to VTA with mean CL of 290 ms(range 200-435) diagnosed by stored electrogram in all the pts. Among the 24 SP pts 13 (54%) had at least 1 app discharge compared to only 3/27 pts (11%) among the PP pts(P=0.0037). Three pts died, 30,55, and 73 mos after the imp from non arrhythmic causes.
Conclusions: Our data support the use of ICD as secondary prevention in post event pts with HCM. However, identification of the high-risk pts candidate for primary prevention implantation remains a challenge.

892 Pregnancy related complications in women with hypertrophic cardiomyopathy

R. Thaman, M.S. Hamid, S. Firoozi, M. Condon, R. Murphy, A. Varnava, P.M. Elliott, W.J. McKenna. *St George's Hospital Medical School, Cardiological Sciences, London, United Kingdom*

Background: Due to lack of systematic data controversy persists as to whether or not pregnancy is well tolerated in hypertrophic cardiomyopathy (HCM).
Methods: Questionnaires were sent to 200 consecutively referred women with HCM. Clinical evaluation included history, family history, resting and ambulatory ECG, echocardiography and symptom-limited cardiopulmonary exercise testing. Obstetric notes (available in 43% of women) were also reviewed.
Results: Questionnaires were completed by 165 (82.5%) women with 127 (age 47 ± 15) having been pregnant and accounting for 271 pregnancies. Clinical data was available before pregnancy in 40 (32%) women. Eighty-seven (69%) women were referred after pregnancy (57 were diagnosed with HCM before, during or between pregnancies and 30 after pregnancy), in these data from their first clinic visit was reviewed.
Forty-three (34%) women reported cardiac symptoms before pregnancy including 10 women that were diagnosed with HCM after pregnancy. Thirty-five (28%) women reported cardiac symptoms antenatally with over 90% having been symptomatic before pregnancy. A deterioration in pre-pregnancy symptoms during pregnancy occurred in less than 10%. Of the 35 women with symptoms, 30 had further pregnancies. Symptoms reoccurred in 18 (60%) but symptomatic deterioration was not reported. Heart failure occurred post-natally in 2 women (1.6%). Nineteen (15%) women required general anaesthesia, no complications were reported. Eleven (8.7%) women known to have HCM before pregnancy received epidural anaesthesia (EA). None of these patients had significant left ventricular outflow tract obstruction (LVOTO), 2 reported dizziness and one had hypotension. No symptoms were reported in another 11 (8.7%) women that received EA that were not diagnosed with HCM before pregnancy, 3 were later found to have significant LVOTO (> 30 mmHg). Three unexplained intrauterine deaths occurred in women taking cardiac medication throughout pregnancy.
No echocardiographic or clinical feature was a useful indicator of pregnancy related complications.
Conclusions: Women with HCM tolerate pregnancy well. Medication should be stopped where possible. EA should continue to be used cautiously.

893 Cost-effectiveness analysis of screening strategies for identification of athletes with hypertrophic cardiomyopathy at risk for sudden death

D. Corrado[1], C. Basso[2], M. Schiavon[3], G. Thiene[2]. [1]*University of Padova, Division of Cardiology, Padova, Italy;* [2]*University of Padova, Department of Pathology, Padova, Italy;* [3]*Institute of Sports Medicine, Padova, Italy*

Background: We previously reported that systematic preparticipation screening by history, physical examination and 12-lead ECG successfully identifies and disqualifies young competitive athletes affected by hypertrophic cardiomyopathy (HCM) and prevents sudden death (SD) during a long term follow-up. The present study performes a cost-effectiveness analysis (cost per year of life gained) of the above preparticipation evaluation (type I screening) as compared with other two recommended cardiovascular screening modalities such as history and physical examination only (type II screening) and history, physical examination and 12-lead ECG plus echocardiography (type III screening). Methods: Among 33,735 young competitive athletes (aged 12-35 years) initially screened at the Center for Sports Medicine in Padua from 1979 to 1996 according to type I screening, only 3,016 (8.9%) were referred for echocardiography and 22 (0.07%) were actually found to be affected by HCM and disqualified from competitive sports. Accordingly, the estimated sensitivity and specificity of type I screening was 70% and 90%, respectively as compared to 20% and 95% for type II and 100% and 100% for type III screening modalities (echocardiography was deemed to be the "gold standard" for HCM diagnosis). For the purpose of the study, it was assumed that athletes with HCM who were identified and disqualified by preparticipation screening (all three screening modalities) will live the following number of years: 10% will live an additional 40 years and 90% will live an additional 20 years. The cost for performing cardiovascular evaluation was estimated at 20 euro for type I, 10 euro for type II and 100 euro for type III screening modalities.Results: The cost to initially screen 33,735 athletes and to further evaluate those 3,016 with abnormal response was 1,176,032 euro by type I screening, whereas it would have been 697,640 euro for type II and 3,373,500 euro for type III screening strategies. The total amount of life gained by type I screening was 484 years as compared with 132 years by type II and 680 years by type III. The approximate costs per year of life saved were: type I screening 2,429 euro, type II 5,285 euro and type III 4,961 euro. Conclusions: History, physical examination and 12-lead ECG was the most cost-effective preparticipation cardiovascular modality for identification of athletes with HCM at risk of SD, with an approximate cost per year of life saved of 2,429 euro.

894 Doppler tissue imaging and hypertrophic cardiomyopathy in genotyped families

P. Charron[1], A. Gackowski[1], P. Richard[2], R. Isnard[1], B. Hainque[2], K. Schwartz[3], M. Komajda[1]. [1]Pitié-Salpêtrière Hospital, Cardiology Dept., Paris, France; [2]Hopital Pitie-Salpetriere, Biochemistry Dept, Paris, France; [3]Hopital Pitie-Salpêtrière, INSERM U523 Dept., Paris, France

Background: In families with Hypertrophic Cardiomyopathy (HCM), the expression of the disease is highly variable and left ventricular hypertrophy (LVH) may even be absent in adults who carry the causal mutation. Pulsed Doppler Tissue Imaging (DTI) was recently proposed as a novel means for early diagnosis of HCM independently of LVH, (sensitivity: 100%, specificity: 90% for Ea <14 cm/s). We tested whether HCM consistently showed reduced myocardial velocities, irrespective of LVH.
Methods and Results: We performed 2D, Doppler and pulsed DTI (mitral annulus: MA) echocardiography in 16 adults with HCM, 7 healthy carriers (adults who carry a mutation but did not have LVH), and 7 age- and sex-matched controls. LV wall thickness, systolic and early diastolic velocities (DTI-MA) were significantly different between adults with LVH and controls ($P<0.05$ for each parameter). Between mutation-positive adults without LVH and controls, neither LV wall thickness nor systolic velocities were different. Early diastolic velocities (DTI-MA) were lower in healthy carriers than in controls (Ea: 16.3 vs 20.2 cm/s, P=0.037), but with a large overlap of individual data. Sensitivity and specificity of DTI for the diagnosis of HCM without LVH were 28% and 100% respectively.
Conclusions: In contrast with a recent report, we found that pulsed DTI at the mitral annulus level was not an accurate and sensitive method for identifying subjects who carry a mutation but have no LVH. For instance, this novel diagnostic approach should probably not be recommended for the screening and management of families with HCM.

895 Hypertrophic cardiomyopathy related deaths in an Italian tertiary center

P. Melacini[1], A. Barchitta[1], B. Tokajuk[1], M. Zucchetto[2], G.F. Buja[1], C. Basso[3], G. Thiene[3], S. Iliceto[1]. [1]Policlinico, Cardiology, Padua, Italy; [2]Padova Ricerche, Padova, Italy; [3]University of Padua, Department of Cardiovascular Pathology, Padova, Italy

Background: Low mortality rates in hypertrophic cardiomyopathy (HCM) are recently reported in some community studies in comparison to higher rates as reported in referral Centers. Quantification of the risk of sudden death (SD) and death due to heart failure (HFD) is difficult to formulate.
Objectives: We calculated mortality rates in our tertiary Center and risk of SD and HFD in relation to clinical and echocardiographic variables as well as nonsustained ventricular tachycardia and atrial fibrillation.
Methods This analysis was undertaken in a population of 308 consecutively enrolled patients in a tertiary HCM center (1 to 79 years old,mean 43±18, 204 males). Twelve variables were considered: age at diagnosis, family history of sudden death (FHSD), NYHA, syncope, maximal left ventricular wall thickness(MLVWT), left ventricular end-diastolic diameter (LVEDD), left ventricular fractional shortening (LV FS),left atrium diameter (LAD), presence of gradient, atrial fibrillation (AF), nonsustained ventricular tachycardia (NSVT), therapy with Amiodarone during follow-up.
Results: HCM related-death occurred in 56 pts over the follow-up (mean of 7.16 ± 6 years, range 5 days to 28.7 years): SD in 30 pts (age 44 ± 16), HFD (of these 9 were transplanted) in 18 pts (age 47± 18) and other HCM-related death in 8 pts (age 43 ± 19). At ten years the SD-free survival rate was 89% (95% CI, 84 to 93), the HFD-free survival rate was 93% (95% CI, 90 to 97). The incidence of SD was 13.6 per 1000 person/year (95% CI, 9.2 to 19.4), the incidence of HFD was 8.2 per 1000 person/year (95% CI, 4.8 to 12.9). A significant association with HFD was identified for: NYHA functional class (I-II vs III-IV ($p<0,001$)) and the absence of outflow obstruction ($p<0,001$) at Fisher's exact test; wall thickness of 15mm or less (p=0,022) and left atrial cavity dimension (p=0,001) at chi square test for trend. The univariate association with SD was identified for LVEDD (p=0,002).Among these risk factors when together considered in the Cox model, MLVWT (cut-off value 20mm) was found to be independently and directly related to the incidence of SD (p=0.04; RR= 4.5) and LAD to the incidence of HFD ($p <0.001$;RR 3.1) and death from any cause (p=0.0054; RR 1.4)Therapy with Amiodarone during follow-up is an independently protective factor for death from any cause p=0,022;RR 0,2).
Conclusions: Among numerous variables only wall thickness greater than 20mm resulted statistically related to the risk of SD. Trigger for SD include not only extreme LVWT but factors as fibrosis and disarray.

MAGNETIC RESONANCE IMAGING IN CARDIAC ARRHYTHMIAS: A NEW ALLIANCE?

915 Non invasive classification and imaging of preexcitation sites by multichannel magnetocardiography

R. Fenici, D. Brisinda, P. Fenici. *Catholic University, Internal Medicine, Clinical Physiology, Rome, Italy*

Multichannel Magnetocardiography (MMCG), is a contactless method which can be used for non invasive localization and imaging of ventricular preexcitation (VPX) sites. Nevertheless so far MMCG studies of VPX patients (pts) had been done in magnetically shielded rooms only, which has limited the acceptance of this new method by clinicians, because of high cost and unfavorable location of MMCG instrumentation. After positive experience with a single channel MCG mapping system we have fostered the development and recently installed the first instrumentation for MMCG operating in an unshielded hospital environment and evaluated its reliability, with the aim to use this novel method for electroanatomical imaging also in the EP catheterization laboratory. **Method:** A 9 channels DC-SQUID MMCG system (sensitivity is 20 fT/Hz1/2) (CardioMag Imaging Inc., USA) has been used. Equivalent current dipole (ECD) and magnetic dipole (MD) models in semi-infinite space were used in the inverse calculations and 3D localization of VPX. A distributed currents model (CDI) was also used as alternative imaging procedure. Localization results were also transferred on patients MRI images. 22 WPW pts have been investigated, at least twice, to test for reproducibility, mapping 36 points from the anterior chest wall (measuring grid 20 x 20 cm). In 14 pts the second procedure was carried out on the same day, in 12 MMCG was repeated after approximately 3 months. In 6 pts, MMCG was also repeated during transesophageal atrial pacing-induced maximal VPX and/or AV reentry tachycardia. As this one was designed and ethically approved as a non invasive study only, MMCG localization of VPX was compared with that achiavable with most recent ECG algorithms. **Results:** MMCG classification of VPX was in agreement with ECG in 18/22 (81.8%). In 4/22 (18%) with conflicting results, MMCG provided a clear-cut localization in all and demonstrated complex activation patters during the delta wave in 3/4. Current density reconstruction and imaging in those cases suggested multiple activation pathways, unpredictable on the basis of ECG, in 1/4. **Conclusion:** This study demonstrates that MMCG is possible, reproducible and reliable also in our unshielded EP catheterization laboratory. As compared to ECG, MMCG classification of VPX, especially of paraseptal and multiple pathways, is more effective because MMCG provides non invasively quasi real-time 3D electroanatomical integration and imaging of the VPX sites directly on anathomical MRI images or 3D cardiac models.

916 MRI of the brain at 1.5 Tesla in patients with antibradycardia pacing: an hazardous procedure?

A. Yang[1], T. Sommer[2], R. Schimpf[1], D. Skowasch[1], T. Lewalter[1], A. Schmiedel[2], M. Hackenbroch[2], B. Lüderitz[1]. [1]Dept. of Cardiology [2]Dept. of Radiology, University of Bonn, Bonn, Germany

Magnetic resonance imaging (MRI) is one of the most important imaging tools, particularly in the diagnosis of cerebral diseases. Most MRI scanners in the Western World operate at a field strength of 1.5 Tesla. The major concerns against their use in patients with antibradycardia pacing are due to the fact that MRI induces the heating of the pacemaker (PM) leads and pulsed magnetic fields may cause oversensing during MRI. The objective of the study was to evaluate the short-term and long-term PM function in patients with antibradycardia pacing who underwent MRI of the brain. **Methods:** A total of 57 patients with strong clinical need for MRI of the brain were scanned at 1.5 Tesla (Intera, Philips Medical Systems) with 22 patients followed up for at least 3 months yet. Patients with an intrinsic heart rate <35/min were excluded. After the PM was programmed to an asynchronous mode the MRI was performed under cardiological surveillance, continous ECG monitoring and pulse oxymetry. Radiofrequency exposure was restricted to the whole-body-averaged maximum Specific Absorption Rate (SAR) of 1.2 Watt/kg, the imaging time of each sequence to 10 min with a pause of at least 5 min between two sequences to allow cooling of the lead tips. The lead impedances, battery function, pacing and sensing thresholds were determined before, immediately after and 3 months after the MRI of the brain. **Results:** All MRI scans were performed safely in the absence of any complications. Pacing thresholds, sensing thresholds, battery function and lead impedances did not change significantly immediately after and 3 months after the MRI of the brain.
Conclusions: 1. Using appropriate strategies (programming to asynchronous mode, MRI adequate cardiac monitoring, restricted radiofrequency exposure) the MRI of the brain at 1.5 Tesla can be safely performed in carefully selected PM patients. The PM testing immediately after and 3 months after MRI did not reveal any short-term or long-term damages of the antibradycardia pacing systems or major temperature-induced injuries at the PM lead insertions. 2. Therefore the MRI of the brain should not be considered as absolute contraindication in PM patients. 3. However, due to its potential risks MRI in patients with antibradycardia pacing should only be performed in experienced centres.

917 Magnetic resonance imaging in arrhythmogenic right ventricular dysplasia: assessment of myocardial abnormalities

R. Maksimovic, T.D. Thorsten Dill, C.H. Breidenbach, W. Ricken, V. Mitrovic, G. Bachmann, C. Hamm, H.F. Pitchener. *Kerckhoff Klinik, Department of Cardiology, CMR, Bad Nauheim, Germany*

Background: Arrhythmogenic right ventricular dysplasia (ARVD) has been increasingly found in patients (pts) with right ventricular (RV) arrhythmia. Although, MRI has been widely applied, diagnostic value of MRI myocardial abnormalities in evaluation of ARVD pts has not been well established. Therefore, the aim of the study was to assess diagnostic value of myocardial abnormalities in these pts and to find the best performing MRI criteria for ARVD.
Patients and Methods: The study group included 307 pts, 51.1% males (157/307), mean age 42.7±15.2 years, who were referred to the Cardiology Department for evaluation of RV arrhythmia. All patients underwent clinical examination, electrophysiologic study, echocardiography and MRI using cine and TSE T1 and T2 sequences on a Siemens Magnetom Sonata, 1.5T scanner. MRI was performed to evaluate presence of the major ARVD criteria and minor ARVD criteria. A scoring system with ranking for major and minor criteria was established. However, only 53 pts (17.6%), 64.2% males (34/53), mean age 44.2±15.4 years, had RV abnormalities on MRI. After complete examination, this group was reviewed and according to the final diagnosis, divided into the group with ARVD {group 1, 17 pts (32.1%)} and the group with other RV abnormalities {group 2, 36 pts (67.9%)}.
Results: Among major criteria, fatty replacement was present only in 3 (17.6%) pts in the group 1, ($p<0.01$). Also, there were significantly more pts with severe RV dilatation in group 1 (64.7%) than in group 2 (17.1%), $p<0.01$, and with localized RV aneurysm (group 1, 41.2%, group 2, 0%, $p<0.01$). Most minor criteria were more frequently in group 1 then in group 2: mild global RV dilatation, (22.5% vs. 34.3%, respectively, $p<0.01$), regional RV hypokinesia (76.5% vs. 41.2% respectively, $p<0.01$), dilatation of RV outflow tract (50% vs. 11.8% respectively, $p<0.01$), prominent trabeculae (82.4% vs. 37.1% respectively, $p<0.01$). The total score for the minor and the major ARVD criteria in group 1 was Median=5, and in group 2 Median=1, which was statistically significant difference, $p<0.01$. Sensitivity of this score was 65% while specificity was 94.4%.
Conclusions: The score of major and minor MRI criteria has been proved to be useful in identifying ARVD pts with high sensitivity and specificity. Although none of the criteria could be considered as pathognomonic for ARVD, MRI could obtain reliable and reproducible data on morphologic and functional abnormalities within one study, which could direct further clinical decision making in these pts.

918 Magnetic resonance imaging of pulmonary veins before and after ablation of atrial fibrillation

J. Vogt[1], L. Krater[1], A. Peterschroeder[2], J. Heintze[1], F. Warzok[1], H. Esdorn[2], H. Meyer[3], D. Horstkotte[1]. *[1]Heart Center North Rhine-Westphalia, Department of Cardiology, Bad Oeynhausen, Germany; [2]Heart Center North Rhine-Westphalia, Dept Mol Biophys, Radiopharm, Nucl Med, Bad Oeynhausen, Germany; [3]Heart Center North Rhine-Westphalia, Department of Congenital Heart Disease, Bad Oeynhausen, Germany*

Pulmonary vein (PV) isolation is a new method to eliminate the trigger for atrial fibrillation. Different mapping and ablation procedures are used to ablate pulmonary vein ostia circumferentially or partially. A severe complication is PV stenosis/occlusion during long-term follow-up. Therefore, reliable and if possible noninvasively obtained information on the anatomy and variation prior to the intervention and on PV stenosis during follow-up is required.
Of 32 patients (P) (mean age 60±7 years, mean follow-up (FU) 5.7 months (m)) with paroxysmal or persistent atrial fibrillation and PV isolation, contrast-enhanced magnetic resonance imaging (3D FFE angiography) was performed in 23 P (9 women) to investigate PV anatomy including craniocaudal diameters (Table) and in 16 P the morphology after 3 m.
17 P had normal PV anatomy. 5 P had a common origin of 2 veins (3 x right upper + right middle lobe vein, 1 x right lower + middle lobe vein, 1 x 2 left upper pulmonary veins). 3 P had 3 right PV, in 4 P the left lower PV was small. At 3-m FU, no P showed PV stenosis. One angiographically confirmed acute stenosis had returned to normal. Two other asymptomatic acute stenoses were detected after 7 days, the 3-month follow-up results are still due.

PV	Diameter (mm)
Right upper	17.3±2.2
Right lower	17.3±2.8
Left upper	17.7±2.5
Left lower	15.0±3.2

Magnetic resonance imaging is an appropriate tool to visualize the exact anatomy of pulmonary veins prior to isolation. Being a nonvasive method it is of particular value to exclude or confirm PV stenosis during follow-up.

919 Diagnosis of pulmonary vein stenosis after radiofrequency ablation by transoesophageal echocardiography and magnetic resonance imaging

N. Jander[1], T. Arentz[1], L. Görnandt[1], D. Kalusche[1], U. Blum[2], R. Fürmaier[2], F.J. Neumann[1]. *[1]Herz-Zentrum, Bad Krozingen, Germany; [2]Institut für Diagnostische Radiologie, Freiburg, Germany*

Pulmonary vein (PV) ablation using radiofrequence energy offers the potential to cure patients with refractory atrial fibrillation. However, stenosis of the treated vessels can occur. Up to now there are no clear criteria for the diagnosis of this "new desease".
Methods: We examined 52 patients (55 ± 10 years old, 40 male) 19 ± 11 months after ablation of one ore more PV for refractory atrial fibrillation with TEE (HDI 5000; ATL, USA; 5 Mhz multiplane tranducer) or angio MRI (Magnetom Sonata; Siemens, Germany; contrast medium: Gadodiamid). The definition of a significant stenosis for TEE was a Doppler peak velocity of > 110 cm/s in combination with turbulence and deformity of the flow signal. On angio MRI stenosis of PV was assessed on angio raw images and after 3D reconstruction, a decrease in PV diameter by > 50% was considered significant. MRI and TEE were studied independently and blindly.
Results: TEE was performed in 48, MRI in 42, and both procedures in 38 patients. MRI was not performed in 6 patients with pacemaker. TEE showed 13 significant stenosis and 4 occlusions. MRI demostrated 7 stenosis > 50% and 4 occlusions. TEE could measure Doppler flow in all but one of 192 PV studied. MRI was able to reveal the complet anatomy and arbitration of all PV, but in 15 of 168 PV (9%) it was difficult to assess the ostial part of the PV because of artefacts and low spatial resolution. 151 PV were studied with both procedures. Concordance with regard to TEE and MRI PV assessment was 97% (147 of 151 PV). TEE showed two significant stenosis of minor side branches which were not detected by MRI. MRI showed 5 additional stenosis < 50%. - In the whole group of patients we found 14 significant stenosis and 5 occlusions in 114 treated PV (17%). 15 of 52 patients (29%) showed at least one significant stenosis or occlusion.
Conclusions: After ablation therapy 17% of PV develop a significant stenosis. Both MRI and TEE are able to detect PV stenosis accurately. Using our criteria of a significant stenosis concordance with regard to PV assessment is 97%. MRI can visualize the complete anatomy of the PV system, but in 9% low spatial resolution and artefacts of the PV ostium makes the exclusion of a stenosis difficult.

MAGNETIC RESONANCE IMAGING IN CARDIOLOGY: ROUTINE OR STILL NEW?

921 Right ventricular remodelling after primary angioplasty for acute myocardial infarction assessed by cine magnetic resonance imaging

F. beygui[1], A. Furber[2], S. Delépine[2], G. Helft[1], P. Geslin[2], C. Le Feuvre[1], J.P. Metzger[1], J.J. Le Jeune[3]. *[1]Necker Hospital, Adult Cardiology, Paris; [2]Angers University Hospital, Cardiology Dept., Angers; [3]Angers University Hospital, Nuclear Medicine And Biophysics, Angers, France*

Few data are available on Right ventricular (RV) remodelling after acute myocadrial infarction (AMI). Cine magnetic resonance imaging (MRI) is one of the few techniques that provide accurate imaging of the right ventricle.
Methods: We sought to study RV volumes and ejection fraction by Cine MRI 8±4 days and 3 months after successful primary angioplasty for acute myocardial infarction in 53 consecutive patients with no clincal or electrocardiograhic evidence of RV infarction.
Results: The results are reported in the table. Compared to in-hospital measurements there was a significant decrease in RV volumes ($p<0.01$) at follow-up in patients with inferior but not anterior wall infarction.

RV volumes and function

	Anterior MI (n=34) In-hospital	Inferior MI (n=19) In-hospital	Anterior MI (n=28) Follow-up	Inferior MI (n=19) Follow-up
RV EDV (ml/m²)	80±25*	98±22	83±27	87±18
RV ESV (ml/m²)	46±17	51±12	48±23	39±10
RV EF (%)	42±13	48±7	42±13*	54±10
RV/LV EDV	1±0.3*	1.2±0.2	1±0.2	1.1±0.2
Changes in RV EDV (ml/M2)			-5.3±53*	33±47

MI: myocardial infarction; RV and LV: right and left ventricular; EDV and ESV: end diastolic and systolic volumes; EF: ejection fraction. *$p<0.01$ anterior vs inferior MI.

Conclusions: Our data show evidence of reversible right ventricular remodelling early after acute inferior wall infarction despite absence of clinical or electrocardiographic evidence of RV infarction. There is no sign of right ventricular remodelling after anterior wall infarction.

922 Safety and feasibility of high-dose dobutamine-atropine stress MRI for diagnosis of myocardial ischaemia: experience in 500 consecutive patients

A. Wahl, A. Gollesch, S. Roethemeyer, I. Paetsch, D. Foell, C. Klein, H. Langreck, E. Nagel. *German Heart Institute Berlin, Cardiology, Berlin, Germany*

Introduction: High-dose dobutamine stress MRI (DSMR) recently emerged as a new highly accurate diagnostic modality. However, prior experience with other methodologies using dobutamine infusions has shown that severe complications may be expected in 0.25-0.6% of patients (pts).
Methods: from 1997-2001, 500 consecutive pts (60±9 yrs, range 23-84; prior myocardial infarction 28%; prior percutaneous or surgical revascularization in 41% and 18%) with suspected (n=195; 39%) or known (n=305; 61%) coronary artery disease underwent DSMR (1.5 T Philips). Images were acquired at rest and during a standardized high-dose dobutamine-atropine protocol in 3 short-axis, a 4- and a 2-chamber view. A single-slice segmented turbo gradient echo technique (TR/TE/flip 5.6/1.9/25; spatial res<=1.5x2.5x8 mm; temporal res<30 ms), and from 2001 on, a balanced FFE technique (TR/TE/flip 3.0/1.5/55; spatial res<=1.7x2.7x8 mm; temporal res<42 ms) were used. Dobutamine was infused at doses of 10, 20, 30, and 40 μg.kg-1.min-1, and supplemented by atropine if needed, until >=85% of age-predicted heart rate was reached. Stress testing was discontinued when >=85% of age-predicted heart rate was reached, on patient request, termination of the protocol, or when new or worsening wall motion abnormalities, severe angina or dyspnea, decrease in systolic blood pressure (BP)>40 mmHg, arterial hypertension (>240/120 mmHg), or severe arrhythmias occurred.
Results: DSMR was successfully performed in all but 2 pts (0.4%, insufficient ECG-triggering). Heart rate increased from 67±12 to 135±18 bpm, systolic BP from 131±22 to 158±34 mmHg, and diastolic BP from 73±12 to 76±16 mmHg (p<0.0001 for all). However, target heart rate was not reached in 69 pts (14%), due to end of protocol in negative submaximal examinations in 25 pts (5%), and limiting side effects in 42 pts (9%), including severe chest pain (n=15) or dyspnea (n=4), ventricular extrasystoly (n=7), severe increase (n=6) or decrease(n=3) in BP, atrial fibrillation (AFib; n=4), nausea (n=1) or patient request (n=2).
In diagnostic examinations, other side effects included a case (0.2%) of sustained ventricular tachycardia (VT) requiring external defibrillation, 3 cases (0.6%) of non-sustained VT, 2 further cases (0.4%) of AFib, and 8 further cases (1.6%) of nausea. 194 pts (39%) showed a new or worsening wall motion abnormality, while 237 (47%) did not.
Conclusions: High-dose DSMR is safe and feasible in pts with suspected or known coronary artery disease. However, pts must be closely monitored, and resuscitation equipment and trained personnel must be available.

923 Utility of quantitative parameters for early diagnosis of right ventricular dysfunction in patients with chronic right ventricular overload

I.I. Tulevski[1], M. Groenink[1], A. Hirsch[1], H.W. Vliegen[2], E.E. van der Wall[2], A. Dodge-Khatami[1], B.J.M. Mulder[1]. [1]*Academic Medical Center, Cardiology B 2 239, Amsterdam, Netherlands;* [2]*Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Background: We examined quantitative parameters for early right ventricular (RV) dysfunction during pharmacological stress and the relation between the cardiac reserve and plasma neurohormones in patients with chronic RV pressure and combined pressure and volume overload.
Methods: Thirty-one patients with chronic RV pressure and/or volume overload (thirteen patients with pulmonary artery stenosis, 15 patients with corrected Tetralogy of Fallot, three patients with pulmonary hypertension)(RVSP>35 mmHg, age 27±7 years, NYHA class I and II) and ten age- and sex matched healthy volunteers were studied. The patients were divided into two groups: pressure (group 1) and pressure combined with volume overload (group 2). Valvular regurgitation of >10 ml/beat was a selection criterion for volume overload. MRI was applied both at rest and during dobutamine stress to determine RV volumes and ejection fraction (EF). Brain natriuretic peptide (BNP) was determined in all patients and controls.
Results: At baseline there were no significant differences in RV parameters between patient group 1 and controls. However, significant differences between patient group 2 and controls were found: RV stroke volume (57±17 vs 43±9ml, p<0.05), RV end diastolic volume (EDV) (113±30 vs 62±14 ml, p<0.001) and RVEF (51±8 vs 69±10%, p<0.001). During dobutamine stress there was a significant decrease of RV stroke volume in both patient groups (1: 44±8 vs 39±10ml, p<0.01 and 2: 57±17 vs 47±17ml, p<0.05) accompanied by a significant decrease in RVEDV. This was in contrast to the controls where a significant RV stroke volume increase was monitored (43±9 vs 52±12ml, p<0.01) without significant changes in RVEDV. RVEF increased significantly in the controls (69±10 vs 84±4%, p<0.001), in contrast to both patients groups where no increase was noticed after dobutamine infusion. Group 2 had significantly higher BNP than the controls and group 1(8.4±4.3 vs 2.2±1.77pmol/L, p<0.0001 and 4.2±4.9 pmol/L, p<0,04, respectively). Significant inverse correlation was found between BNP and the change in stroke volume during dobutamine infusion r=0.51; p=0.005.
Conclusion: In asymptomatic patients with chronic RV pressure and volume overload a decreased RV stroke volume is accompanied by both impaired RV filling (diastolic dysfunction) and a failure to augment RVEF (systolic dysfunction) during dobutamine stress. Adverse stress reaction and increase in BNP levels were more accentuated in patients with combined pressure and volume overload. Diminished cardiac reserve correlates with increased plasma neurohormones.

924 Diagnostic value of MRI in patients with atrial septal defect in comparison to heart catheterization and transoesophageal echocardiography

T. Dill[1], T. Neumann[1], R. Maksimovic[1], M. Rau[1], W. Ricken[1], G. Bachmann[2], C. Hamm[1]. [1]*Kerckhoff-Clinic, Department of Cardiology, Bad Nauheim, Germany;* [2]*Kerckhoff-Clinic, Department of Radiology, Bad Nauheim, Germany*

Background: The defect diameter, shunt volume and size of right atrium (RA) and right ventricle (RV) are essential data for planning transcatheter closure of an atrial septal defect (ASD). Although, balloon sizing of the defect on heart catheterization (HC) is still mandatory, and transesophageal echocardiography (TEE) is widely used as non invasive imaging technique, magnetic resonance imaging (MRI) may play an important role in preprocedural evaluation of these patients. Therefore, we assessed the diagnostic value of MRI in the evaluation of size defect, shunt volume and RV diameters in comparison to HC and TEE.
Patients and Methods: Sixty patients, male 30% (18/60), average age 44.3±15.7 (range 15-74 years) with an ASD II were enrolled. They underwent TEE, HC and MRI (1.5T Siemens Vision® or Sonata system®). A Flash 2D cine GRE sequence (TR 60ms, TE 5ms, slice 6 mm) and a TrueFISP cine sequence (TR 32ms, TE 1.6ms, slice 5 mm) were used. On MRI Qp/Qs was calculated and compared to the HC Qp/Qs ratio. Defect size measurements of different techniques were compared. Investigators were blinded to the results of the other techniques.
Results: Qp/Qs ratio on baseline MRI examination was 1.56±0.29 (range 1.05-2.2) while on HC 1.71±0.30 (range 1.2-2.4). Correlation was statistically significant (r=0.65, p<0.01). Defect size on MRI was 15.3±7.4 mm (range 3-30 mm), on TEE 14.3±4.9 mm (range 4-24 mm), and the balloon stretched diameter on HC was 23.4±4.2 mm (range 14-32 mm). Correlation between defect size as on MRI vs TEE was (r=0.67, p<0.01), MRI vs HC (r=0.77, p<0.01), respectively. Linear regression equation for prediction the defect size on heart catheterization based on MRI is as follows (R=0.77, R2=0.59, F=38.1, p<0.01): y=14.9 + 0.6 x MRI defect size.
Conclusions: Thus, MRI proved to be an accurate diagnostic tool in pre interventional assessment of ASD patients planned to undergo transcatheter occlusion. These data indicate that MRI allows complete assessment of morphological and hemodynamic parameters in these patients without radiation and only minimal patient discomfort.

925 MRI of aortic coarctation. Pre and postoperative correlation with echocardiography, catheterization and surgery

C. Saint-Martin[1], C. Lapierre[2], M. Beghetti[3], E. Jaeggi[3], I. Oberhansli[3], W. Habre[4], A. Kalangos[5], D. Didier[6]. [1]UCL Cliniques universitaires St Luc, Medical Imaging: Pediatric Radiology, Brussels, Belgium; [2]Hôpital Sainte-Justine, radiology, Montreal, Canada; [3]Pediatry, [4]Anesthesiology, [5]Surgery, Geneve, [6]Radiology, Hôpital Cantonal Universitaire, Geneve, Switzerland

Objectives: Pre and postoperative MRI results were correlated in a retrospective study with echocardiography, catheterization and surgical findings.
Material and methods: 111 MRI were performed in 96 patients, separated in two groups: group I, preoperative: 49 MRI and group II, postoperative: 62 MRI: The study was conducted on a Picker 1.5 Tesla scanner and consisted of spin-echo T1 weighted sequences in all cases, cine-GE sequences in 103 cases, Gadolinium-enhanced MR angiography in 53 cases and velocity-encoded cine MRI in 40 cases (VEC-MRI). In group I, correlation was made with echocardiography (n=49), catheterization (n=14) and surgery (n=34) while in group II correlation was made with echocardiography in 51 cases.
Results: 2 MRI were nondiagnostic due to poor-quality images. Aortic coarctation was not asserted in 6 cases of group I. Other MRI correlated well with surgery for morphological measurements of the preductal aorta (r=0.93), the post ductal aortic diameter (r=0.81), the left subclavian artery involvement (r=0.88) and the presence of an associated aortic hypoplasia. Correlation was less good for measurement of the isthmic narrowing (r=0.44). Correlation of MRI and Doppler estimates of pressure gradients was possible in 20 cases with good results (r=0.69). In group II, 21 patients had a persistant pressure gradient in Doppler (> 20 mmHg). MRI was normal in 2. In 19 cases, abnormal turbulent flow was demonstrated by MRI, corresponding to recoarctation (n=5), kinking without stenosis (n=2), and persistence of a significant aortic arch hypoplasia (n=12). In 27 cases of normal echocardiography, MRI demonstrated: a large pseudoaneurysm (n=1), recoarctation (n=1), kinking without stenosis (n=2) and persistence of aortic arch hypoplasia.
Discussion: MRI provided an excellent morphologic assessment of aortic coarctation and the oblique sagittal and coronal planes seemed to be the most informative. GE-cine sequences, associated with VEC-MRI in multiple planes, allow a complementary functional dynamic evaluation of the malformation. Gadolinium-enhanced breath-hold MR angiography advantageously replaces conventional angiography. MRI is the technique of choice in the postoperative follow-up of these patients superior to echocardiography.
Conclusion: This retrospective study of aortic coarctation is the largest one published so far, and the first one with surgical correlation of MRI anatomic findings. Our results are in agreement with previous reports of the literature and provide more informations in the technique of MRI examination in aortic coarctation.

926 Aortic elasticity of the Marfan aorta: comparison between patients with and without aortic root replacement

G.J. Nollen[1], L.J. Meijboom[1], M. Groenink[1], J.O. Barentzs[2], J. Timmermans[3], E.E. van der Wall[4], J.P.G Tijssen[1], B.J.M Mulder[1]. [1]Cardiology Dept., Academic Medical Center, Amsterdam; [2]Radiology, [3]Cardiology, University Medical Center St Radboud, Nijmegen; [4]Cardiology Dept., Leiden University Medical Center, Leiden, Netherlands

Objective: Aortic elasticity is related to aortic rupture behavior and may serve as an additional risk factor. Aortic elasticity can be expressed in terms of distensibility and flow wave velocity, and is decreased in Marfan patients. Aim of this study was to compare aortic elasticity assessed with magnetic resonance (MR) imaging in Marfan patients with and without an aortic root replacement.
Design and patients: Forty-two Marfan patients (mean age 33 (12) years, age range 16-55 years) with an elective aortic root replacement and 78 Marfan patients without aortic root replacement (mean age 31 (8) years, age range 18-50 years) underwent MR flow mapping at four levels (1: ascending aorta, 2: thoracic descending aorta, 3: descending aorta at the level of the diaphragm and 4: abdominal descending aorta) in the aorta. Distensibility at each level and flow wave velocity between levels were calculated.
Results: There was no significant difference in clinical characteristics between the operated and non-operated patients. Operated Marfan patients had significantly increased flow wave velocity in the aortic arch (FWV 1-2) compared to non-operated Marfan patients (5.4 (2.7) m/s vs. 4.4 (1.1) m/s, $p<0.01$). At all other levels, no significant differences in aortic elasticity between Marfan patients with and without aortic root replacement were shown. A positive correlation was found between FWV in the entire aorta and age in operated Marfan patients (r=0.69).
Conclusions: Marfan patients with aortic root replacement had higher FWV in the aortic arch, which can be attributed to more severe involvement of the cardiovascular system, older age, and/or the Dacron graft in the ascending aorta. In the descending aorta, no significant difference in elasticity between patients with and without aortic root replacement was found. These results suggest that patients after an elective aortic root replacement are not at higher risk for aortic complications in the residual aorta than non-operated patients.

COMPUTER DEMONSTRATION

937 Secure internet-based transmural heart failure registry to support interacting health care providers

E D. Gommer[1], F E A. van den Hoef[1], M H. Baljon[1], W R M. Dassen[2]. [1]Interuniv Cardiology Inst Netherlands, ICT, Utrecht, Netherlands; [2]Maastricht University Hospital, Cardiology Dept., Maastricht, Netherlands

Introduction: The growing number of patients with chronic heart failure (HF) and their frequent hospital admissions create an increasing load on hospital facilities. By performing intensive monitoring the fragile equilibrium of these patients can be better controlled, e.g. by fine tuning their medication, thus preventing rapid deterioration of the patient's condition resulting in hospital admissions. Monitoring can be performed in dedicated outpatient clinics or by specialized nurses visiting them at home or performing telephone-checkups. However, this approach requires the different health care providers to have online access to accurate patient data of previous contacts. The security issues related to such a transmural information system have to be covered conscientiously. Applying state of the art encryption technology and authentication by client certificates, unauthorized access can be prevented, and information can be distributed securely over the Internet. **Methods:** To support the MAastricht Heart failure Study (MAHS) a secure web server was built that only accepts clients who can identify themselves with a certificate issued by the hospital's own Certificate Authority (CA). In the pilot phase these client certificates are stored on the user's PC but in the near future every user will obtain a hardware key containing this certificate. A secure SSL-connection is setup based on a high-grade encryption key of 128 bits. The heart failure registry is implemented as a PostgreSQL-database and interfaced to the user via web pages created by pre-hypertext processing (PHP) scripts. After patient selection the templates for data entry and retrieval are accommodated to the role of the user. Based on the class of users they belong to, they can enter, view and/or modify data. This class also determines which views are presented. Data presentation is tailored to each different health care provider. At a glance cardiologists or general practitioners can obtain an overview of e.g. all visits the patient made or received. In the future also patients will be able to enter data concerning their physical condition and basic measurements from home-monitoring devices. Based on the incoming information the automatic generation of alerts can be enabled.
Conclusion: The use of certificates in combination with data encryption facilitates a secure interactive means of information transfer between the different professions that is essential to improve the quality and availability of professional health care for the rapidly increasing number of patients.

938 CardioCard™ – A credit card-sized electronic patient record: first experiences

A. Bernheim, C. Kaufmann, M. Keiser, P. Buser, M. Pfisterer, S. Osswald. University Hospital, Cardiology, Basel, Switzerland

Background: The CardioCard©;, a credit card-sized CD-ROM has been developed at the University Hospital of Basel to facilitate communication between the Department of Cardiology and other physicians involved in the follow-up of patients (pat). All the cardiologic data collected at the clinic (i.e. examination reports, ecg signals, etc.) are stored on the card and secured by a code word. This information system helps to improve outpatient management and to avoid redundant examinations. **Aim:** The aim of the present study was to document the first pat experiences one year after implementation of the CardioCard©; and to evaluate possibilities of improvement. **Results:** 351 of the 536 pat who received a CardioCard©; in 2001 replied to the questionnare. 55% have the card always with them, 45% keep it at home. The majority of pat consider the CardioCard©; a useful information system (74% useful versus (vs) 8% not useful vs 18% no statement). 78% would even agree to share expenses. Only 5% expressed concerns about data security. In contrast, 40% would fear insufficient data safety in case of a transmission by internet. During a mean observation time of 6.3 ± 3.1 months data were interrogated by 26% of the pat. Pat > 60 years used the card more frequently than those ≤ 60 years (39% vs 19%). Lack of equipment was the most common reason for not using the card (62%). 14% of primary care physicians obtained informations from the card. Technical problems during interrogation of data occurred in 29%, mostly due to incorrect handling (22%). **Conclusion:** The majority of pat consider the electronic patient record CardioCard©; a useful and safe information system. Despite the short observation period the card has already been used in 26% of cases. Lack of hardware, poor computer knowledge, and insufficient information concerning purpose and features of the card are essential reasons for non-use. Thus, a carefully directed instruction for the utilization of the card and better education of concerned physicians are needed to establish the CardioCard©; in the daily medical routine.

POSTER DISPLAY II

MODERATED POSTER SESSION II

P939 Increased platelet reactivity is associated with restenosis 6 months after coronary angioplasty

O. Johansen[1], M. Brekke[2], I. Seljeflot[3], A.G. Semb[4], H. Arnesen[5]. *[1]Ullevaal Uni. Hospital, Cardiolgy, Oslo, Norway; [2]Ullevaal Uni. Hospital, Cardiovasc. Radiology, Oslo, Norway; [3]Ullevaal Uni. Hospital, Center for Clinical Research, Oslo, Norway; [4]Aker Uni. Hospital, Cardiology, Oslo, Norway; [5]Ullevaal Uni. Hospital, Cardiology, Oslo, Norway*

Restenosis occurs in 40-50% of patients treated with PTCA. No systemic drug have convincingly reduced the rate of restenosis, except from one minor study using antibodies against platelet derived growth factor (PDGF) showing reduction in the frequency of restenosis.

The present study was undertaken to investigate possible biochemical changes, especially related to platelet function, in blood simultaneously sampled from the aortic root (AR) and the coronary sinus (CS) during PTCA in LAD.

Methods: Blood from AR and CS were drawn before, 1 and 15 minutes after PTCA in 26 patients and the results related to the presence of restenosis 6 months later as evaluated by quantitative coronary angiography. Plasma levels of PDGF and beta thromboglobulin (BTG) were analyzed with commercial methods. Platelet counts (TRC) and hematocrit (HCT) were also measured.

Results: In blood from AR (Table 1), a significant increase in the levels of PDGF was encountered 1 min after PTCA in the patients who developed restenosis after 6 months. This difference in PDGF levels between patients with and without restenosis was sustained after 15 min. The same pattern was seen in BTG levels, whereas the other variables measured were unaffected during PTCA. Significantly higher levels of TRC were observed in the restenotic group (table). No statistically significant changes in the measured variables were found in CS during PTCA.

	Restenosis (n=14)			No restenosis (n=12)		
	Pre PTCA	1 min. after	15 min. after	Pre PTCA	1 min. after	15 min. after
HCT vol %	35.8	34.3	35.5	37.7	36.6	37.0
TRC x109/l	203¶	198	207¶	167	163	164
BTG IU/ml	43	160*¶	115¶¶	45	93	72
PDGF pg/ml	481	2417*¶¶	1367¶	825	1007	715

Median values. *p<0.05 for difference from baseline; ¶p<0.05 for restenosis vs non restenosis; ¶¶ p<0.01 for restenosis vs non restenosis

Conclusion: Individuals who later presented with restenosis had a highly significant increase in the levels of PDGF and BTG in the aortic root after PTCA, and also significantly higher number of platelets. This points to a hyper reactive state of platelets in patients prone to restenosis after PTCA, and these findings may also strengthen the hypothesis that PDGF contributes to the process of restenosis.

P940 Optimal management of neonates with large ventricular septal defect and aortic coarctation

S. Di Filippo, F. Sassolas, A. Bozio. *Hôpital Cardiovasculaire, Cardiologie Pédiatrique, Lyon cedex 03, France*

The aim of this retrospective study is to review our experience with large ventricular septal defect (VSD) associated with aortic coarctation in neonates, in order to assess outcome and to determine the optimal surgical option.

From 1990 to 2000, 44 neonates, aged 8 ± 7 days were referred for diagnosis of aortic coarctation associated with one large VSD. Aortic arch was hypoplastic in 35 cases (79.5%). All presented with congestive heart failure, severe in 70% needing prostaglandines and mechanical ventilation. One patient died from sepsis before surgery and 43 were operated on. First surgery was performed at the age of 13.5 ± 12 days, and included: 9 complete reparative surgery (group A), 10 isolated Crafoord operation (group B) and 24 Crafoord associated with pulmonary banding (group C). Second surgery for closure of VSD was performed later in group C (9.6 ± 9 months) than in group B (2.8 ± 2 months). Overall mortality was 34%, higher in groups A (44.5%) and C (37.5%) than in group B (20%). Four patients in group C (Crafoord with banding) died before reoperation whereas none in group B (Crafoord without banding). Survival was 90% at 1 month, 83% at 6 months, 80% at 1 year and 79% at 10 years. Aortic restenosis was observed in 11 cases (25.5%), 3 days to 10 months (mean 3.3 months) after surgery. The incidence of restenosis was not different between the 3 groups; percutaneous aortic angioplasty was performed in 5 cases (2 to 8 months postCrafoord, mean 3.8 months) and surgical aortic repair in 2 cases, with no residual stenosis.

In summary, these results show that staged surgical treatment without banding lead to a lower mortality despite earlier closure of VSD. It seems to be the best surgical management for neonates with large VSD and aortic coarctation,

P941 Eustachian valve in adult patients: association with interatrial communications and cerebrovascular events: a TEE study on 306 patients

H. schuchlenz, G. saurer, W. Weihs. *LKH-GRAZ, 2.Med., Graz, Austria*

Background: The eustachian valve (EV) is a remnant of the embryonic right valve of the sinus venosus, embryologically EV directs the oxygen-rich blood from the inferior vena cava across the patent foramen ovale and into the systemic circulation. The EV is seen in the majority of newborn infants but much less frequently in adults studied by transthoracic echocardiography. However, neither prevalence of EV in adult patients studied with TEE, nor cinical significance of EV has been studied so far.

Purpose: We dertermined wheter this embryologic remnant is associated with interatrial communications or clinical findings.

Methods: The frequency and size of the eustachian valve was studied in 306 consecutive patients undergoing TEE in search of cardiac sorce of embolism after a cryptogenic stroke and in 95 consecutive control subjects without cerebrovascular events. The prevalence of interatrial communications was studied in all 308 patients by 2D-TEE, color-Doppler and contrast echo studies.

Results: VE was present in 182 of 306 patients (prevalence 59%). The mean size was 1,1±0.5 cm, range 0.5-2,5 cm. The Eustachian valve was associated in 70% with an interatrial communication (Correlation-coefficient r = 0.63; p < 0.001). The prevalence of interatrial communications was 31% in the control group vs 61% in patients with presumed paradoxical embolism (p< 0.001). Therefore VE prevalence was significantly higher in patients with presumed paradoxical embolism 68% (143 of 211 pts) than in the control group 33%, (31 of 95 pts; p < 0.001). There was no significant difference in the size of the EV between these groups.

Conclusion: Due to its association with interatrial communication, the Eustachian valve is a frequent finding in patients with cryptogenic stroke. By directing the blood from the inferior cava to the interatrial septum, persitence of an EV may prevent spontaneous closure of PFO after birth. EV persistence increases right to left shunting across interatrial communications which enhances the chance of paradoxical embolisation.

P942 Percutaneous closure of Ostium Secundum ASD with the Helex™ septal occluder – Results of a European multicentre study

F. Maymone-Martins[1], H. Sievert J Hess[2], P. Ewert M Schneider[3], M. Carminati[4], A. Salmon[5], S. Qureshi[6], J. De Giovanni[7], N. Wilson[8]. *[1]Hospital de Santa Cruz, Cardiologia Pediatrica, Carnaxide, Portugal; [2]Frankfurt, München, Germany; [3]Berlin, Germany; [4]Milano, Italy; [5]Southampton, United Kingdom; [6]London, United Kingdom; [7]Birmingham, United Kingdom; [8]Glasgow, United Kingdom*

Background: The Helex™ septal occluder is made of ultrathin ePTFE mounted on a wire frame of nitinol available in sizes between 15 and 35 mm, with 5 mm increments. It is a non self-centering device inserted via a special 9F catheter. A device/defect ratio of 1.8/1 to 2/1 is usually recommended. After deployment it assumes the form of a flat, circular, soft double disk. Delivery can be demanding but the device can be repositioned and retrieved at any time prior to release. Previous experience suggests that it represents a good alternative for the percutaneous closure of Ostium Secundum ASD and Patent Foramen Ovale.

The purpose of this study was to evaluate data collected in a European study combining multiple centres aiming at further assessing the safety and efficacy of the device for the percutaneous closure of Ostium Secundum ASD.

Methods: ASD percutaneous closure was attempted at cardiac catheterisation performed under general anaesthesia and transesophageal echo guidance. All patients (pts) in whom implantation was attempted were included in the study. They were reviewed at 1, 6 and 12 months (M) with physical examination, ECG, chest X-Rays, transthoracic echo and fluoroscopy.

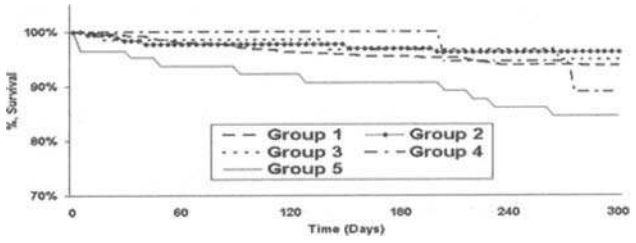
Results: Implantation was attempted in 116 pts and achieved in 114 (98%). Follow-up includes 111 pts (97%). Their ages ranged from 1 to 75 (mean 21) years and weights from 8 to 102 (mean 43) Kg; 68% were female. Balloon stretched diameters ranged from 5 to 21 (mean 13) mm; 18 pts had multiple defects and 8 had septal aneurysms. Mean implant duration ranges from 61 to 939 (mean 401) days. Complete closure was noticed in 68% of the pts prior to discharge, in 80% at 6 M (n=55) and in 89% at 12 M (n=35) the remaining having trivial/small shunts. In 5 pts embolization occurred during the procedure or within 24 hrs. Percutaneous retrieval was achieved in all, followed by the insertion of a larger Helex™ in 2 and Amplatzer™ in 3. The latter are not included in the follow-up. Late wire fracture was noted in two pts, one of them having had surgical removal and ASD closure.

Conclusions: Percutaneous closure of Ostium Secundum ASDs can be safely and efficiently achieved with the Helex™ septal occluder. Its advantages include a flexible, low profile ePTFE patch with little metal. It seems especially convenient for ASDs with multiple orifices due to its non self-centring features. Residual shunts have a low incidence and tend to decrease with time.

P943 Impact of serum troponin-I elevation on long-term survival following percutaneous coronary intervention

B.K. Nallamothu[1], S. Chetcuti[2], D. Mukherjee[2], P.M. Grossman[2], S. Werns[2], E. Bates[2], M. Moscucci[2]. [1]*B1 F245 University Hospital, Division of Cardiology, Ann Arbor, United States of America;* [2]*University of Michigan, Department of Internal Medicine, Ann Arbor, Michigan, United States of America*

Background: Large elevations in CPK-MB following PCI are associated with decreased long-term survival. Results from studies using serum troponin-I (Tn-I) - a more sensitive biomarker of myocardial injury - have been mixed.
Objective: To estimate the impact of Tn-I elevation on survival following PCI.
Methods: We collected clinical data on consecutive subjects undergoing PCI from July 1997 to September 2000. Patients with acute ST elevation MI, non-ST elevation MI, and baseline Tn-I elevations were excluded. Tn-I levels were obtained 6 hrs and 12 to 24 hrs after PCI. Peak Tn-I levels were then used to divide subjects into 5 groups: 1) G1 - Tn-I <2.0 ng/dl (< 1 x nl); G2 - >=2.0 to <6 ng/dl; G3 - >=6 to <10 ng/dl; G4 - >=10 to <16 ng/dl; G5 - >=16 ng/dl. Follow-up data were collected at 1 mo and/or 1 yr after PCI. Using a Cox proportional hazards model, we assessed for the impact of Tn-I elevation on survival adjusting for age, gender, DM, CRI, smoking, CHF, prior MI/CABG, and procedural factors (e.g., graft PCI, stent use).
Results: 1123 subjects undergoing 1611 PCIs were analyzed with a mean follow-up of 301 days (SD, 147). Mean age was 64; 33% of subjects were women, 25% had DM, and 60% had multivessel disease. 780 (69%) subjects were in G1 based on Tn-I, 177 (16%) in G2, 68 (6%) in G3, 26 (2%) in G4, 87 (8%) in G5. After adjustment, only subjects in G5 had an increased risk of death (hazards ratio, 2.3; P=0.012). Log-rank test for equality of survival functions showed statistically significant differences between the groups (P=0.017) (Figure).



Survival After PCI based on Tn-I.

Conclusions: Tn-I elevations following PCI are common, occurring in 31% of cases. Sizeable Tn-I elevations (>8 x nl) - but not minor increases - are associated with worse survival after PCI.

P944 Fetoscopic assistance improves alignment of interventional devices during percutaneous ultrasound-guided direct fetal cardiac punctures in sheep

T. Kohl[1], M.A. Große Hartlage[2], M. Westphal[1], D. Kienitz[1], S. Aryee[1], T. Buller[1], H. Van Aken[2], U. Gembruch[3]. [1]*Münster University Children's Hospital, Department of Pediatric Cardiology, Münster, Germany;* [2]*Münster University Medical School, Department of Anesthesiology, Münster, Germany;* [3]*University of Lübeck, Department of Obstetrics & Gynecology, Lübeck, Germany*

Background: Difficulties with the alignment of interventional devices with the fetal cardiac outflow tracts have contributed to the unsatisfactory technical success rate of percutaneous ultrasound-guided balloon valvuloplasties in human fetuses. The purpose of this pilot study in fetal sheep was to assess the potential of a fetoscopically assisted percutaneous procedure for achieving adequate alignment with the fetal outflow tracts.
Methods: We studied a total of 4 fetal sheep between 92-102 days of gestation (term=145 days). We percutaneously entered the amniotic cavity with three trocars with an external diameter of 4 mm. Following the decision which valve ought to be passed with interventional material, fetal posturing and fixation were performed employing fetoscopic instruments. Then, a 10 F phased-array intravascular ultrasound catheter was inserted into the fetal esophagus for fetal transesophageal echocardiography. Following these steps, one or more ultrasound-guided direct punctures of the fetal heart using 16-18-gauge needles with trocar were performed. We tested adequate alignment with the right or left ventricular outflow tracts by advancing a 0.014"-guide wire across the respective semilunar valve, and recorded difficulties and complications from the procedure.
Results: Fetoscopically assisted direct ultrasound-guided cardiac punctures with optimum alignment with the outflow tracts were successfully achieved in 3 of the 4 sheep. Multimodal fetal TEE permitted imaging of the needle shafts inside the fetal heart and placement of the guide-wires across the semilunar valves in 3 of the 4 sheep. In one fetus, the needle was falsely oriented toward the right ventricular inflow tract such that wire placement across the pulmonary valve was not achieved. Because we lacked an arm (e.g. robotic arm) that permits secure fixation and precise steering of the needle inside the small fetal heart, the needle shaft dislodged in two fetuses resulting in hemopericardium, profound bradycardia, and demise. The two other fetuses were born healthy at term.
Conclusion: Fetoscopic assistance facilitates alignment of interventional devices with the fetal outflow tracts during percutaneous ultrasound-guided direct fetal cardiac punctures in sheep. This novel approach carries important potential to achieve balloon valvuloplasties in human fetuses as young as 16 weeks. Yet, further efforts, incorporating surgical robotics, need to be undertaken for securing and steering the interventional devices inside these tiny hearts.

P945 A substantial reduction in instrument size heralds clinical introduction of fetoscopic fetal cardiac interventions

T. Kohl[1], M. Westphal[2], M.A. Große Hartlage[2], D. Kienitz[1], S. Achenbach[1], T. Buller[1], H. Van Aken[2], U. Gembruch[3]. [1]*Münster University Children's Hospital, Department of Pediatric Cardiology, Münster, Germany;* [2]*Münster University Medical School, Department of Anesthesiology, Münster, Germany;* [3]*University of Lübeck, Department of Obstetrics & Gynecology, Lübeck, Germany*

Background: Percutaneous intraamniotic insertion of 3-5 trocars that had an external diameter of 8 mm was employed for fetoscopic cardiac interventions in our early studies in sheep. Whereas the 8-mm-approach was instrumental for assessing the feasibility and for the training of various fetal cardiac interventions it might be associated with an increased risk for postoperative uterine contractions, premature rupture of membranes and premature delivery in the human. Therefore, the purpose of our experimental studies was to reduce uterine and chorioamniotic membrane injury from fetoscopic cardiac procedures by more than 75% by operating through trocars with an external diameter of only 4 mm and by modifying our technique of trocar support throughout the operations.
Methods: We studied a total of 15 fetal sheep between 68-103 days of gestation (term=145 days). We percutaneously entered the amniotic cavity with 3-4 4-mm trocars. We analyzed the success of amniotic fluid exchange, amniotic insufflation, fetal visualization, and posturing, and tried to perform various fetoscopic cardiac procedures (fetal thoracotomy, pacing, cardiac catheterization, fetal transesophageal echocardiography, overdrive stimulation) using instruments and endoscopes with diameters ranging from 1.9-3.4 mm.
Results: Percutaneous fetal access was achieved in all sheep and did not result in any fetal injury. Amniotic fluid exchange with saline followed by partial insufflation of the amniotic sac with filtered air could be achieved through the small trocars. In smaller fetuses weighing between 110–500 g the 1.9-mm endoscope was sufficient for fetal visualization and posturing. Similarly, in fetuses no larger than 1000 g the 3.4 mm endoscope was sufficient for the same purposes. The small grasping pieces of both the 2.3 and 3-mm instruments were too small for grasping the fetus. Fetal posturing was yet achieved in all instances by using the instrument shafts. The desired fetal position was maintained by T-fasteners or stay sutures that were percutaneously inserted into the amniotic cavity. Fetal thoracotomy, pacing, cardiac catheterization, fetal transesophageal echocardiography, and overdrive stimulation were all possible via the small trocars.
Conclusion: Maternal and fetal injury have now become minimal from fetoscopic fetal cardiac interventions in sheep. Fetoscopic fetal overdrive stimulation and cardiac pacing will now become clinically feasible in selected immature human fetuses with life-threatening arrhythmias refractory to conventional therapies.

P946 Percutaneous aortic valve replacement with a self-expanding stent – First animal results

M. Ferrari[1], G. Hellige[2], M. Schlosser[1], K. Lang[3], I. Frerichs[2], E. Mueller[4], G. Eisold[5], H.R. Figulla[1]. [1]University of Jena, Clinic of Internal Medicine III, Jena, Germany; [2]University of Goettingen, Cardiac Center, Goettingen, Germany; [3]Schwalm-Eder-Kliniken, Clinic of Internal Medicine, Schwalmstadt, Germany; [4]Fraunhofer Institute, Optic And Miniaturized Mechanics, Jena, Germany; [5]Translumina GmbH, Hechingen, Germany

Background: Due to increasing number of elderly patients with relevant comorbidity surgical aortic valve replacement may be associate with an enormous risk. Therefore, we evaluated the feasibility of transvascular aortic valve replacement in animal experiments.
Methods: Pulmonary valves from pigs were sutured in a self-expanding stent after low-pressure fixation in glutaraldehyde solution for 72 hours. The 6 cm stent containing the biologiocal valve in its proximal part was implanted in 3 pigs (88-104 kg) by means of a 25F catheter. The catheter was introduced into the left subclavian artery. By guidance of fluoroscopy and trans-oesophageal ultrasound the valve was implanted orthotopic in the aortic position. During the implantation, the original aortic valve was pushed against the aortic wall, and the new valve was unfolded by the self expanding stent in the same moment. It was possible to replace the aortic valve in the beating heart without any complication or even relevant drops in blood pressure. Under standard hemodynamic monitoring we infused dopamine with doses of 5 μg/kg/min., 10 μg/kg/min., and 15 μg/kg/min.
Results: Cardiac output increased from 3,8 to 9,7 l/min., and the blood pressure rose from 96/54 mmHg to 138/111 mmHg respectively. The maximal peak to peak pressure gradient measured by repetitive catheter pullbacks from the left ventricle to the aorta trough the valve carrying stent increased from 0-2 mmHg at rest to 5-8 mmHg under infusion of dopamine. At the end of the acute experiments, all pigs were sacrificed by intra-coronary injection of potassium chloride after 5 hours post transvascular aortic valve replacement. The chest was opened and the left ventricle and the ascending aorta was carefully dissected. There were now signs of damage of the implanted biological valves. We did not observe any perforation of the aortic vessel wall, neither any obstruction of the coronary ostiums by the stent.
Conclusion: This study proves the feasibility of trans-vascular aortic valve replacement in the beating heart. However, further diameter reduction of the implantation-catheter-device, and additional chronic animal experiments are necessary before this technique might be an alternative for aortic valve replacement in multi-morbid patients.

P947 Treatment of pseudoaneurysms of the femoral artery by thrombin-injection: the German multicenter registry

H. Sievert[1], W. Pfeil[2], O. Pusankov[2], A. Baser[2], A. Fach[2], R. Jacksch[3], M. Kotzerke[4], J. Selbach[5], M. Conze[6], P. Meyer[7], J. Demharter[8]. [1]Frankfurt, Germany; [2]Cardiovascular Center Bethanien, Frankfurt, Germany; [3]St Vincenz Krankenhaus, Essen, Germany; [4]Hegau Klinikum, Singen, Germany; [5]Caritas Krankenhaus, Bad Mergentheim, Germany; [6]Klinikum Fulda, Germany; [7]Kreisklinik Mindelheim, Germany; [8]Klinik f. Diagnostische Radiologie, Zentralklinikum Augsburg, Germany

Background: Iatrogenic pseudoaneurysms of the femoral artery after catheter interventions can be treated by surgery or ultrasound guided compression. Thrombin injection into the aneurysm had been proposed as an alternative.
Methods: In consecutive 145 patients (age 68 ±11.3 years), a pseudoaneurysm of the femoral artery diagnosed 1 to 30 days (Median: 2 days) after catheterisation via the femoral artery was treated by local injection of thrombin solution (Thrombin Topical U.S.P. in 134 patients; Beriplast Combiset HS in 10 patients; Duett Haemostat in 1 patient). The mean diameter of the aneurysm was 2.8 ±1.1 cm.
Results: Thrombin solution (0.03 to 2.1 ml, mean 0.6 ± 0.6) was slowly injected under ultrasound guidance. In all cases, this led to immediate thrombus formation within the aneurysm. However, in 4 patients, a second thrombin injection and in 2 patients a third injection of thrombin was necessary. One patient experienced mild fever. Three patients later needed surgical removal of the resulting hematoma, one patient needed surgery for recurrent bleeding (uneventful). No other complications occurred. Follow-up duplex studies revealed no recurrences.
Conclusion: Iatrogenic pseudoaneurysms of the femoral artery can easily and effectively be treated by direct ultrasound-guided thrombin injection. In this multicenter registry the complication rate of thrombin injection was low, although the initial learnino curve was included in all centers.

P948 No impact of type of contrast medium on MACE in unselected randomized patients undergoing coronary stenting with appropriate antiplatelet therapy

G.B. Danzi[1], C. Capuano[1], M. Sesana[1], R. baglini[1], E. Quaini[2]. [1]Casa di Cura Poliambulanza, Interventional Cardiology, brescia, Italy; [2]Casa di Cura Poliambulanza, Cardiac Surgery, Brescia, Italy

Background: The influence of type of contrast medium on ischemic complications after coronary stenting is still controversial. The aim of this study was to assess the impact of an ionic low-osmolar, and two different nonionic contrast media on major adverse cardiac events at 30 days in unselected patients undergoing coronary intervention with the use of new generation stents and appropriate antiplatelet agents.
Methods and Results: Nine-hundred and twenty eight patients treated with stent implantation were allocated to receive ioxaglate (306 patients) iopamidol (314 patients) and iopromide (308 patients). Most of these patients (55%) had an acute coronary syndrome. Glycoproteins IIb/IIIa inhibitors were used in 33% of cases. All of the patients were taking aspirin and ticlopidine for 1 month after the procedure. The primary endpoint, a composite of major adverse cardiac events at 30 days after stenting was not statistically different among the three groups (ioxaglate 3.6%; iopamidol 2.5%; iopromide 5.5%; P=0.15). Adverse drug reactions occurred more frequently in the ioxaglate patient group (4.6% vs 1.6% vs 0.6%; P=0.001). At multivariate analysis diabetes mellitus (P=0.001), intracoronary thrombus (P=0.007), multivessel CAD (0.01), and the length of the stented segment (P=0.03) were independently correlated to adverse outcome at 1 month.
Conclusions: In this unselected patients population who was treated with new generation stents and with an appropriate antiplatelet therapy no significant differences in terms of 30-day major ischemic complications were observed among patients receiving either ioxaglate, iopamidol or iopromide. These data seem to suggest that the type of contrast medium do not adversely effect stent patency.

PACING – COMPLICATIONS AND TECHNICAL ASPECTS

P949 Isolated local complications at the PM implant site are infectious complications

D. Klug[1], F. Wallet[2], C. Marquié[1], C. Kouakam[1], D. Lacroix[1], S. Kacet[1]. [1]University of Lille, Dept.Cardiology A, Lille, France; [2]University of Lille, Bacteriology Dept., Lille, France

Local symptoms on the PM site can be associated with infection leading to leads extraction or due to mechanical problems requiring no extraction. Patients with isolated local symptoms is a population in which a mechanical complication is often evocated, but local infection is a possible mechanism. We have try to answer at 2 questions: What is the proportion of infection in this population? And what is the optimal management of this PM complication?
Methods: In a prospective study of suspected PM infection with 224 patients included, 132 patients (45%) (68 ± 18 y.o) were referred to our institution for local symptoms on the PM site. We have studied a sub-population of patients with isolated local symptom defined as 50 patients hospitalized for local symptoms without fever, pulmonary symptoms, biologic marker of inflammation or anomalies disclosed by transesophageal echocardiography. All the implantable material (PM and leads) were systematically extracted.
Results: Only 4 patients with isolated collection of puriform liquid had negative lead cultures. In the remaining patients lead cultures were positive on the extra vascular portion. Moreover lead cultures on the intra-vascular part were positive in 31/43 (72.1%). After a follow-up of 24±17 months, recurrences of the infection occurred in 2/50 (4%) patients with isolated local symptoms. Infection recurred in 2/7 (28%) patients without complete removal of the leads.
Conclusion: Isolated local symptoms are associated with PM infection. The extravascular part of the leads but also the intravascular parts are infected. Consequently, the management of this complication, even when apparently confined to the pulse generator implantation site, should include the extraction of the entire system. A recurrence rate of 28% in patients whose lead was not completely extracted strongly supports this recommendation.

P950 Usefulness of intracardiac echography to monitor transvenous lead extraction procedures

G. Arena, M.G. Bongiorni, E. Soldati, C. Nardi, R. Dell'Anna, F. Baldi, M. Mariani. *University Cardiology, CardioThoracic Dpt, Pisa, Italy*

Transvenous lead removal is an effective technique, but possible life-treathening complications may occur, which require careful monitoring and fast diagnosis. The availability of information about 1) the condition of the intravascular part of leads, 2) the presence and extension of adhaerences to the venous wall, 3) the dimension of vegetations and their relation with the cardiac structures, may be very helpful to plane the removal procedures. Intracardiac Echography (ICE) has proven useful in the field of interventional arrhythmology and cardiac catheterization. The aim of our study was to evaluate the usefulness of ICE during transvenous lead removal procedures.

Materials and Methods: ICE was performed in 48 patients (35 men, mean age 66.3 years) who underwent removal of 90 leads (84 pacing, 6 defibrillating) due to Class I (37 pts) and Class II (12 pts) indications. The procedures were performed using the Cook Extraction kit (Cook Vascular Inc., Leechburg, PA, USA). ICE was performed using a 9 French 9 Mhz catheter, connected to Clear View Ultra EC 1003 ultrasound console (Boston Scientific Corp., S. JosE, CA, USA).

Results: the removal of leads was completed in all the patients. ICE allowed clear visualization of the leads and their adhaerences to the venous wall such as monitoring the dilation by sheaths, and the relation between the sheaths and the anatomical structures. Vegetations were observed in 66% of pts with systemic infection while Transesophageal Ecocardiography was positive in 33% of these pts. During the removal procedure, the position of the vegetations and their relation with the dilating sheaths were easily monitored. No complication related to the use of ICE was observed.

Conclusions: transvenous lead removal represents another field of application of ICE. Our experience confirmed the usefulness of this imaging technique in guiding the procedure and monitoring the possible complications.

P951 Monoclonal or polyclonal origin of pacemaker lead infection

D. Klug[1], F. Wallet[2], C. Marquié[1], R. Courcol[2]. [1]*University of Lille, Dept.Cardiology A, Lille, France;* [2]*University of Lille, Bacteriology Dept., Lille, France*

The notion of poly microbial infection is particularly important for anti microbial therapy and blood culture interpretation. We have looked at the leads cultures in 224 patients included in a prospective study on PM lead infection to determine if PM lead infection was due to a single or to several different microorganisms. A same species could have different clonal origins, so we have more precisely compared the DNA by pulse field gel electrophoresis (PFGE) of the coagulase negative Staphylococcus (CNS) recovered on leads in 15 patients.

Results: In 12,3% of patients no microorganism was found on the leads. An homogeneous lead cultures with the same microorganism cultured on the both extra vascular and intra vascular parts of the leads were found in 88.5% of the positive lead cultures. The extra vascular and the intra vascular parts of the leads were infected in 99.4% and 92.9%. Infection was due to Staphylococcus epidermidis and CNS in 66.0% and 29.5% respectively. Infection was poly microbial in 25.6% of cases. PFGE confirmed the monoclonal origin of species recovered on the different parts of the leads in 70.8% of the microorganism. The results of lead cultures were independent of the initial presentation (systemic infection or isolated local symptoms)

Conclusion: whatever the initial clinical presentation of PM lead infection we found the same lead culture results with infection by a CNS of both the extra vascular and intra vascular part of the leads. We can hypothesize a common mechanism of infection. In 25.6% of patients several species of microorganisms were found, and a same species could have a plolyclonal origin. This result is important for blood culture interpretation and PM lead infection management.

P952 Infected pacemaker lead extraction by means of an electrosurgical dissection sheath

J. Sperzel[1], T. Schwarz[2], C. Reiner[1], W. Ehrlich[2], G. Siemon[1], J. Goetzke[3], H.F. Pitschner[1]. [1]*Kerckhoff Heart Center, Cardiology, Bad Nauheim, Germany;* [2]*Kerckhoff Heart Center, Surgery, Bad Nauheim, Germany;* [3]*Guidant, Cardiac Rhythm Management, Brussels, Belgium*

Introduction: Extraction (E) of infected pacemaker leads (L) is a difficult and dangerous procedure. It is influenced by the fixation mechanism (active/passive) and anatomic position (atrial/ventricular) of the L and the period of time the L were implanted. A new bipolar electrosurgical dissection sheath (EDS, Cook Vascular Inc., Leechburg, USA) was evaluated with regard to safety and complications.

Methods: The E was preceded by various examinations (especially a transoesophagal echocardiography TEE). After preparation and cutting of the infected L a locking stylet (LS, Liberator™, Cook Vascular Inc., Leechburg, PA USA) was introduced. A combination of an outer sheath (OS) and a 9F or 11F EDS was pushed forward over the L. Radio frequency (RF) energy (50W) was applied by means of two electrodes on the tip of the EDS if needed. A standard electrosurgical generator and an adapter were used together with the EDS. During the procedure the patient was continuously monitored by means of TEE in order to allow an instant reaction to early complications (rupture, tamponade). Cardiopulmonary bypass possibilities were always in standby. Follow up examinations were done after 24h, 3 and 30 days.

Results: 25 L (9 passive and 16 active fixation) were extracted in 14 patients. Mean time from implant to E of the L was 8,2±4,1 years. All L were removed transvenous without complications. Mean E duration was 9,5±7,8 min with an energy release for 1,8±2,0 min. Fluoroscopy time is not listed on purpose as 11 of 14 patients received a new pacemaker system during the same procedure. No complications referring to the E were observed in any patient up to 30 days after the procedure. Two patients showed minor formations of haematoma in the region of the device pocket without the need of any surgical intervention.

Conclusion: A safe use of the EDS for E of infected, transvenous L was documented. Especially the possibility of mechanical push by means of the LS, the passive mobilization of the L with the OS and the application of RF energy by means of the EDS itself are allowing to push the system forward even under difficult anatomic circumstances such as stenosis or venous caliber steps. The distinct visibility of the distal pair of electrodes is a big advantage in terms of ease of use and an increase of safety because it allows the user to align the direction of energy release away from the vessels' wall to a more central axis of the lumen. When the energy is released circularly like it is known from laser based methods the danger of creating vascular lesions seems to be much higher.

P953 The medical virtual reality lead implant simulator (VRLIS), a novel tool for education and practice of implant procedures

L. Binner[1], H. Retzlaff[2]. [1]*University of Ulm, Internal Medicine II - Cardiology, Ulm, Germany;* [2]*Medtronic, Düsseldorf, Germany*

Introduction: Precise lead placement is mandatory in pacing therapy. Additionally, optimization of hemodynamics reqires special lead positions in the right and left heart. The Virtual Reality Lead Implant Simulator (VRLIS) can be used to practice the positioning of leads for standard antibradycardia implants as well as left heart leads for heart failure therapy. VRLIS consits of a computer with a heart and lead model software and an interface device allowing the simulation of the handling of transvenous pacing leads at implant. The mechanical user interface mimics the lead, inserted into a vein at the implant site. The interface translates the user interaction with the lead or catheter and stylet into electrical input to the simulation software on a computer. The simulation software is based on a model of the selected lead, catheter and/or stylet and a model of the heart. Force feedback can be provided to simulate friction, entanglement or fixation of a lead. A computer display shows the ECG and the x-ray view of the respective implant situation. Different x-ray views (frontal, LAO,RAO) can be chosen, x-ray is operated by foot pedal. PSA-measurements can be taken, on-screen simulation of different stylet shapes is possible.

Method: The acceptance of VRLIS was evaluated during the meetings of the national pacing societies of Germany and Switzerland in 2001. Experienced physicians were asked to perform two virtual implants and to fill out a questionnaire. In addition, the educational effect of VRLIS was tested in community hospitals of both countries.

Results: The quality of simulation was rated by numbers from 1(poor) to 10 (excellent): lead handling 8.0 (6-9), stylet handling 8.0 (5-10), x-ray 9.4 (8-10), ECG/PSA 8.1 (3-10). All physicians trained in the community hospitals reported improvements of lead handling.

Conclusion: The VRLIS system provides a realistic impression of the lead handling during an implant simulation. VRLIS is a new, cost-effective method of accomplishing physician training/education.

P954 A new fiberoptical sensing system for the registration of changes in right ventricular contraction pattern and haemodynamics under ischaemia

A. Kloppe[1], A. Prenger-Berninghoff[2], S. Müller[2], M. Hexamer[2], C. Drewes[1], A. Mügge[1], J. Werner[2]. [1]St. Josef-Hospital, Cardiology, Bochum, Germany; [2]Ruhr-University, Biomedical Engineering, Bochum, Germany

Purpose: In the electrical therapy of patients with symptomatic arrhythmia it is the objective to restore the physiologic performance as close as possible. It is desirable to achieve information about the inotropic status in addition to the electrical information of the heart. Therefore we developed a new fiberoptical sensor system for measuring heart contraction.
Method: For this study we used 6 normal hearts from adult German farm pigs. They were reperfused in an experimental set up with autologous blood for isolated biventricular working heart function. The blood volume and the preload pressures were kept constant and the new fiberoptical sensor system was placed in the left as well as in the right ventricle. The light which was emitted into the fiber was being reflected at the mirrored tip located in the heart. The contraction of the heart during each cycle caused bends of the fiber which lead to optical attenuation. All hearts were paced just above the intrinsic rate for constant heart rate during study period. The right coronary artery (RCA) was ligated proximally. The hemodynamic data were measured consistently.
Results: The sensor signal showed cyclic alterations with typical light attenuation during systolic contraction and an increase in signal amplitude during diastolic relaxation. It also showed a fast reaction to the contraction behavior and could be measured as a beat to beat change. Approximately 10 minutes after RCA occlusion the RVP has dropped by 34 ± 6%, the LVP stayed nearly constant. The pulmonary flow dropped by 38 ± 7%. At the same time the fiberoptical signal amplitude of the right ventricle dropped by 16 ± 5%, the fiberoptical signal in the left ventricle diminished only by 5 ± 4%. None of the hearts developed ventricular fibrillation directly after coronary artery occlusion but in 3 cases the rhythm converted into fibrillation 15 to 20 minutes after interruption of myocardial perfusion.
Conclusion: The fiberoptical signal is a fast reacting, beat to beat measurable, non electrical signal for registrating heart contraction. It shows a close correlation to the ventricular performance respectively to each ventricle.

P955 Correlation of device-based intra-thoracic impedance and patient fluid status during intravenous diuretic therapy in acute CHF

C.M. Yu[1], L. Wang[2], E. Chau[3], W.F. Lam[3], M.O. Tang[1], H. Lin[1], S.L. Kong[1], C.P. Lau[1]. [1]Univ. of Hong Kong, Queen Mary Hospital, Hong Kong, China; [2]Medtronic, Inc., Minneapolis, United States of America; [3]Grantham Hospital, Hong Kong, China

Background: In patients (pts) with congestive heart failure (CHF), fluid overload may lead to hospitalization due to pulmonary congestion/edema. Monitoring of the amount of fluid retention is helpful to refine treatment and reduce hospitalizations. As fluid accumulates in the thorax, impedance is expected to decrease. Based on the preliminary results from an ongoing study, monitoring of intra-thoracic impedance (Z) using a pacemaker has been shown to provide early "warning" of impending acute CHF decompensation requiring hospitalization. During CHF hospitalization, the increase in Z correlated well with the reduction of pulmonary capillary wedge pressure (PCWP), demonstrating Z as a measure of pt's congestion. This data analysis aimed to look at the Z changes as a result of the intravenous diuretic therapy in these pts during CHF hospitalization.
Methods: Eighteen CHF pts with NYHA class III-IV (mean age 71±11 years, 14 male) received a special single chamber pacemaker (Medtronic Inc., Minneapolis, MN) with a defibrillator lead. Z was measured between the right ventricular electrodes and pacemaker can, and averaged to eliminate respiratory and cardiac influences. When the pts were hospitalized due to CHF, Z was measured every 30 min., hemodynamic intervention with PCWP measurement was performed, and the fluid status of the pts was carefully monitored. The maximum changes of Z and PCWP, as well as urine output (UO) and fluid input/output (FIO) as a result of intravenous diuretics (20-80 mg of frusemide) were calculated within the 6 hours of the therapy and averaged.
Results: Of the 16 survivors with a mean follow up of 7.9±6.1 months, 8 were hospitalized with PCWP measurement. As expected, Z increased while PCWP decreased significantly along with significant volume reductions (FIO/UO) after intravenous diuretic therapy. The increase in Z inversely correlated with FIO (r=-0.95, p=0.0003) and UO (r=-0.92, p=0.009).

PCWP Change (mmHg)	UO (ml)	FIO (ml)	Z Increase (ohms)
-3.5±4.7 (p=0.03)	-958±497*	-656±580**	6±4.5%*

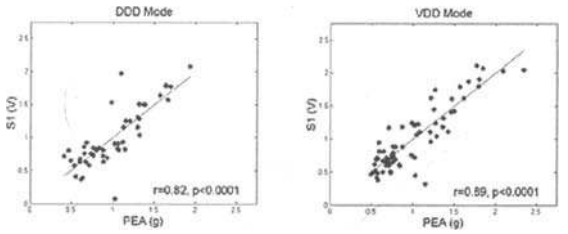
*: p<0.01; **: p=0.015

Conclusion: Within 6 hours of intravenous diuretic therapy, the increase in Z closely reflects the pt's fluid balance (FIO) and diuresis. The data further validates the pacemaker-based Z as a valuable surrogate measure of fluid status in CHF pts.

P956 Peak endocardial acceleration responds as first heart sound to variation of atrioventricular delay

J. Victor[1], J.M. Dupuis[1], G. Gaggini[2], A. Kobeissi[2], L. Vitali[2], F. Rouleau[1], G. Leftheriotis[3]. [1]University Hospital ofAngers, Department of Cardiology, Angers, France; [2]Sorin Biomedica CRM, R&D, Saluggia, Italy; [3]Faculté de Médecine, Laboratoire de Physiologie, Angers, France

Background: PEAI is defined as the Peak Endocardial Acceleration during the isovolumic contraction phase of the cardiac cycle. Previous works showed good correlation between PEAI and LVdP/dt max, as well as its dependence on AV Delay. A similar dependence of First Heart Sound (S1) on AV Delay is also known.
Study Objective: To demonstrate the relationship between PEAI and S1 amplitudes with respect to variations in paced/sensed AV Delay.
Methods: On 7 patients (age 81±4y,3M) with high degree AV Block, simultaneous recordings from a phonocardiograph and an intracardiac accelerometer (BEST, Sorin Biomedica, Italy) were taken during execution of an AV Delay Scan (60 to 300ms, step=30ms, 60 cycles/step), in DDD (90BPM) and VDD mode. PEAI and S1 were calculated cycle-by-cycle and averaged for each AV delay. PEAI vs. S1 correlation analysis was performed after normalization to individual mean value of PEAI.
Results: Correlation for DDD mode was r=0.82, p<0.0001; for VDD mode was r=0.89, p<0.0001 (see figures)



Conclusion: This study demonstrates a high and significant correlation between PEAI and S1. S1 measurement by an implanted sensor are inherently stable and accurate.

P957 Comparison of atrial pacing from different single and dual sites: does the P-wave duration represent total atrial activation time?

S. gozolits[1], G. Fischer[2], F. Hanser[2], T. Berger[1], O. Pachinger[1], B. Tilg[2], F. Hintringer[1], F.X. Roithinger[1]. [1]University Hospital Innsbruck, Department of Cardiology, Innsbruck, Austria; [2]Technical University, Department of Biomedical Engineering, Graz, Austria

Background: The effect of dual site pacing for prevention of atrial fibrillation may be due to synchronization of right and left atrial activation. Little is known, however, about the correlation between P wave duration on the surface ECG (PWD) and endocardial total atrial activation time (TAT).
Methods: Fifteen patients without structural heart disease (9 female, 6 male, age 45±14) were studied, following ablation of supraventricular arrhythmias (AVNRT, n = 11; WPW, n = 4). Single site pacing [high right atrium (HRA), coronary sinus ostium (CSos), distal coronary sinus (CSd), high right atrial septum (Bachmann's bundle, BB)] and dual site pacing (various combinations) 10 bpm above sinus rate, and recording was performed, using standard multipolar catheters. The 65-lead body surface ECG was recorded simultaneously. Endocardial TAT was assessed offline (stimulus - last bipolar recording). The respective PWD was assessed visually after baseline correction, using the body surface root-mean-square plot and the 65-channel summary plot (stimulus - end P wave).
Results: The PWD was 121±15 ms during pacing in HRA, 108±9 ms during pacing in CSos (P<0,01), 126±14 ms during pacing in CSd (P<0,01), and 96±12 ms during pacing from BB (P<0,01). The PWD during dual site pacing (HRA+BB = 91±14 ms, HRA+CSos = 96±7 ms, HRA+CSd = 90±7 ms, BB+CSos = 91±9 ms, BB+CSd = 96±12 ms) was not significantly different as compared to pacing from BB. Pacing from BB resulted in the shortest TAT of all single sites (81±15 ms), compared to pacing in HRA (112±16 ms; P<0,01), in CSos (90±16 ms; P=0,165), and in CSd (123±17 ms; P<0,01).
Conclusions: 1) The 65-lead ECG allows for precise measurement of the PWD during pacing from all single as well as dual atrial sites; 2) surface PWD correlates with endocardial TAT; 3) BB pacing results in the shortest PWD from all single pacing sites and is comparable with dual site pacing; 4) these findings may have implications for selecting the mode and predicting the effect of preventive pacing in patients with atrial fibrillation.

P958 Comparison of long-term performance of VDD pacemakers to DDD pacemakers

T. Maounis[1], G. Kourgiannides[2], G. Poulos[1], V. Vassilikos[1], A. Manolis[3], D.V. Cokkinos[1]. [1]*Onassis Cardiac Surgery Center, 1st Dpt of Cardiology, Athens, Greece;* [2]*Onassis Cardiac Surgery Center, 1st Cardiology, Athens, Greece;* [3]*Patras University, Cardiology Dpt, Patras, Greece*

Introduction: The aim of the present study was to compare the long-term performance of VDD pacemaker(PM) implantation to DDD PM in patients(pts) with heart block and free of chronotropic incompetence.
Methods: We studied the long term performance (mean 3 years) of VDD PM in 23 pts(mean age 75±12 years, 14 male 9 female) (group I) to 23 matched pts (age 75±10 years,14 male, 9 female) with DDD PM (group II). In both study groups, the indication for implantation was 2nd or 3rd degree AV block in the absence of chronotropic incompetence. Satisfactory sensing and pacing thresholds were achieved at the implantation procedure in both groups. At a long term follow-up we defined the pacemaker performance as satisfactory when adequate atrioventricular synchrony was preserved. We use the following criteria as a marker of unsatisfactory long term performance in both study groups: 1) low P wave defined as less than double of the minimun programmable atrial sensitivity (PAS), resulting in suboptimal p wave sensing, 2) the onset of chronic atrial fibrillation (cAFib). Additional criteria suggestive of unsatisfactory performance were in group I, low sinus rate resulting in more than 20% of VVI pacing, as well as high atrial capture threshold defined as more than half the maximum atrial output in group II. Chi-square test was performed to compare the long term performance in both groups.
Results: The two study groups had a similar mean follow-up (56±18 m in group I and 62±21 m in group II). More pts in group I had unsatisfactory performance (9 pts in group I vs 2 pts in group II)($p<0.05$). In detail, the incidence of chronic atrial fibrillation was 4/23 (17.4%) in group I compared to 1/23(4.3%) in group II ($p<$NS). The incidence of low P wave, as defined previously, was 3/23(13%) to 0/23(0%) respectively ($p<$NS). Two pts in group I (8.7%) had more than 20% VVI pacing. One patient (4.3%) in group II had high atrial capture threshold.
Conclusions: According to our data DDD pacing is superior to VDD pacing in pts with high degree AV block. There is no justification for the use of VDD pacing in this group of patients. The higher incidence of atrial fibrillation in patients with VDD pacing cannot be excluded. Further studies should be carried out to elucidate this issue.

P959 Outcome and costs with an indication-optimized pacemaker selection: a prospective randomized study

C.H. Kaufmann, B. Schaer, A. Remondino, P.H. Weiss, T. Cueni, T.A. Cron, S. Osswald. *Kantonsspital Basel, Cardiology, Basel, Switzerland*

Background The selection of the optimal pacemaker system (PM) depends on the index arrythmia (sick sinus syndrome (SSS), AV block (AVB), atrial fibrillation (AF) and in the near future more and more on cost-effectiveness. Data regarding quality of pacemaker therapy versus costs are missing so far.
Methods All pts. who received a PM between 7/99 and 8/01 in the university hospital of Basel were randomized to group A (system choice according to NASPE Guidelines) or B ("optimized" system choice: AAI in isolated SSS and Wenckebach point >120/min. and not more than isolated left anterior hemiblock; VDD in AVB with chronotropic competence; otherwise DDD or VVI) or were treated open labeled (OL). Primary end points were death, heart failure (CHF), stroke (CVI), AF or angina (AP), secondary endpoints were costs. Analysis was performed on a intention-to-treat basis.
Results Out of 281 pts. receiving a PM (age 74±14y, 57% men) 94 (34%) were randomized to A and 104 (38%) to B. 83 (29%) were treated OL due to emergencies, physician's or patient's preference or concommitant studies. Regarding indications (symptoms and ecg-diagnosis) A and B were comparable as was OL (syncope 41%, dizzyness 34%, bradycardia 17%, prophylactically 10%, CHF 9% // AVB or bundle branch block 55%, SSS 28%, AVB and SSS 10%, AF 15%; all $p>0.1$). In accordance with the protocol pts with AVB in A got more DDD systems (30 vs 5) and in B more VDD (46 vs 3), with SSS in A more DDD (23 vs 10) and in B more AAI (15 vs 1), all $p<0.0001$. In binodal disease (AVB and SSS) 9 DDD and 2 VVI were implanted in each group, in AF 16 vs 11 VVI respectively ($p>0.6$). Complications did not differ between groups (hematoma (1 vs 3), pneumothorax (1 vs 1), dislocation (1 vs 3), revision (3 vs 6), $p>0.3$). Average follow-up was 351±228d. Neither mortality differed significantly (10 vs 13, log rank 0,5 (LR)) nor the combined endpoint of CHF/AP/Dyspnea (LR 0,9), nor did CVI and impaired exercise tolerance (LR 0,6). AF was even slightly increased in A (LR 0,02). Implant costs were reduced significantly in B (on average 16% or 1900 EUR/pt., ($p<0.001$).
Conclusion With our "optimized" selection of the PM-system implant costs could be reduced significantly, without a detectable impairment regarding primary end points death, heart failure, angina or exercise tolerance during 1y follow-up.

P960 Interatrial septum pacing guided by three-dimensional intracardiac echocardiography

T. Szili-Torok, G.P. Kimman, M.F. Scholten, N. Bruining, J. Ligthart, P. Klootwijk, J.R.T.C. Roelandt, L.J. Jordaens. *Thoraxcentre, Rotterdam, Clinical Electrophysiology, Rotterdam, Netherlands*

Background: Interatrial septum (IAS) pacing may be beneficial for the prevention of paroxysmal atrial fibrillation. Currently, the IAS pacing site is indirectly selected by fluoroscopy and P-wave analysis. The aim of the present study was to develop a novel approach for IAS pacing using intracardiac echocardiography (ICE). Methods: Cross-sectional images are acquired during a pull-back of the ICE transducer from the superior vena cava (SVC) into the inferior vena cava by an ECG- and respiration-gated technique. Both atria are then three-dimensionally (3D) reconstructed. Using an "en face" view of the IAS the desired pacing site is selected, which serves as a reference point for creating a horizontal two-dimensional (2D) template. Real-time, 2D images are then used to guide the implantation of the atrial pacing lead. After lead placement and electrical testing another 3D reconstruction is performed to verify the final lead position. Results: Thirteen patients were included in this study. IAS pacing was achieved in all patients including 6 suprafossal (SF) and 7 infrafossal (IF) lead locations all confirmed by 3D imaging approach. The mean duration of the atrial lead implantation time and fluoroscopy time were 70±48.9 min and 23.7±20.6 min, respectively. IAS pacing resulted in a significant reduction of the P-wave duration as compared to sinus rhythm (98.9±19.3 ms vs. 141.3±8.6 ms; $p<0.002$). SF pacing showed a greater reduction of the P-wave duration than IF pacing (59.4±6.6 ms vs. 30.2±13.6 ms; $p<0.004$). Conclusions: 1. Three-dimensional ICE is a feasible tool for guiding IAS pacing. 2. 3D ICE allows selection of the optimal anatomical pacing site. 3. These data suggest that the SF pacing site is preferable for pacing the IAS as it results in the shortest P-wave duration.

P961 Effect of DDDRP pacing in patients suffering from symptomatic sick sinus syndrome and paroxysmal atrial fibrillation

I. Fernandez Lozano[1], J. Roda[2], E. Selva[3], J.M. Ferrer[4], F. Andrade[5], J. Errejon[6], J. Toquero[6], J. Marquez[6]. [1]*Clinica Puerta de Hierro, Cardiologia, Madrid, Spain;* [2]*Hospital General, Cardiology, Valencia, Spain;* [3]*Hospital General Gomez Ulla, Cardiology, Madrid, Spain;* [4]*Hospital Txagorritxu, Cardiology, Vitoria, Spain;* [5]*Hospital Merida, Cardiology, Merida, Spain;* [6]*Clinica Puerta de Hierro, Cardiologia, Madrid, Spain*

Introduction Algorithms designed to prevent the occurrence of episodes of Paroxysmal AF, have become available for clinical practice. Several studies have described the high incidence of paroxysmal AF in patients with Sick Sinus Syndrome (SSS). This study will primarily focus on patients with SSS to show the efficacy of the preventive pacing algorithms available in the Vitatron DDDRP pacemakers.
Methods: This is a prospective, non-randomized, multi-center trial. Patients are eligible if they have SSS with or without pre-existing paroxysmal AF. Study procedures were based on the following steps:
1. Maturation phase of 2 weeks.
2. A monitoring phase of 1 month for monitoring the occurrence of AF and the individual onset mechanisms. The cardiac stimulator is programmed to standard dual chamber pacing with the preventive pacing algorithms OFF.
3. During the preventive pacing phase the algorithms were programmed based on the analysis of the AF diagnostics. The third and subsequent follow-ups are used to assess the efficacy of the therapy and optimise it further.
Results: From April 2000 to April 2001, 68 patients (33 m, 35 f) have been included in the study in 14 Hospitals in Spain. Mean age was 72±12 years and the pacemaker indication was SSS in 15 patients (22%) and SSS with paroxysmal AF in 53 patients (78%).
In 32 patients with pre-existing paroxysmal AF a sufficient number of follow-ups was performed in order to analyse the difference between the first follow-up and the last follow-up. The preventive pacing algorithms were programmed for each patient on an individual basis using the diagnostic features of the devices. This analysis includes 267 follow-ups, which is a mean of 4 per patient.

Endpoints	1 follow-up	2nd follow-up	Variation
AF Burden	4,9%	2%	– 61% *
N° episodes	112	62	– 60,6% *
% Atrial pacing	66%	77,6%	+15%

*$p<0,05$

Conclusions: 1. Dedicated AF diagnostics were key to adapting the optimal pacing during follow up. 2. AF prevention pacing significantly improved all AF endpoints

P962 Transvenous pacemaker implantation in children <10 kg body weight

J.A.E. Kammeraad[1], N. Sreeram[1], J. Bostock[2], J. Rogers[2], E. Rosenthal[2].
[1]Wilhelmina Children's Hospital, Dept of Cardiology, utrecht, Netherlands; [2]Guy's Hospital, Dept of cardiology, London, United Kingdom

Background: For the majority of small children requiring permanent pacing, the epicardial approach has hitherto been preferred, due to concerns about venous access or obstruction in the long term. We report our experience with transvenous pacemaker implantation in children <10kg.
Patients: 39 children, median age 3.8 months (2 days-35 months), weight 7.5 (2.3-10)kg underwent transvenous permanent pacing (VVIR in 38, DDDR in 1). Indication for pacing was complete heart block (CHB, N=34)- congenital (21), post-surgical (11), idiopathic (2). Other indications included long QT syndrome (3), sinus node disease (2).
Methods and Results: Percutaneous transvenous access was obtained for the subclavian vein for lead introduction. Lead characteristics were as follows: 24 steroid-eluting leads and 16 non-steroid leads; 19 active fixation leads and 21 passive fixation; 13 unipolar and 27 bipolar leads. Generator location was abdominal (9), subpectoral (7) or pre-pectoral (23). In 2 patients, wound closure problems were encountered; there were no other procedural complications. Two children with post-surgical CHB died 7 days and 3 weeks post-implantation respectively, due to heart failure and septicemia, despite appropriate pacemaker therapy.
Follow-up: Over a median follow-up of 3.8 years (3 months-14.8 years) 4 patients underwent upgrading to DDDR pacing, which was successful in 3, and failed in one due to intractable AF induced by introduction of the atrial lead. Lead extraction was attempted 11 times in 9 patients and succeeded 10 times. The subclavian vein was completely thrombosed in 3; in one of them no further pacemaker therapy was performed and was well tolerated; one received a transvenous system via the same subclavian vein, and the 3rd patient received an epicardial system. In 1 patient a redundant atrial loop of a ventricular lead was adherent, and the lead was abandoned; a new transvenous lead was implanted via the cephalic vein. Other late complications included infective endocarditis of the lead (N=1, 9 months post-implant) requiring removal of the system, and pacemaker pocket infection (N=1, 19 months post-implant). Nine patients underwent 11 ventricular lead advancements, without any problems. Thirteen generators were electively replaced in 10 patients, without problems.
Conclusions: Transvenous permanent pacing is feasible and effective in children <10 kg, with a small risk of venous occlusion. There is a need to develop smaller diameter leads to avoid this.

P963 Validation of dual chamber pacemaker diagnostic data with the help of dual channel stored electrograms

B. Nowak[1], J. McMeekin[2], E. Castellanos[3], G. Mascioli[4], G. Pettinati[5], K. Nispel[6], D. Pecora[7], S. Henry[8]. [1]CCB, Cardiovascular Center Bethanien, Frankfurt a.M., Germany; [2]Royal University Hospital, Saskatoon, Canada; [3]Hospital Virgen de la Salud, Toledo, Spain; [4]Ospedale Civile della Valle, Esine, Italy; [5]Presidio Ospedaliero F. Ferrari, Casarano, Italy; [6]St.-Elisabeth Krankenhaus, Bad Kissingen, Germany; [7]Congreg. Suore Ancelle della Carita, Brescia, Italy; [8]Guidant Europe, Diegem, Belgium

Device pacemaker diagnostic counters have been documented to include a substantial amount of false-positive or false-negative data. Aim of this multicenter study was to validate pacemaker diagnostic data using stored intracardiac electrograms (EGM) with marker annotations.
Methods: The study includes 351 pts (191 male, age 71 ± 10 y) with a dual chamber pacemaker (Pulsar Max II 1280 and Discovery II 1284, Guidant Inc.) implanted for standard indications. The devices were programmed at predischarge to store 5 dual chamber EGMs with a duration of 8 s each, including marker annotation and 4 s of onset-recording. EGM triggers have been set to: atrial tachycardia (AT), ventricular tachycardia (VT), sudden bradycardia response (SBR) and pacemaker mediated tachycardia (PMT). At the 3 month visit the EGMs were interrogated and analysed. They were classified as "confirmed" if the EGM validated the trigger, and as "false-positive" if the EGM showed an event being different from the trigger.
Results: A total of 1003 EGMs was analysed. Triggers were AT in 640 (64%), VT in 76 (8%), SBR in 105 (10%) and PMT in 178 EGMs (18%). 4 EGMs were triggered by magnet application. The trigger event was confirmed by the EGM in 618 episodes (62%). EGMs confirmed 62% of AT episodes, 18% of VT episodes, 100% of SBR episodes and 54% of PMT episodes. In 385 episodes (38%) the EGMs revealed a false-positive event. This was due to far-field sensing in 39%, noise and myopotential sensing in 26%, sinus tachycardias in 21%, double counting in 9%, exit block in 4% and undersensing in 1%.
Conclusion: This large scale study of pacemaker stored dual chamber electrograms proves their value in validating diagnostic counter data. With the exception of the sudden bradycardia response trigger, all other triggers included a considerable amount of false-positive episodes. These false-positive EGMs provided important information with the potential to optimize device programming.

P964 Benefit of the autocapture function in increasing pacemaker longevity in patients wuth a DDDR pacemaker

G. Boriani[1], M. Biffi[1], L. Rusconi[2], M. Sassara[3], M G. Bongiorni[4], L. Padeletti[5], S. Datteri[6], P. Giovanzana[6]. [1]Inst of Cardiology, Bologna; [2]Ospedale Ceccarini, Div. of Cardiology, Riccione; [3]Ospedale degli Infermi, Viterbo; [4]Ospedale Cisanello, Inst. of Cardiology, Pisa; [5]Ospedale Careggi, Div. of Cardiology, Firenze; [6]St. Jude Medical Italy, CRMD, Milan, Italy

Aim of the study: To evaluate, in a series of patients implanted with a DDDR pacemaker, the effect of ventricular Autocapture (AC) function on longevity of a dual-chamber device.
Methods: 114 patients were implanted with a DDDR pacemaker (St. Jude Medical Affinity, Entity) with Membrane E 1450T and EX 1470T ventricular leads. The ventricular pulse width was randomized at 0.3ms or 0.4ms at predischarge, with a cross-over every 4 weeks; AC was programmed On and ventricular threshold recordings were collected in order to calculate the battery current consumption and the projected device longevity. Current drain with AC was compared with a standard setting at discharge (3,5V/0,4 ms) and with a conventional low output setting (2,5V/0,5 ms).
Results: As shown in Table 1, a significant difference was found in projected longevity comparing different output settings. AC function allowed a prolongation of more than 1 year in the expected life of a DDDR pacemaker in comparison with projections of programming at 2.5Vx0.5 ms. Ventricular capture thresholds higher than 2,5V and 1,5V were observed in 9/114 (8%) and 24/114 (21%) pts, respectively. According to these findings, programming of a fixed 2,5V output setting would potentially result in loss of capture in 8% of pts and in lack of ventricular capture safety margin in 21% of the pts.

Table 1: Expected longevity (months)

A = 2.5V × 0.5 ms V = AC × 0.3 ms	A = 2.5V × 0.5 ms V = AC × 0.4 ms	A, V = 2.5V × 0.5 ms	A, V = 3.5V × 0.5 ms
130±6†,‡	128±8*,**	115±6	83±6

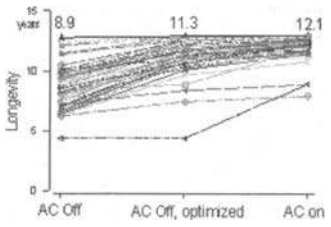
† $p < 0.001$ vs A, V = 2.5V × 0.5 ms; ‡ $p < 0.001$ vs A, V = 3.5V × 0.4 ms
*$p < 0.001$ vs A, V = 2.5V × 0.5 ms; **$p < 0.001$ vs A, V = 3.5V × 0.4 ms

Conclusions: By using AC for venticular stimulation, a significant prolongation in pacemaker longevity may be predicted, thus leading to a more favorable cost-effectiveness. The projected improvement in longevity is significant even in comparison to conventional low output pacing which, moreover, may not guarantee in all the patients maintenance of appropriate safety margins for ventricular capture.

P965 Automatic adjustment of pacing output in the clinical setting

A.L. Ribeiro[1], L.G. Rincon[1], B.G. Guimarães[1], C.R. Vinha[2], D. Melatto[2], A.A. Torres[1], V.C. Barros[1], M.T. Pires[1]. [1]Federal University of Minas Gerais, Belo Horizonte, Brazil; [2]St.Jude Medical, São Paulo, Brazil

Background and aim: AutoCapture (AC) is a programmable feature which allows the recognition of cardiac evoked response for the automatic adjustment of pacing output. Although AC reduces safely the current drainage, some authors argued the longevity benefit of such a system is overstated. This study aims to estimate the longevity extension which can be obtained, in the clinical routine, by turning the AC on, when compared to factory and optimized output programming.
Methods: We selected 83 consecutive patients who had had implanted St Jude's Affinity pacemakers for at least 6 months before. Eight patients died or were lost and, in other 9 subjects, the AC could not be turned on due to lead issues. In the remaining 66 patients (33 DDDR), current drainage and estimated longevity were compared in 3 situations: I. AC on; II. AC off, optimized programming (100-150% voltage threshold); III. AC off, factory output (3.5 V). An estimate of the number of backup pulses in 24h with the AC on was obtained by Holter monitoring. The number of atrial and ventricular paced beats occurred since the last telemetric evaluation (mean: 137 days) was retrieved using the programmer.



Pacemaker longevity.

Results: The current drainage (I = 11.3 ± 2.3 mA) was reduced by optimized programming (II = 8.7 ± 1.8 mA) and, mainly, with AC on (III = 8.0 ± 0.9 mA, $p < 0,01$). Five patients had large variations (> 1V) of the AC threshold. Estimated longevity was significantly extended by AC when compared to factory (21.6 ± 10.5%) and optimized programming (7.2 ± 5.6%, $p < 0.01$).
Conclusion: Reprogramming the pacemaker output significantly enhanced its estimated longevity; AC adjusting added a moderate extension over manual reprogramming, associated with increased safety in patients with large ventricular threshold variations.

P966 Clinical evaluation of a new algorithm for closed loop stimulation

P. Pieragnoli[1], A. Colella[1], A. Michelucci[1], N. Giusti[2], C. Militello[2], R. Audoglio[3], L. Padeletti[1]. [1]*Inst. of Int. Medicine and Cardiology, Florence, Italy;* [2]*Biotronik-Seda, Trezzano S/N, Italy;* [3]*Linarolo (PV), Italy*

Background: Closed Loop Stimulation (CLS), a physiologic algorithm to drive rate responsivity based on variations of intracardiac impedance signal, is triggered, up to now, by paced ventricular beats only. Recently it was developed an enhanced CLS algorithm (ECLS) that is driven by both sensed and paced ventricular beats.
Aim of this study was to validate the safety of ECLS algorithm and to compare its effectiveness with that of the standard one (SCLS) presently in use.
Methods: in 10 pts (9m; mean age 69±7 yrs), all implanted with a pacemaker model INOS2+ CLS (Biotronik, Germany), SCLS and ECLS were evaluated in a randomized and crossed over sequence at 15 and 30 days from discharge. During each control an ambulatory exercise [walking level (WL), upstairs (WU) and downstairs (WD)], mental stress and postural tests were performed. In addition, a 24-h Holter recording (Unylizer, Biotronik) was retrieved to evaluate heart rates (HR) during daily activity.
Results are shown as SCLS vs. ECLS mean data. HR increase: 23 ± 7.4% vs 28.9 ± 15.6% during WL, 45.2 ± 13.5% vs 37.9 ± 16.6% during WU, 9.2 ± 8.7% vs 23.3 ± 10.4% during WD. Time to maximum HR: 60 ± 42 vs 83 ± 49 sec during WL, 79 ± 33 vs 67 ± 45 sec during WU, 30 ± 21 vs 37 ± 12 sec during WD. P was not significative for all groups of data.
In all pts, the response of both algorithms was appropriate during all test procedures, but the proper rate response was achieved with the 93.5% of ventricular sensing in ECLS vs. the 0.7% only in SCLS ($p<0.001$). Postural changes and mental stress influenced HR by few bpm with both algorithms (p=ns). During Holter recordings ECLS showed a prompt, safe and effective rate-response suitable to patient activities. Daily ventricular pacing with ECLS was significantly lower than with SCLS (25.7% vs. 98.4%, $p<0.001$).
Conclusions: Notwithstanding the limited number of pts, data demonstrates that the enhanced CLS algorithm is safe, effective and well tolerated as the standard one. The ECLS allows to pace the ventricle only when necessary, preserving the natural ventricular activation pattern and reducing battery consumption.

P967 Closed loop stimulation and quality of life: objective and subjective results

A. Menezes[1], A. Nascente[2], H. Gama[2], W. Mendonça[2], J. Neto[2], J. Filho[2]. [1]*Hospital Santa Helena, Golânia, Brazil;* [2]*Univ Federal de Goiás, Faculdade de Medicina, Goiânia, Brazil*

Introduction: The Inos2+ CLS adjusts the pacing rate accordingly to the myocardial contractility variations. It enables the cardiovascular regulatory centers to coordinate correctly the heart rate in every kind of physiological stress, improving the patient's quality of life.
Aim: To compare the subjective and objective clinical results, in DDD-CLS and DDD modes, in patient (P) with Inos2+ CLS and sinus sick syndrome.
Material and Method: Prospective and randomized (2 months after implant) study; crossover (3 months in each pacing mode), single-blind. Subjective evaluation (Quality of life - Karolinska). Objective evaluation (atrial and ventricular arrhythmias incidence by 24h Holter, in each study phase). Results: 42 P (31 chronotropically incompetent). 67% male. All P with Chagas disease and NYHA I-II.
Results:

Parameter	Result	value (t Student)
symptoms of cardiovascular disease	DDD-CLS > DDD	$p < 0.001$
physical activity and sleep	DDD-CLS > DDD	$p < 0.01$
emotional function	DDD-CLS > DDD	$p < 0.05$
cognitive skills	DDD-CLS > DDD	$p < 0.001$
sociability	DDD-CLS = DDD	NS
preferred pacing mode	DDD-CLS	$p < 0.01$ (Mann-Whitney)

Discussion: 24h Holter showed a significantly lower rate of atrial arrhythmias in P with DDD-CLS.
Conclusion: The CLS have the potential to increase the tolerance to physical activities in P chronotropically incompetent and hence improve several aspects of quality of life. This pacing mode can also be considered, an option when handling P with associated atrial arrhythmias.

P968 Vasovagal syncope and CLS pacing: preliminary results of the "INVASY" study

E. Occhetta[1], M. Bortnik[1], R. Audoglio[2], C. Vassanelli[1] on behalf of the INVASY Study Group. [1]*Piemonte Orientale University, Cardiology Div., Faculty of Medicine, Novara, Italy;* [2]*Linarolo (PV), Italy*

Aim of the INVASY Study is to investigate whether DDD-Closed Loop Stimulation (CLS), which is sensitive to changes in myocardial contractility, can prevent malignant vasovagal syncopal recurrence (VSR) and, by consequence, it may improve the Quality of Life (QOL) in these pts.
At present 28 pts (17 m, age range 31-76yrs) were enrolled in the study and implanted with an INOS2 CLS pacemaker (Biotronik, Germany). All complied the inclusion criteria: >2 VSRs reported in the last year before implant (mean 5.4), Head-up Tilt Test (HUTT) induced syncope with hypotension and bradycardia or asystolia, cause of syncope not related to cardiac or neural pathologies. At discharge 9/28 pts were randomized in back up DDI (@40bpm) pacing mode to verify the placebo effect of pacing.
After a mean F-U time of 10.9 months: 6/9 pts paced in DDI mode had two VSRs (confirmed by HUTT) before the end of the one year F-U and were reprogrammed in DDD-CLS mode. The remaining 3/9 pts had one VSR each and are still in F-U. Of the 19 pts programmed in DDD-CLS: 9 completed the F-U without VSR (3 remained positive to HUTT); 10 are still in F-U, but none reported VSRs (5 are still positive to HUTT, 3 reported occasional symptoms of pre-syncope not followed by lost of consciousness). QOL significantly improved in all pts paced in DDD-CLS.
In conclusion, the results achieved in this early phase of the INVASY Study seems to confirm the preventive effects of DDD-CLS pacing in malignant vasovagal syncopes as previously showed by some preliminary studies.

P969 Increased morbidity related to pacemaker implantation in patients receiving chronic oral anticoagulation

C. Marquie[1], G. De Geeter[1], D. Klug[1], C. Kouakam[1], O. Jabourek[2], N. Trillot[2], D. Lacroix[1], S. Kacet[1]. [1]*CHRU Lille, Cardiologie A, Lille, France;* [2]*cardiologie, Lille, France*

The incidence of perioperative severe adverse events (SAE) related to the management of oral anticoagulation (OA) in patients (pts) undergoing pacemaker implantation is scarcely documented. We retrospectively quantified and characterized SAEs in a case-control study between 01-1998 and 12-2000 in 114 pts with OA, mechanical valve (MV) 33%, atrial fibrillation (AF) 67%, matched with 114 control pts for age, gender, number of leads, year of implantation and type of venous access. SAE was defined as any unwanted and unexpected clinical event leading to death, reoperation or prolonging hospital stay. Procedure relatedness was defined from patients files by 3 investigators. OA was suspended 5 days before admission and heparin was substituted until 5 hours prior to surgery then resumed 5.7 ± 5.1 hours later at the discretion of the operator. In all pts, surgery was undertaken with INR and aPTT below 1.2 and 45 s respectively.
Results: Overall, SAEs occurred in 25 OA pts (22%) vs 10 control pts (9%) ($p<0.01$, RR 2.5, CI 1.3-5). Procedure-related SAEs occurred in 23 OA pts (20%) vs 8 control pts (7%) ($p<0.01$, RR 2.9, CI 1.3-6.1). These SAEs were non fatal, thrombotic SAEs were absent, bleeding and hematomas accounted for 19 SAEs in OA pts (16%) and 2 SAEs in control pts (2%) (p=0.0001, RR 9.5, CI 2.3-39.9). The sole independent variable identifying OA pts at risk for hemorrhagic SAE was the presence of MV ($p<0.05$). When restricting the analysis to the 38 MV pts and their 38 matched controls, the relative risk of hemorrhagic SAE was 11 (CI 1.5-81, $p<0.01$) with hospital stay prolonged by 9.9 days ($p<0.001$). CONCLUSIONS: OA pts are at increased risk of SAE after pacemaker implantation, the vast majority of these SAEs are hemorrhagic. Pts with MV prosthesis are at higher risk than pts with AF. Further studies are needed to define the optimal management of anticoagulant drugs in this setting.±

P970 Analysis of invasively measured pulse pressure amplitudes to optimize the av-delay in biv paced patients. Comparison with an echo and electrocardiogram method

M. Schlegl, C. Butter, M. Schurr, E. Fleck. *Deutsches Herzzentrum Berlin, Cardiology, Berlin, Germany*

Background: Optimization of the atrio-ventricular delay (AVD) is a major hemodynamic factor of biventricular (BIV) pacing therapy for cardiac resynchronization. The aim of the study was to compare an intraoperative invasive method (PP-a) to determine the optimal AVD with an echocardiographic (ECHO-a) and a surface 12-channel ECG analysis (ECG-a).
Methods: The invasive blood pressure (PP) was intraoperativly monitored during BIV pacemaker implantation in 25 patients through the femoral artery. Raising AVD, beginning from 60ms to a loss of capture, were tested in 20ms intervals. The time of stimulation was 1 min preceded by a similar
intrinsic period. Accordingly to an obvious increase of the PP-amplitude, the optimal AVD was semiquantitatively determined (PP-a method). ECHO-a was performed by standard pulse doppler measurements of the mitral valve inflow from the beginning of left ventricular activation (onset QRS) to the end of E-wave (Ritter method). ECG-a was measured by the Koglek method, which uses the isovolumetric contraction time (ISVC) from the end of the p-wave to the peak of the QRS complex. The optimal AVD is the difference between programmed AVD plus 100ms and the ISVC.
Results: The mean PP-a AVD was 116 ± 21ms. In comparison the ECHO-a AVD and the ECG-a AVD was 113 ± 36ms and 117 ± 31ms. There was no significant difference between these analyzing procedures. Between PP-a and ECHO-a AVD there was a good statistical correlation (R^2 = 0,68). ECHO-a AVD vs. ECG-a AVD and PP-a AVD vs. ECG-a AVD showed less correlation (R^2 = 0,32 and 0,3).
Conclusions: The optimal AVD is simply determined intraoperatively by semiquantitative invasive measurement of the PP-amplitudes, if a raise of 10% is detectable. There is a good correlation to the echocardiographic AVD analysis, which should be additively used in patients with a hemodynamic low response.

CATHETER ABLATION – VENTRICULAR TACHYCARDIA

P971 Delineation of areas with abnormal electrograms prior to ablation of ventricular tachycardia using a three-dimensional real-time position management system

N.M.S de Groot, M. Bootsma, E.T. vd Velde, A.E. Borger vd Burg, E.E. vd Wall, M.J. Schalij. *Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Background: Fractionated electrograms represent sites of abnormal conduction patterns which might be target sites for radiofrequency catheter ablation (RFCA) of ventricular tachycardia (VT). In this study, we used a 3D real-time position management system (RPM) to delineate areas of fractionated electrograms.
Methods: Pts (n= 8, 6 male, 55±20yr) with ventricular tachycardia referred for RFCA were studied. A M-mode of the left ventricle was made to estimate the left ventricular end-diastolic diameter (LVEDD). RFCA of VT was guided by the RPM system. This system uses ultra-sound ranging techniques to determine the position of the ablation catheter relative to 2 reference catheters which are positioned into the right atrium and right ventricle. The length and width of the area from which fragmented electrograms were recorded were measured. Within this area, selection of target sites for RFCA was based on localization of early fragmented signals and concealed entrainment. Successful ablation was defined as non-inducibilty of the clinical VT after termination during ablation.
Results: Etiology of the VT: myocardial infarction (n=5), arrhythmogenic right ventricular dysplasia (n=1) and idiopathic (n=2). The mean LVEDD was 5.5 ± 1 cm and the area delineated in these pts was 13± 8 cm.2 In pts with a right sided VT, target sites for RFCA were located just beneath the tricuspid valve and in the RV outflow tract. Ablation was successful in 75%. In 2 pts with post-myocardial infarction VT (lateral infarction), it was not possible to terminate the VT. The area with abnormal electrograms in these patients was 8 and 10 cm.2
Conclusion: Accurate delineation of areas with abnormal electrograms prior to VT ablation with the RPM system facilitates RFCA of VT.

P972 The use of pacemapping to identify sites for ablation in patients with post myocardial infarction ventricular tachycardia

D. O'Donnell, J.P. Bourke, S. Furniss. *Freeman Hospital, Department of Academic Cardiology, Newcastle Upon Tyne, United Kingdom*

Background Defining the sites for ablation in patients with haemodynamically unstable post myocardial infarction ventricular tachycardia (VT) requires the majority of the mapping to be performed in sinus rhythm. This study systematically evaluated multisite pacemapping in identifying sites for ablation.
Methods 10 Patients referred for catheter ablation of haemodynamically tolerated post infarction VT were enrolled and underwent study using Carto electroanatomical mapping. At each site used in construction of the baseline anatomical map, a stimulation threshold was determined by constant cycle length pacing whilst the stimulus voltage was reduced from 10 mv until the failure to capture occurred. A threshold map was created off line using the electroanatomic map as a template. The VT circuit was subsequently identified during VT by conventional means using entrainment mapping, early activation, the presence of diastolic potentials and fragmented electrograms. Radiofrequency ablation was performed and sites at which VT terminated were identified.
Results 10 patients were enrolled and decremental voltage pacemapping performed from a mean of 63 sites (range 50-73). Overall the correlation between threshold and voltage was high.Correlation coefficient r=-0.55. In the border zones between normal myocardium and dense scar, zones with significant variation between threshold and voltage were identified: 17 type A zones - with low voltages and normal thresholds and 12 type B zones - with significant variations in threshold at adjacent sites. In addition a total of 72 sites (6-10 per patient) were identified at which the S-QRS lengthened by more than 10% with decremental stimulus voltage. 86% of type A and 87% of type B zones with sites that exhibited lengthening S-QRS were located in the critical VT isthmus.
Conclusions
Pacemapping looking at stimulation threshold and S-QRS duration can identify the critical VT isthmus. This finding will assist the sinus rhythm mapping of haemodynamically unstable VT.

P973 Catheter ablation of pleomorphic ventricular tachycardia in post myocardial infarction: new goals with individual linear ablation strategies

H. Kottkamp, U. Wetzel, A. Dorszewski, P. Schirdewahn, C.H. Elsner, G. Hindricks. *University Leipzig Heart Center, Electrophysiology, Leipzig, Germany*

Radiofrequency catheter ablation (CA) of ischemic ventricular tachycardia (VT) is done in most patients (pts).after implantation of cardioverter/defibrillators (ICD). New ablation strategies with modification of the arrhythmogenic substrate using individually targeted linear lesions aim at complete noninducibility with an impact on the overall future therapy of these pts.
In 38 pts (age, 63 ± 8 years) with remote myocardial infarction (ejection fraction, 30 ± 15%) and pleomorphic and/or incessant (n=23) VT, electroanatomic (Carto) mapping using activation as well as voltage maps was performed. According to the analysis of the voltage map in addition to a limited activation map, individually designed linear lesions were placed aiming at a modification of the substrate with ablation of all potential so-called central common pathways. These strategies included connection of different scar areas, transsection of scar areas carrying surviving muscle strands, and/or connection of arrhythmogenic areas to anatomic boundaries. After CA, 26 pts (68%, group I) were completely noninducible, in 6 pts (16%, group II) nonclinical VTs were inducible after ablation, and in 6 pts (16%, group III) the target VTs could not be ablated successfully. Pts. with primary successful ablation had significantly more often incessant VT but did not differ from pts. of the other groups in respect to age, ejection fraction or medication. Successfully ablated VTs were slower compared to partially successfully ablated VTs (cl 430 ± 80ms vs, 360 ± 90ms; $p<0,05$). During the follow-up period of 126 months, 4 pts of group I (16,7%) experienced further episodes of VT, 4 pts of group II (67%) and 1 pt of group III (17%), respectively, but frequency of VT episodes and concomitant ICD discharges was significantly reduced. Within the this period, 4 pts died (2 pts. of group I and III each), all of whom had an ICD, one pt. of group I died of incessant VT.
A detailed analysis of the arrhythmogenic substrate using voltage mapping as well as limited activation mapping with subsequent placement of strategic linear lesions can result in a complete noninducibility in 75% of pts with previously pleomorphic and/or incessant VT.

P974 Radiofrequency ablation for incessant ventricular tachycardia or arrhythmic storm in patients with implantable defibrillator

L. Mont, R.M.F.L. Silva, U. Rojel, M. Matas, J. Brugada. *Hospital Clínic, Cardiology, Barcelona, Spain*

Despite Implantable defibrillator (ICD) is an effective therapy for ventricular tachycardia (VT), some patients (pts) need aditional measures to control their arrhythmic episodes. The purpose of the study was to analyze the proportion of pts requiring VT radiofrequency ablation during follow up, after ICD implant, and to describe the characteristics and results of the ablation procedure.

Methods and Results: Among 403 consecutive pts that received an ICD, fourteen (3.5%) required a VT ablation procedure after a mean of 12±13 months (from 15 days to 45 months). the precipitating event was incessant VT in 10 pts and arrhythmic storm in 4 pts. There were 12 men and 2 women, mean age was 63±16 years (range: 15-78). Nine had coronary artery disease, 4 had idiopathic dilated cardiomyopathy and 1 patient had arrhythmogenic right ventricular dysplasia (a 15 year old girl). Mean ejection fraction was 26±7% (range: 17 to 40%). VT was hemodinamically tolerated (mean cycle length 422±100 ms from 280 to 620 ms). The mean duration of the procedure was 84±27 min and number of pulses was 14±10. Two patients underwent an epicardial approach (one because intraventricular thrombus and a second due to failure of the endocardial procedure during the same session). The RF ablation was effective in 11 pts (79%). Three of them required a second procedure. In 3 pts the ablation was unsuccessful. One was submitted to heart transplant, one pt died in incessant VT. Another patient underwent successful DC ablation. The only complication was a fatal ischemic stroke. Pts were discharged on amiodarone (12 pts) or sotalol (1 pt). During a mean follow up of 11±16 months only 2 pts had an episode of VT treated successfully by the device. Two pts died during follow up because of heart failure (3 and 6 months after ablation).

Conclusions: In ICD recipients, the development of incessant VT or arrhythmic storm requiring VT ablation was very uncommon. The arrhythmic episode was successfully controlled in the majority of pts with endocardial or epicardial radiofrequency ablation, or DC shock ablation. Mortality during follow up was related to heart failure but not to arrhythmia recurrence.

P975 Identification and three-dimensional display of scar related areas of block in patients with postinfarct ventricular tachycardias during sinus rhythm

F. Bogun[1], E. Wissner[2], S.C. Krishnan[3], J.E. Marine[3], C. Schuger[3]. *[1]Henry Ford Hospital, Cardiology Section, Detroit, United States of America; [2]Henry Ford Hospital, Internal Medicine, Ann Arbor, United States of America; [3]Henry Ford Hospital, Cardiology Section, Detroit, United States of America*

Isolated potentials (IP) during sinus rhythm (SR)indicate the presence of an area of fixed block. Areas of fixed block might form one of the boundaries of a reentry circuit in postinfarct patients with ventricular tachycardia (VT). The 3 dimensional display of such a contiguous area with IPs during SR and its relation to the reentry circuit of postinfarct VT has not been described.

Methods: In 10 patients (pts)(all men, age 69±7yrs EF: 0.25±0.13) with recurrent postinfarct VT, the left ventricle (LV) was mapped with respect to activation time (AT) and bipolar electrogram (EGM) amplitude during SR (CARTO, Biosense, Inc.). Ten clinically relevant VTs were targeted in the 10 pts. Low-voltage segments (LVS)(amplitude <1mV) were distinguished from higher voltage segments (amplitude >1mV). AT during SR was color-coded and superimposed onto the geometrical reconstruction of the LV using a fixed reference point. IPs were defined as potentials separated from the ventricular EGM by an isoelectric line. The AT of sites with IPs was defined at the offset of the isoelectric line separating the ventricular EGM from the IP. Contiguous isochronal segments with IPs during SR were marked. Their relationship to the reentry circuit of postinfarct VT was then assessed during VT by entrainment mapping. Results: In all of the pts contiguous areas with isolated potentials could be identified. Multiple isochronal segments of IPs were identified within a single low-amplitude area in 7/10 pts. In 3/10 pts the isochronal IP area formed a border with another anatomically fixed barrier (in 2 pts with the mitral valve annulus and in 1 pt with a surgical scar after aneurysmectomy). Concealed entrainment could be demonstrated adjacent to the contiguous isochronal segments of IPs originating from the latest ventricular activation during SR in all pts. RF ablation of 8/10 targeted VTs was successful.

Conclusion: IP isochrones identify areas of fixed block during SR. The IP isochrones associated with the latest ventricular AT during SR identify a protected area that borders part of the reentry circuit of postinfarct VT.

P976 Selection of target sites for ablation of ventricular tachycardia using non-contact ventricular waveforms

N.M.S de Groot, M.J. Schalij, E.E. vd Wall. *Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Introduction Target sites for ablation of ventricular tachycardia (VT) are crucial pathways of slow conduction, which can be identified by the presence of prolonged, low voltage electrograms. Mapping for identification of successful target sites can be performed during sinus rhythm (SR), pacing (P) and VT. This study evaluated differences between non-contact unipolar ventricular waveforms (VW) recorded from normal and infarcted myocardium.

Methods VW were recorded from pts (n=10, age 55±12 yr.) who underwent an ablation of drug-refractory post-infarction VT (CL 230±25 ms), using a non-contact mapping system (Ensite). VW's were off-line obtained from a rectangular area (n=32, ±12X15 mm, inter-electrode distance 3-4 mm) from both normal and infarcted (ablation area) myocardium during SR, P and VT. Duration and morphology of VW's between different sites and rhythms were compared.

Results Duration of VW's recorded from the infarcted area was longer than from normal myocardium during SR, P and VT ($p<0.01$)*. The morphology of VW's recorded during VT was complexer than during SR and P ($p<0.01$)**. Selection of target sites was performed during VT and successful ablation was achieved in 80%. All target sites were characterized by fragmented electrograms.

Ventricular Waveforms

	Duration (ms)		Morphology	
	+	−	+	−
SR	162/11	183/8*	biphasic (100%)	biphasic(42%), low voltage (58%) **
P	157/9	173/10*	biphasic (100%)	biphasic (26%), low voltage (74%) **
VT	105/7	142/7*	biphasic (100%)	biphasic (9.7%), low voltage (65%), fragmented (25.3%) **

+ = normal myocardium, − =infarcted myocardium, */**P<0.01

Conclusion Duration and morphology of VW's are suitable parameters to distinguish normal from infarcted myocardium. In normal myocardium, there was an uniform morphology during SR, P and VT, indicating tight electrical coupling. In infarcted myocardium, morphology of VW's varied with different rhythms, indicating non-uniform anisotropy of infarcted tissue. The duration of VW's during SR and P can be used to identify the arrhythmogenic substrate and the morphology of VW's during VT can be used for the selection of target sites for ablation of VT.

P977 Radiofrequency catheter ablation of ventricular tachycardia late after myocardial infarction: short- and long-term outcome

A.E. Borger van der Burg, L. van Erven, M. Bootsma, E.E. van der Wall, M.J. Schalij. *Leiden University Medical Center, Cardiology, Leiden, Netherlands*

Introduction: Radiofrequency catheter ablation (RFCA) of ventricular tachycardia (VT) is potentially curative. The aim of this study was to evaluate both short- and long-term outcome in a consecutive series of pts with ischemic heart disease.

Methods: From 1997 until 2001, 89 consecutive pts (70 male, 66±10 yrs, 5 pts with incessant VT) underwent RFCA for drug refractory VT due to previous MI. Thirty pts (34%) had a ventricular aneurysm. LV ejection fraction was 29±11%.

Results: In total, 187 VT morphologies were induced and targeted for ablation (2.1±1.3 VT/pt). Majority of the VT's originated from the LV (149, 95%). The procedure was successful in 79% (non-inducibility of VT after RFCA). Procedure-related complications were observed in 7 pts (8%). Two pts died (2.2%, both with incessant VT) due to hemodynamic deterioration despite a successful ablation procedure. Two pts (2.2%) suffered from an ischemic stroke and 3 pts (3.4%) had a complete heart block. Before discharge, an ICD implantation was performed in 25 pts (29%) because of a non- successful procedure and/or hemodynamically non-tolerable VT/Ventricular Fibrillation (VF). During follow-up (19±20 months), a recurrence occurred in 24% of all pts. Significantly more recurrences were observed in the non-successfully ablated pts than in the successfully ablated pts (53% vs 16%, $p<0.001$). Eleven pts with an ICD (44%) experienced ICD therapy for VT/VF (25±65 therapies/pt, range 0-257). Eight pts died during follow-up because of heart failure, whereas 2 pts died a non cardiac death (sepsis:1, malignancy:1). No patients died suddenly.

Conclusion: RFCA of VT is successful and relatively safe. The recurrence rate of the successfully ablated pts is promising. During follow-up no pts died due to VT/VF.

P978 Isthmus characteristics of reentrant ventricular tachycardia after myocardial infarction

C. de Chillou[1], D. Lacroix[2], D. Klug[2], I. Magnin-Poull[1], M. Andronache[1], B. Brembilla-perrot[1], E. Aliot[1], S. Kacet[2]. [1]*CHU Brabois, Cardiology Dept., Nancy, France;* [2]*university hospitals, cardiology, Lille, France*

Background: The reentrant mechanism of post-infarct ventricular tachycardia (VT) has been documented by per-surgical mapping analysis, but little is known about post-infarct VT circuits and characteristics of their related protected isthmus using 3D catheter mapping systems.
Methods and Results: A 3D electroanatomic mapping was performed in 21 consecutive patients with well-tolerated post-infarct sustained VT. In total, 33 VTs (mean cycle length = 432±74ms) were induced and mapped. Complete maps demonstrated macroreentrant circuits with 1 (n=8) or 2 loops (n=25) rotating around a protected isthmus bounded by two approximately parallel conduction barriers which either consist of a line of double potentials, a scar area of the mitral annulus. A total of 26 critical isthmuses were identified for the 33 VTs mapped, the same isthmus being shared by 2 to 4 different tachycardia morphologies in 5 patients. On average, isthmuses were 31±7 mm long (ranging from 18 to 41 mm), 16±8 mm wide (ranging from 6 to 36 mm) and harbored diastolic electrograms. The isthmus axis was oriented parallel to the mitral annulus plane in perimitral circuits and circuits and perpendicular to the mitral annulus plane in all other circuits. Linear radiofrequency ablation performed across the most accessible part of the isthmus prevented VT recurrence in 19 patients (90%) with a follow-up of 16±8 months.
Conclusions: Detailed 3D electroanatomic mapping is helpful in reconstructing post-infarct VT circuits and in defining the characteristics of their related protected isthmuses. The wide range of isthmus width values supports the need of linear RF lesions to eliminate the reentrant substrate of post-infarct VTs.

P979 Endocardial line ablation during sinus rhythm as first line treatment of post-infarction ventricular tachycardia

A. Pastor, A. Núñez, C. Kallmeyer, S. Schames, M. Alvarez, A. Goicolea, F.G. Cosio. *Hospital Universitario de Getafe, Servicio de Cardiología, Getafe, Spain*

Background: Applicability of radiofrequency ablation (RFA) of post-infarction ventricular tachycardia (VT) has been limited by TV tolerance. Recent studies have described techniques for VT RFA in sinus rhythm. We have developed a strategy including RFA as first line treatment of VT using lack of inducibility of clinical VT as the endpoint.
Objective: To report preliminary results of this treatment strategy in a non-referral VT population with cycle length of 340 ms (range 500-290 ms).
Population: 9 patients (P) aged 56-75 years with an old myocardial infarction (inferior in 7, anterior in 2). Mean left ventricular ejection fraction 32%. In 6 P clinical VT was hemodynamically unstable. VT was recurrent (post ablation) on amiodarone for atrial fibrillation in 2 P, in 7 P it was a first episode. VT was unstable at EP study in 7 P and non-sustained in 2 P.
Methods: VT was induced at baseline. Scar edge was delimited with fluoroscopy-based mapping by change from high to low voltage (<2 mV) electrograms. Clinical VT "exit site" was localised pacing scar edge. Lines were drawn with overlapping, point-by-point RFA applications (8 mm electrode, max 100 W), from the edge to the center of the scar, in different directions, including at least 1 through the exit site.
Results: Ablation included 2-4 lines (total 15-25 points, median 23). Clinical VT became non-inducible in 8 P. A non-clinical VT (cycle <250 ms) was inducible in 3. A defibrillator was implanted in 1 P remaining inducible for clinical VT and 1 with reproducibly inducible non-clinical VT.
Follow-up: The P with inducible clinical VT had multiple VT treated by the defibrillator. The remaining 7 P were free of arrhythmic events after a mean follow-up of 21 month (8-39), including the one with inducible non-clinical VT. Two P died of pump failure: one 20 month after RFA without VT recurrence, the other with an acute myocardial infarction 48 h after RFA.
Conclusion: This preliminary experience suggests that endocardial line RFA of VT substrate in sinus rhythm can be applied to all post-infarction patients with a first episode of VT as first line treatment. Suppression of clinical VT inducibility marks a clinical course free of arrhythmias at mid-term, suggesting no need for defibrillator implantation.

P980 Linear ablation guided by CARTO for control life-threatening ventricular tachycardia in patients with ischaemic cardiomyopathy

A.M. Wnuk-Wojnar, C. Czerwiński, M. Trusz-Gluza, W. Orszulak, E. Konarska-Kuszewska, A. Hoffmann. *University Hospital Silesian Med. Acad, 1st Dept. of Cardiology, Katowice, Poland*

Background: Ventricular tachycardias in patients with low ejection fraction after myocardial infarction can be lifethreatening in spite of ICD implantation because these VT are often incessant or very frequent (electrical storm). In addition, induced VTs are often unstable, preventing extensive mapping to localize all VT circuits.
Methods and Results: Between Mar 2001 and Dec 2002 a total of 12 pts after MI with EF<30%, 2-6 month after ICD implantation were referred for RF ablation because of incessant VT in 1 patient, unmappable polymorphic VT/VF in 1 patient and recurrent VT in 10 patients. Electro-anatomical mapping (EAM)was performed using CARTO system in all but 1 patient (incessant VT) during sinus rhythm. Voltage maps were used to determine the area of dense scar (<0,5 mV), normal myocardium (>1.5 mV) and border zone (>0.5mV and <1.5 mV). Extensive set of linear ablations were done around areas of scar (3 - 6 lines per patient). In patient with incessant VT tachycardia was terminated during 3rd line application. In 3 patients ablation session was repeated because of early VT recurrence after 3-7 days and in 2 patients after 6-7 months. No complications were observed after ablation. Mean fluoroscopy time was 9.2± 4.3 min. No worsening in EF was observed during follow-ups (ECHO). During 3-11 month FU 7 patients are free of arrhythmia (ICD-Holter), In 2 patients after 6-7 months procedure was repeated because of episodes of symptomatic VT terminated by ATP. In further 2 pts 1-2 asymptomatic, ATP terminated VT were recorded. 1 patient died due to heart failure with no arrhythmia in ICD memory.
Conclusion: EAM during sinus rhythm is safe and very useful method to identify target sites for RF lines application especially in patients with severely depressed LV function, unstable and unmappable VT and polimorphic VTs.

ELECTROCARDIOGRAM IN BRUGADA'S SYNDROME, WOLFF–PARKINSON–WHITE'S SYNDROME AND OTHER CLINICAL CONDITIONS

P981 Right precordial early repolarization in Brugada patients and trained athletes: the need for a differential diagnosis

D. Corrado[1], A. Pelliccia[2], L. Loira[1], F. DiPaolo[2], B.J. Maron[3], G. Buja[1], G. Thiene[4]. [1]*University of Padova, Division of Cardiology, Padova, Italy;* [2]*Institute of Sports Sciences, Roma, Italy;* [3]*Minneapolis Heart Institute Foundation, Minneapolis, United States of America;* [4]*University of Padova, Department of Pathology, Padova, Italy*

Background: Brugada syndrome is a cardiac ion channel disease characterized by a distinctive ECG pattern of high take-off ST-segment elevation in V1-V2/V3 ("early repolarization") and the risk of life-threatening ventricular arrhythmias in young people. ECG abnormalities that mimic early repolarization of Brugada syndrome have been reported in up to 8% of young trained athletes.
Methods: In the present study we compared the ECG pattern of right precordial J-point and ST-segment elevation (of 2mm or more) in 30 Brugada patients (aged 34±7years) and 30 healthy trained athletes (aged 22±6 years) in order to identify criteria for differential diagnosis. For the study purpose, the analysis of 12-lead ECG focused on heart rate, conduction times and depolarization/repolarization intervals and abnormalities. The amplitude of maximum ST-segment was measured at J-point (STJ) and after 80 msec (ST80), and a STJ/ST80 ratio was calculated in both subgroups.
Results: Despite similar degree of maximum amplitude of STJ (3.2±1.1mm vs 3.1±0.9mm; p=0.12), Brugada patients had a downsloping ST segment with a STJ/ST80 ratio of 1.7±0.4 as compared with an upsloping ST segment with a STJ/ST80 ratio of 0.73±0.15 in athletes (p<0.0001). A cut off value STJ/ST80 ratio of 1 or more had a sensitivity of 95% and a specificity of 100% for the diagnosis of Brugada syndrome. As compared with athletes, Brugada patients also had a significantly higher heart rate (RR interval of 0.8±0.1 sec vs 1.22±0.21 sec; p<0.0001), a shorter QTc interval (0.35 ±0.04 sec vs 0.39±0.02 sec; p<0.0001) and a longer QRS duration (0.11±0.02 sec vs 0.09±0.01 sec; p<0.0001) as well as exhibited more often a "S1S2S3 pattern" (53% vs 27%; p=0.04). There were no differences between the 2 subgroups with regard to PR interval duration and number of precordial leads (beyond V1) showing inverted T waves.
Conclusions: A STJ/ST80 ratio of 1 or more accurately differentiated the ECG pattern of early repolarization in patients with Brugada syndrome from healthy trained athletes. A longer QRS interval duration and the presence of a "S1S2S3 pattern" refined the diagnosis.

P982 Body surface potential mapping in long-QT syndrome: the role of lead positioning for the identification of patients with ventricular arrhythmias

H.J. Bruns, G. Mönnig, C. Vahlhaus, G. Breithardt, W. Haverkamp. *University Hospital Münster, Dept. of Cardiology and Angiology, Münster, Germany*

Background: The identification of symptomatic patients with long-QT(LQT) syndrome remains difficult in clinical routine. The interpretation of the standard 12-lead ECG has a major impact for the individual risk stratification.
Methods: 14 patients with LQT and ventricular arrhythmias (syncope or survived sudden cardiac death) were enrolled into the study. A 120-channel body surface potential mapping (BSPM) covering the entire torso surface was performed. For all surface leads, the frequency-corrected interval between QRS onset and the maximal T amplitude (QTcmax) was analyzed. The diagnostic value of each lead position of the BSPM was indicated calculating discrimination factors (DF), which for each lead position described the individual difference to the corresponding mean values of a group of healthy subjects (n=11), divided by the standard deviation of this group.
Results: The left-precordial leads of the standard ECG leads presented with high DF levels regarding QTcmax (DF(V5): 2.5±2.0; DF(V6): 2.6±2.0). In the BSPM, inferior lead positions showed even higher values for the discrimination compared to healthy subjects (V7: 3,2±2,6; V8: 3,2±2,9).
Conclusions: Additional ECG recordings in lead V7 and V8 improve the individual identification of patients with long-QT syndrome. In the future, individual risk stratification and the individual strategy for an appropriate therapy may be based on BSPM measurements.

P983 Clinical outcome of asymptomatic individuals with a Brugada-like electrocardiogram pattern

D. Corrado[1], L. Leoni[1], P. Delise[2], E. Bertaglia[3], A. Raviele[4], F. Naccarella[5], G. Buja[1], G. Thiene[6]. *[1]University of Padova, Division of Cardiology, Padova, Italy; [2]Civil Hospital, Division of Cardiology, Conegliano, Italy; [3]Civil Hospital, Division of Cardiology, Mirano, Italy; [4]Civil Hospital, Division of Cardiology, Mestre, Italy; [5]Civil Hospital, Division of Cardiology, Bologna, Italy; [6]University of Padova, Department of Pathology, Padova, Italy*

Background: The ECG pattern of right precordial ST-segment elevation may be associated with life-threatening ventricular arrhythmias and sudden death in young people (so called "Brugada syndrome"). However, this ECG patten is increasingly found in healthy individuals without arrhythmic symptoms. The aim of the present study was to assess the clinical outcome of these asymptomatic individuals with a Brugada-like ECG pattern and to establish prognostic value of programmed electrical stimulation.
Methods: We studied 62 consecutive patients (57 males and 5 females, aged 37±12 years) with the distinctive ECG pattern - spontaneous (56) or induced by sodium channel blockers (6) - characterized by high take-off ST-segment elevation (2 mm or more) in right precordial leads, of either "coved" or "saddleback" type, in the absence of structural heart disease. All patients were asymptomatic and the ECG was obtained during routine examination or at cardiac evaluation because of nonspecific symptoms; a familial form of asymptomatic ECG abnormalities were ascertained in a total of 7 subjects. The occurrence of major arrhythmic events such as cardiac arrest, syncope or appropriate shock discharge by ICD at follow- up was analyzed in all patients. In 26 individuals, who underwent programmed ventricular stimulation (up to 3 extrastimuli from both right ventricular apex and outflow tract), clinical outcome was correlated with the inducibility to sustained polymorphic ventricular tachycardia (VT) or ventricular fibrillation (VF).
Results: Nine individuals (35%) were inducible to sustained ventricular arrhythmias at PVS (polymorphic VT in 2 and VF in 7), and were treated by ICD (5) or antiarrhythmic drugs (beta-blockers in 2 and amiodarone in one). During a mean follow-up of 35±13 months, none individuals developed symptoms or arrhythmic events.
Conclusions: Asymptomatic individuals with a Brugada-like ECG had a benign outcome during a long term follow-up regardless of results of PVS. These data suggest the need to distinguish between patients with Brugada syndrome (ECG pattern and spontaneous ventricular arrhythmias) and individuals with just a Brugada-like ECG pattern. In this latter subgroup, less aggressive diagnostic and management strategies should be adopted.

P984 The Ajmaline challenge in Brugada syndrome: is it dangerous?

S. Rolf, L. Eckardt, P. Kirchhof, P. Loh, M. Ribbing, G. Breithardt, W. Haverkamp. *University of Muenster, Department of Cardiology and Angiology, Muenster, Germany*

Background: The Brugada Syndrome (BS) describes a subgroup of patients (pts) without structural heart disease associated with atypical right bundle block and coved-type ST-segment elevation in the right precordial leads at risk for the occurrence of ventricular tachyarrhythmia (VT). The early identification of affected pts is crucial, because at present the implantation of a cardioverter defibrillator is the only safe treatment. The diagnostic ECG pattern can transiently normalize and may be unmasked by sodium channel blockers like ajmaline. Due to anecdotal reports of occurrence of VT during the Ajmaline Challenge we studied the risks of the test.
Methods: During a period of 30 months n=125 pts underwent the Ajmaline Challenge at our institution. Some had either experienced resuscitation from near sudden cardiac death (SCD) (n=16), episodes of unclear syncope (n=71) or VT (n=19). Others had a suspicious ECG at rest (n=31) and/or a family history of SCD or BS (n=24). Target ajmaline dose was 1 mg/kg body weight intravenously under continuous ECG monitoring. Indications to terminate the test were QRS prolongation > 30%, occurrence of the classic Brugada-type ECG or VT.
Results: In n=37 pts (30%) the typical ECG pattern of BS was uncovered. Symptomatic VT appeared in only n=2 pts (2%). Both had a positive reaction to Ajmaline. In one case, the immediate discontinuance of drug supply lead to termination of non sustained VT. The other patient with classic coved-type ECG before the test required multiple defibrillations for sustained polymorphic VT.
Conclusions: (1) The Ajmaline Challenge is a relatively safe method to diagnose BS. It should be performed in the hospital under continuous monitoring. Termination criteria like reaching target dose, QRS prolongation > 30%, presence/appearance of the typical ECG and the occurrence of VT should be met carefully. (2) Due to the prognostic importance of BS all pts with aborted sudden death or syncope of unknown origin without demonstrable heart disease should undergo the Ajmaline Challenge.

P985 Electrocardiographic risk stratification of genotyped patients with long QT-syndrome

G. Moennig[1], H.J. Bruns[1], E. Schulze-Bahr[1], H. Wedekind[1], H. Funke[2], G. Assmann[2], G. Breithardt[1], W. Haverkamp[1]. *[1]University of Muenster, Cardiology, Muenster, Germany; [2]University of Muenster, Institute of Arteriosclerosis Research, Muenster, Germany*

Background: In patients with long QT(LQT)-syndrome, the ECG is used for risk assessment.
Method: To test the value of different ECG-leads regarding risk stratification, discrimination of rate-corrected QT-interval (QTc) of all ECG-leads in 49 genotyped LQT-patients (age: 36 ± 19; LQT1: 25; LQT2: 16; LQT5: 8) between symptomatic (n=21; no of syncope: 7.5 ± 11.2; survived cardiac death: n=10) and asymptomatic (n=28) mutation carriers were studied using Receiver Operating Characteristic Analysis (ROC = area under curve). Additionally, the cut-off values for QTc with the highest sum of sensitivity and specificity for identifying symptomatic patients among LQT mutation carriers were calculated.
Result: In all ECG-leads, QTc was significantly prolonged in symptomatic compared to asymptomatic LQT mutation carriers. The highest discrimination was found in lead II (ROC: 0.85) and lead V6 (ROC 0.82). At a cut-off value of 485 ms in V6, sensitivity was 83% and specificity was 85% for identifying symptomatic mutation carriers. In lead II at a cut-off value of 478 ms 80% and 86%, accordingly.
Conclusion: The surface ECG may help in risk stratification for syncope or sudden cardiac death in patients with LQT syndrome. In our cohort a cut-off value of about 480 ms in lead II or V6 is a reasonable and practicable parameter for identifying LQT patients with a potential risk for symptoms.

P986 Activation-recovery interval measurements in evaluation of global sequence and dispersion of ventricular repolarization in patients

S. Yuan[1], E. Hertervig[1], O. Kongstad[1], Z. Li[1], M. Holm[2], S.B. Olsson[1].
[1]*University Hospital, Dept. of Cardiology, Lund, Sweden;* [2]*Biosense Webster, Clinical Dept., Waterloo, Belgium*

Background: Activation-recovery interval (ARI) measured from unipolar electrograms has been used as an index of myocardial repolarization time. However, it is unknown if the global sequence and dispersion of ventricular repolarization evaluated using monophasic action potential (MAP) mapping technique could be estimated from the ARI measurements.
Methods: Endocardial MAPs and unipolar electrograms were simultaneously recorded from 34±12 left (LV, n=5) or right ventricular (RV, n=9) sites in 14 patients using the NaviStar catheter and the CARTO system. Local activation time (AT), end-of-repolarization (EOR) time were calculated from the MAPs and the ATs and ARIs from the unipolar electrograms, based on which 14 sets of 3-dimensional maps of global EOR and that of the ARI were reconstructed. The ARI was compared with the EOR at each site. The correlations between the ARI and the EOR, between the ARI and the AT and between the EOR and the AT were analyzed. The global sequence and dispersion of ventricular repolarization were compared for each map.
Results: (1) A significant positive correlation between the ARI and the EOR was found in all the maps, the r value being 0.53±0.27. The mean differences between the ARI and the EOR were 5,57±21 ms for the total 473 paired measurements in the 14 maps (NS). (2) The global dispersion of ARI was 64±15 ms, as compared with that of EOR 68±22 ms (NS). (3) Repolarization sequence was recognizable in 13/14 ARI maps as compared with that in 14/14 EOR maps. (4) ARI sequence was similar to the EOR sequence in 12/14 maps. (5) The ARI was positively correlated with the AT in 12/14 maps, as compared with that between the EOR and the AT in 14/14 maps.
Conclusion: The ARI measurements from the unipolar electrograms well-estimated the EOR measurements from the MAPs, suggesting the usefulness of the former method in evaluation of ventricular repolarization.

P987 Is it possible to distinguish Brugada syndrome patients with a SCN5A mutation from those without using phenotypical characteristics?

J.P.P. Smits[1], L. Eckardt[2], H. Le Marec[3], C.R. Bezzina[1], E. Schulze-Bahr[2], D. Escande[3], W. Haverkamp[2], A.A.M. Wilde[1]. [1]*Academic Medical Center, Experimental and Molecular Cardiology, Amsterdam, Netherlands;* [2]*Universitätsklinikum Münster, Kardiologie/Angiologie, Münster, Germany;* [3]*Hôpital Hotel-Dieu, INSERM U533, Nantes, France*

Introduction The Brugada syndrome (BS) is an inherited cardiac disease characterized by a varying degree of ST-segment elevation in the right precordial leads, and (non) specific conduction disorders. BS patients may develop malignant ventricular arrhythmias.
In a minority of patients mutations in the gene encoding the cardiac sodium channel (SCN5A) can be found. Genetic heterogeneity has been demonstrated but other casually-related genes await identification.
We have tested whether a genotype-phenotype relation exists in BS by trying to distinguish BS patients with (carriers) and without (non-carriers) a SCN5A mutation using clinical parameters. Existence of such a relation might facilitate genetic screening.
Methods In a multi-center study we have collected data on; demographics, clinical and family history, ECG parameters, HV interval and ECG parameters after pharmacological challenge with INa blocking drugs, in BS patients with (n=23) or without (n=54) an identified SCN5A mutation (genetic screening by SSCP).
Results The two groups did not differ in demographics, clinical or family history. Carriers had a significantly longer PQ interval on the baseline ECG (209±51ms vs 163±25ms ($p<0.001$)) and a significantly longer HV-time (66±13 vs 48±9ms ($p<0.001$)). A PQ interval of >=210ms predicts the presence of a SCN5A mutation with a sensitivity of 48% a specificity of 98% a positive predictive value of 92% and a negative predictive value of 81% ($p<0.0001$). For a HV interval >=60ms values were respectively 88%, 82%, 50% and 97% ($p<0.001$). After infusion of INa blocking drugs carriers had a significantly longer PQ interval (222±37ms vs 195±33ms ($p<0.05$)) and QRS interval (142±31ms vs 118±21ms ($p<0.005$)). Carriers also had more increase in QRS duration (38±31ms vs 18±18ms ($p<0.05$)).
Conclusion We observed significant longer conduction intervals (PQ, HV and QRS increase upon class I drugs) in patients with established SCN5A mutations. These results concur with the observed loss of function (i.e. reduced sodium current) of mutated BS-related sodium channels. BS patients with and without a SCN5a mutation can be differentiated with a high specificity on the basis of phenotypical differences.

P988 Usefulness of the 12-lead electrocardiogram for locating the site of origin of idiopathic left and right ventricular outflow tract tachycardia

R. Peinado, L. Ramírez, J.L. Merino, A. Peinado, M. Abello, F. Lopez, J.A. Sobrino. *Hospital Universitario La Paz, Unidad de Arritmias, Madrid, Spain*

Background and Purpose: Pace mapping is the most efficient technique for locating the successful ablation site of an idiopathic ventricular tachycardia (IVT) originating from the right or left ventricular outflow tract (RVOT, LVOT). This study was aimed at analysing the 12-lead QRS characteristics during pacing from different sites of the RVOT and LVOT to obtain useful criteria for predicting site of origin of these VT.
Methods: We prospectively studied 24 patients without structural heart disease undergoing catheter ablation of a left accessory pathway by a transaortic approach. To mimic spontaneous tachycardia, continuous pacing at twice the diastolic threshold and a 350 ms coupling interval was performed from the distal electrode pair of a 4 mm tip ablation catheter at 10 different sites on the LVOT, aortic cusps and RVOT. A 12-lead ECG was recorded during pacing at each site where ventricular capture was successful. ECG's were analysed for QRS pattern, axis and width, the point of precordial transition, QRS morphology in leads I, aVL, aVR, V5 and V6, r wave amplitude in V1, and delta wave-like beginning of the QRS.
Results: V2 transition was not observed when pacing from the RVOT but in 26% of patients when pacing from the LVOT or aortic cusps. V3 transition was observed in 9% of cases paced from the RVOT, in 32% from the LVOT and 56% from the aortic cusps. In 20% and 26% respectively, of LVOT and aortic cusp pacing occasions, transition was obtained in V4. The presence of a s wave in V5 or V6 predicted a LVOT pacing site (51,5% sensitivity, 95% specificity, 66% + predictive value and 88% - predictive value). An rS, RS or Rs morphology in lead I was the best predictor for left aortic cusp or mitroaortic continuity pacing (87,5% sensitivity, 90% specificity, 89,7% + predictive value and 88% - predictive value). QRS was significantly narrower in septal LVOT (143 ± 22 ms vs. 170 ± 12; $p < 0.001$) than in the other pacing sites.
Conclusions: Precordial transition, and the presence of s wave in leads I, V5 and V6 were the most useful criteria for determining the pacing site from the LVOT and RVOT. Although a left bundle branch block morphology, inferior axis, late transition is the only pattern obtained during pacing from the RVOT, different sites from the LVOT and aortic cusps can origin this morphology.

P989 Distinct electrocardiographic patterns for right ventricular outflow tract tachycardia – Verification of electrocardiogram algorithms by CARTO

C. Czerwiński, A.M. Wnuk-Wojnar, M. Trusz-Gluza, A. Hoffmann, S. Nowak. *University Hospital Silesian Med. Acad, 1st Dept. of Cardiology, Katowice, Poland*

Right ventricular outflow tract tachycardia (RVOT-T) originates from RV free wall (A-anterior) vs septal (P-posterior) side, left (L) vs right (R) side and proximal (S-superior) vs distal (I-inferior) side below pulmonic valve. Identification of these sites of origin (SOO) using ECG criteria facilitates localization during catheter ablation (CA). Prior attempts to identify ECG patterns by pace mapping at these sites using body surface ECG mapping (BMS) and fluoroscopy (F) alone were limited by reproducibility of localization. Methods and Results: To overcome this limitation we used CARTO (electro-anatomic mapping - EAM) for precise localization of RVOT-T SOO based on activation and propagation maps obtained in 23 pts who underwent successful CA for RVOT-T and analyzed 12 lead ECG during RVOT-T or VEB identical with RVOT-T. The ECGs were analyzed for QRS amplitude/width, morphology and patterns of precordial transition (table below).

ECG Patterns

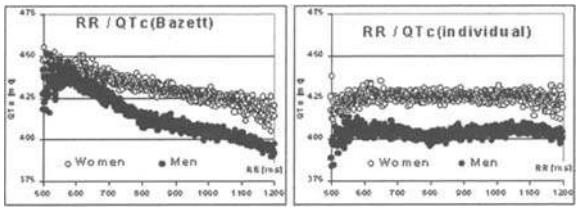
A vs P	QRS>140ms	QRS<140ms	II,III:RR', Rr'	II,III: R
A (6)	5	1	1	5
P (17)	16	1	7	9
L vs R	aVR <aVL	aVR>aVL	I negative	I: positive
L (17)	8	9	9	8
R (6)	3	3	3	3
S vs I	V1, V2 initial r>0.2mV	V1, V2 initial r<0.2mV		
S (18)	10	8		
I (5)	2	3		

It was found, that posterior RVOT-T SOO obtained by EAM was accompanied with a sharp R wave without any notching in lead II and III QRS complex ($p<0.05$). Similarly, inferior RVOT-T SOO localization coexisted with low r amplitude (< 0.2 mV) in V1 and/or V2 QRS complexes. Conclusion: EAM would potentially allow developing ECG algorithms to facilitate rapid arrhythmia localization during CA for RVOT-T.

P990 The individually derived formulae are superior to Bazett and Fridericia formulae for heart rate correction of the QT interval

V. Batchvarov, P. Smetana, A. Ghuran, K. Hnatkova, A.J. Camm, M. Malik.
St.George's Hospital Medical School, Department of Cardiological Sciences, London, United Kingdom

Background: It is considered that most formulae for heart rate correction of the QT interval over- or undercorrect the QT interval at extreme heart rates, but perform satisfactorily at physiological resting heart rates. We compared Bazett and Fridericia formulae with an individually derived heart rate correction formula over a wide range of physiological heart rates.
Methods: 24-hour 12-lead digital ECGs (SEER MC, GE Marquette, one 10-second ECG every 30 sec, 2880 ECGs/24 hours) were recorded in 22 healthy men (age 27±7 years) and 24 healthy women (27±8 years). The QT intervals of all ECGs were measured automatically (QT Guard, GE Marquette, downslope inflex tangent method). In each subject, all QT intervals were corrected by 1) Bazett formula, 2) Fridericia formula and 3) by an individual formula QTc=QT/RR(power of beta), where the optimum value of beta was derived in each subject by a power model QT = alpha + (RR)(power of beta), which was best-fitted to her/his 24-hour QT/RR data. The linear correlations between the RR intervals and QTc(Bazett), QTc(Fridericia) and QTc(individual) were estimated.
Results: Even within the physiological range of resting heart rate (i.e. 60-90 beats/min), QTc (Bazett) and QTc(Fridericia), were significantly correlated to the RR interval (Bazett: r=-0.87 and r=-0.92 in women and men, respectively; Fridericia: r=0.90 and 0.54). QTc(individual) was not correlated to the RR interval (r=-0.06 and 0.09 in women and men, respectively).



Conclusion: Both Bazett and Fridericia formulae may over- or undercorrect the QT interval even at physiological heart rates. Correction formulae derived in each subject from her/his 24-hour QT/RR data provide superior heart rate correction of the QT interval.

P991 Prevalence of a wide QRS complex in candidates to coronary artery bypass grafting and relationship with clinical outcome

M. Biffi, G. Boriani, M. Bertini, L. Bacchi Reggiani, M. Bartolotti, A. Branzi.
Institute of Cardiology, University of Bologna, Bologna, Italy

We investigated the prognostic weight of several factors on the risk of heart failure in patients undergoing CABG. We followed 300 consecutive patients up to 1 year after surgery to assess clinical outcome, presence and degree of heart failure. The risk of developing heart failure > class 2 at 1 year was investigated by logistic regression on the following preoperative variables: sex, age, left ventricular EF, NYHA class, QRS duration, previous MI, previous CABG, previous class 3 or 4 heart failure (PHF), atrial fibrillation (AF), history of ventricular arrhythmias, hypertension, hypercholesterolemia, diabetes, coexistent non-cardiac disease. Age was 70±8 years and EF was 52±13% at the time of surgery. Average follow up was 19±8 months. Heart failure > class 2 occurred in 108/300 patients (36%) at 1 year. Among the abovementioned clinical variables, only sex,previous severe heart failure, coexistence of AF, and QRS duration were predictive of heart failure development at follow up (table). All the other variables were not risk markers for heart failure at logistic regression. Heart failure > class 2 developed in 67/84 patients with QRS>130 ms vs 41/216 with QRS<130 ms ($p < 0.01$).

		OR	95% CI
Female sex	66/300	5.9	2.3- 15.4
PHF	101/300	3.2	1.4-7.1
Atrial Fibrillation	19/300	11.4	1.3-100
QRS duration (ms)	108±19	1.22	1.16-1.30

CI=confidence interval; OR=odds ratio; PHF=previous class 3 or 4 heart failure.

Forty-six patients (15%) had QRS>140 ms suitable for LV-based pacing. In the current surgical era, candidates to CABG (50% older than 70 years) have a relevant likelihood of heart failure at follow up, despite myocardial revascularisation. Risk stratification may rely upon inexpensive variables as previous severe heart failure, presence of AF, and QRS duration. A minority of patients could benefit from LV-based pacing, which should be considered at the same surgical time of CABG via an epicardial implantation.

P992 The role of resting electrocardiogram in the assessment of viable myocardium in ischaemic cardiomyopathy; comparison with positron emission tomography

A. Desideri[1], S. Coscarelli[1], M. Bertella[2], R. Bigi[1], P. Zanco[3], L. Cortigiani[1], J.J. Bax[4], L. Celegon[1]. [1]*Cardiovascular Research Foundation, S.Giacomo Hospital, Castelfranco Veneto, Italy;* [2]*Vimercate Hospital, Division of Cardiology, Vimercate, Italy;* [3]*S.Giacomo Hospital, PET Center, Castelfranco Veneto (TV), Italy;* [4]*University Medical Center, Department of Cardiology, Leiden, Netherlands*

Objectives: We assessed the value of ST-segment elevation at rest to identify viability in the anterior wall in pts with anterior wall akinesia and depressed LV function; the results were related to positron emission tomography (PET) and coronary angiography.Methods:32 pts (29 male, age 63±8 years, LVEF 31±8) with chronic ischemic cardiomyopathy had a 12-lead ECG recorded at rest, and underwent PET with fluorine-18-fluorodeoxyglucose(FDG), and coronary angiography. The extent of ST-segment elevation (mm) was calculated from leads V1-V6, I and aVL. Uptake of FDG in the anterior wall >50% of the maximum uptake indicated the presence of viable myocardium. Coronary stenoses >70% were considered critical.Results: Based on the PET results, 21 pts were classified as viable and 11 as nonviable; 11/21 (52%) PET-viable pts showed ST-segment elevation <1 mm in 1 or more anterior leads, as compared to only 1/11 (9%) pts with scar tissue (OR 11, CI 95% 1.1-101.9, p= 0.02). Mean ST-segment elevation at rest was significantly lower in the viable as compared to the nonviable pts in leads V2 (1.07±0.61 mm vs 1.76±0.49 mm, p=0.003), V3 (0.81±0.61 mm vs 1.79±0.55 mm, p= 0.0001), V4 (0.24±0.48 mm vs 1.35±1.12 mm, p=0.0005) and V5 (0.03±0.15 mm vs 0.57±0.87 mm, p=0.009). ROC curve analysis identified ST-segment elevation <1 mm in lead V3 as the optimal cut-off for identifying viable myocardium (sensitivity 76%, specificity 91%, AUC 0.87). At coronary angiography, 13 pts with viability at PET had an occluded left anterior descending coronary artery (LAD) with collateral circulation and 8 had a critical stenosis. Among the 11 pts without viable tissue 6 had an occluded LAD (in 4 cases with collateral vessels) and 5 had a critical stenosis.
Conclusions: ST-segment elevation<1 mm in lead V3 is an accurate marker to identify the presence of viable tissue, in pts with ischemic cardiomyopathy and akinesia of the anterior wall. This electrocardiographic pattern is frequently correlated with multivessel disease and presence of coronary collaterals to the occluded vessel.

P993 Natural history of Brugada syndrome: insights for a novel risk stratification algorithm

C. Napolitano[1], M. Grillo[1], M. Gasparini[2], C. Pappone[3], U. Giordano[4], R. Folli[1], J. Nastoli[1], S.G. Priori[1]. [1]*Salvatore Maugeri Fondation, Molecular Cardiology Dept., Pavia, Italy;* [2]*Humanitas Hospital, Cardiology Division, Rozzano, Italy;* [3]*IRCCS, S Raffaele Hospital, Cardiology, Milan, Italy;* [4]*Ospedale Civico ARNAS, Cardiology Division, Palermo, Italy*

Brugada syndrome (BS) is an inherited arrhythmogenic disease characterized by increased risk of sudden cardiac death in young individuals. BS is characterized by a wide spectrum of manifestations ranging from completely asymptomatic individuals to highly malignant variants with recurrent life-threatening events. However, the clinical approach to BS patients is made difficult by the incomplete information on the natural history of the disease and by the conflicting evidences on the predictive role of programmed electrical stimulation (PES). In this study we present data on a large group of BS patients and propose a new risk stratification scheme. Clinical data were collected for 200 consecutive patients (152 men; age 41±18 years) diagnosed as BS by the presence of the typical ECG abnormalities (ST elevation in V1-V3 ad right bundle branch block) either spontaneously or after administration of sodium channel blocker (Flecainide 2mg/kg or Ajmaline 1mg/Kg, i.v.). Genetic analysis was performed and mutations on the SCN5A gene were identified in 28/130 (22%) probands. The analysis of cardiac events between birth and the last follow up documented cardiac arrest (CA) in 22 individuals (20 males; 33±13 years); 5/22 (23%) patients experienced multiple CAs. History of syncope was present in 34/200 patients (17%). A family history of unexplained sudden death was present in 26/130 (20%) probands. Multivariate analysis showed that patients at higher risk for CA are those with a combined presence of spontaneous ST segment elevation in V1-V3 and history of syncope (HR 6.4; 95% CI 1.9-21; p<0.002), while patients with a spontaneous ST segment elevation without syncope constitute a group with moderately increased risk (HR 2.1; CI 0.68-6.9). On the other hand, PES showed fairly good sensitivity (66%) but a very low specificity (34%) in predicting CA and no statistically significant association between inducibility and occurrence of ventricular fibrillation was identified.
In conclusion, this study provides for the first time data on the natural history of BS in a large cohort of patients and in the largest reported group of genotyped individuals. Risk stratification of BS patients based on the clinical presentation allows the identification of those individuals at higher risk. Our data also show that inducibility at PES has a very low specificity and point to the need of specifically assessing its predictive value with specific protocols.

DIABETES AND ATHEROSCLEROSIS

P994 Insulin enhances vascular cell adhesion molecule-1 (VCAM-1) expression in human endothelial cells

R. Madonna[1], A. Pandolfi[2], G. Pellegrini[2], G. Lazzerini[3], A. Consoli[2], R. De Caterina[4]. [1]*Ospedale S. Camillo De Lellis, Chair of Cardiology, Univ. of Chieti, Chieti, Italy;* [2]*University of Chieti, Department of Diabetology, Chieti, Italy;* [3]*CNR Institute of Clinical Physiology, Laboratory for Thromb & Vasc Research, S.Cataldo - Pisa, Italy;* [4]*Chair of Cardiology, Univ. of Chieti, Ospedale S. Camillo De Lellis, Chieti, Italy*

Hyperinsulinemia has been proposed among the causes of accelerated atherosclerosis in non-insulin-dependent diabetes mellitus (NIDDM). The expression of several endothelial leukocyte adhesion molecules has a critical role in the initiation and progression of atherosclerosis. We hypothesized that insulin, alone or in the presence of submaximal concentration of lipopolysaccharide (LPS), a well-known inducer of endothelial activation, may directly affect the expression of endothelial leukocyte adhesion molecules in the endothelium and, particularly, the expression of vascular cell adhesion molecule (VCAM)-1, intimately involved in early atherogenesis. Human umbilical vein endothelial cells (HUVEC), at passage 4-5, were incubated with insulin for 24 hours, at concentrations ranging from 0.01 to 100 nmol/l, thus covering a range from low physiological to high pharmacological levels, followed by co-incubation with LPS for further 0-24 hours. After this time, VCAM-1, E-selectin and ICAM-1 expression were assessed by cell surface immunoassay (EIA). At none of the concentrations tested, insulin showed any cytotoxicity. VCAM-1 levels (mean ± SD, with 5 replicates in each condition) at the various insulin concentrations, expressed as percent of control, were as in Table.

Effects of insulin on VCAM-1 expression

	Insulin				
	0.01 nmol/L	0.1 nmol/L	1 nmol/L	10 nmol/L	100 nmol/L
no stimulus	97 ± 20	94 ± 27	134 ± 57*	145 ± 61*	158± 76*
with LPS 0.1 ng/mL	99 ± 8.3	105 ± 11	170 ± 64	243 ± 87*	229 ± 70*

values are expressed as mean ± SD, as % of control. *=P<0.05

Thus, at concentrations of 10 and 100 nmol/l, pretreatment with insulin significantly potentiates the induction of VCAM-1, but not of ICAM-1 and E-selectin, by LPS. Moreover, at concentrations ranging from 1-100 nmol/l, insulin alone (in the absence of LPS) is sufficient to induce VCAM-1 induction. This might increase vascular inflammation in vivo and thereby foster atherosclerosis in hyperinsulinemic subjects with NIDDM.

P995 Vitamin C improves endothelial function in type II diabetic patients with coronary artery disease but not in patients with diabetes only

C. Antoniades[1], D. Tousoulis[1], C. Tountas[2], K. Marinou[1], C. Tentolouris[1], C. Pitsavos[1], C. Stefanadis[1], P. Toutouzas[1]. [1]*Cardiology Unit,* [2]*Diabetology Dept., Hippokration Hospital, Athens University, Athens, Greece*

Background: Oxidative stress is an important mechanism of endothelial dysfunction observed in patients with coronary artery disease (CAD) or diabetes mellitus (DM). However, the possible role of antioxidant administration in diabetic patients, is still unclear. In this study we examined the effect of chronic treatment with vitamin C on endothelial function in diabetic patients of type 2 with or without CAD.
Methods: In a double-blind placebo-controlled study, 38 patients (30 males, 8 females, aged 65±1.6 years) with DM of type 2, were enrolled. 26 of them had angiographically established CAD while the rest of them had no clinical evidence for the disease. 11 patients with CAD+DM (group A) and 7 patients with DM only (group B) received vitamin C 2g/d for 4 weeks. 15 patients with CAD+DM (group C) and 5 patients with DM only (group D) received placebo for the same period of time. Forearm blood flow was measured using venous occlusion strain-gauge plethysmography, at baseline and after treatment. Endothelium dependent flow mediated vasodilation (FMD) was expressed as the % change from baseline to post reactive hyperemia blood flow. Endothelium independent flow (NTG%) was expressed as the % change from baseline to post sublingual nitroglycerin administration flow.
Results: Basal blood pressure, heart rate, body weight, basal forearm blood flow and NTG% remained unchanged in all groups. All values are expressed as mean±SEM. FMD and NTG% were not significantly different between patients with CAD+DM (51.5±6.0 and 61.0±6.4% respectively) or DM (53.3±9.1 and 71.7±12.8% respectively, p=NS). FMD in groups A, B, C and D was before treatment: 66.5±11.6%, 53.8±11.2%, 36.3±6.3% and 55.2±12.1% respectively and after treatment: 84.3±15.1% (p<0.05), 55.6±6.9%(p=NS), 36.3±3.4%(p=NS) and 56.8±7.9%(p=NS) respectively.
Conclusions: Chronic administration of vitamin C seems to improve endothelial function only in patients with combined coronary artery disease and diabetes mellitus of type 2, while it is not effective in diabetic patients without coronary artery disease.

P996 Vitamin C and Insulin therapy decrease factor VIIa and insulin improves fibrinolytic activity in type 2 diabetes (T2DM)

R.A. Anderson, G.R. Ellis, L.M. Evans, P. Collins, J. Giddings, M.J. Lewis, M.P. Frenneaux. *Wales Heart Research Institute, Cardiology, Cardiff, United Kingdom*

Background: Post-prandial lipaemia (PPL) is associated with an elevation of factor VIIa, a potent procoagulant, initiating the thrombotic response to atheromatous plaque rupture. Factor VIIa increases after a fatty meal, correlates with the degree of postprandial (PP) triglyceridaemia and seems related to free fatty acid production during lipolysis of TG-rich lipoproteins by lipoprotein lipase on the endothelial cell surface. There is also evidence that PAI-1 activity/antigen is increased acutely after a fat load. This infers relative fibrinolytic resistance 2 and 4 hours after a fatty meal. Vitamin C blunts PPL induced endothelial dysfunction/damage and may attenuate PP elevations in FVIIa. Insulin therapy increases LPL activity attenuates TG rises post-prandially. Insulin therapy in NIDDM may decrease PAI-1 activity by decreasing VLDL levels by upregulating LPL activity.
Methods: 18 T2DM subjects with moderate glycaemic control and no overt vascular disease were studied. All subjects had an overnight fast and received a standard fat meal. Lipid profiles, activated factor VII (ng/ml), PAI-1 (UA/ml) were measured in the fasting and PP phase over 8 hours. The study was repeated in a double-blinded manner with placebo/oral VC (1g) prior to meal then randomized to either VC/placebo and Insulin therapy for 3 months. A repeat fatty meal was then ingested and the experiment repeated.
Results (Mean±SD) There was a significant decrease in factor VIIa at 0, 4 and 8 hrs in response to PPL with VC; 7.6±1.3 to 4.97±1.2 (0hrs), 6.7±1.2 to 4.8±1 (4hrs) and 6.24±0.7 to 5.3±0.5 at 8hrs. Insulin also decreased factor VIIa to 4.25±1, 4.45±1.4 and 4.45±1.4 respectively (p<0.05). In response to insulin therapy there was a significant decrease in PAI-1 levels at 4 and 8hrs PP, 29.1±3.1 to 25,1±3.3 (0hrs), 20.5±3 to 13.8±2.2 (4hrs) and 23.3±1.6 to 18.37±1.3 (8hrs), p<0.05. There was no change in tPA levels.
Conclusion: Vitamin C and Insulin therapy attenuates factor VIIa levels postprandially in T2DM after a fatty meal. Insulin therapy also decreases PAI-1 levels at 4 and 8 hours postprandially. Therefore both Vitamin C and insulin therapy in T2DM, have beneficial effects on the thrombogenic mileu postprandially. In particular insulin has additional effects on the fibrinolytic system by decreasing PAI-1, possibly by decreasing VLDL levels and improving endothelial function.

P997 Effects of diabetes on endothelial function and adhesion molecules serum levels, in patients with or without coronary artery disease

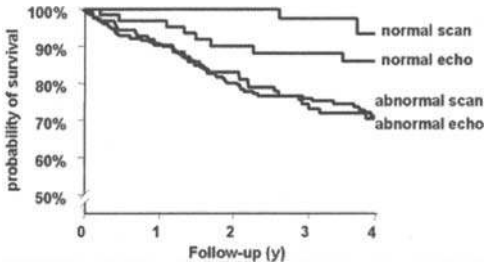
C. Antoniades, D. Tousoulis, M. Toutouza, C. Vasiliadou, C. Pitsavos, C. Tentolouris, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, Cardiology Unit, Athens University, Athens, Greece*

Background: Diabetes mellitus (DM) and coronary artery disease (CAD) are both associated with endothelial dysfunction. Serum levels of soluble vascular cell adhesion molecule (sVCAM-1) and soluble intercellular adhesion molecule (sICAM-1) are increased in patients with CAD. However, the effect of combined CAD and diabetes mellitus on endothelial function and on serum levels of sICAM-1 and sVCAM-1 is not well studied.
Methods: We studied 19 patients with CAD without DM (Group A), 11 patients with CAD+DM (group B), 11 patients with DM without CAD (group C) and 11 healthy controls without CAD or DM (group D). Forearm blood flow was measured using venous occlusion strain-gauge plethysmography. Endothelium dependent flow mediated vasodilation (FMD) was expressed as the % change from baseline to post reactive hyperemia blood flow. Endothelium independent flow (NTG%) was expressed as the % change from baseline to post sublingual nitroglycerin administration flow. Serum levels of sVCAM-1 and sICAM-1 were determined using an immunosorbent assay (ELISA) and expressed in ng/ml. All values were expressed as mean±SEM.
Results: FMD was not significantly different between group A (68±7%) and C (72±19%). FMD was significantly less in group B (51±3.7%) compared to groups A (p<0.05), C (p<0.05) and D (111±17%, p<0.01). FMD was significantly greater in group D compared to groups A and C (p<0.05 for both). NTG% was not significantly different between the groups. Serum levels of sICAM did not differ between groups (280±35, 297±45, 250±19 and 243±22 ng/ml in groups A, B, C and D respectively). Serum levels of sVCAM-1 were significantly greater in groups B (484±43 ng/ml) and C (585±67 ng/ml) compared to groups A(358±25 ng/ml, p<0.05 for both) and D (340±21 ng/ml, p<0.05 for both).
Conclusions: Both diabetes mellitus and coronary artery disease are associated with endothelial dysfunction. sVCAM-1 serum levels are elevated in patients with diabetes mellitus with or without coronary artery disease. These findings indicate that the inflammatory process with the contribution of endothelial dysfunction, might be a connective link between diabetes of type II and coronary atherosclerosis.

P998 Comparison of dobutamine stress echocardiography and dobutamine stress scinitigraphy to asses the prognosis of patients with diabetes mellitus

A.F.L. Schinkel, D. Poldermans, F.B. Sozzi, A. Elhendy, R.T. van Domburg, J.J. Bax, E.C. Vourvouri, J.R.T.C. Roelandt. *Erasmus Medical Center Rotterdam, Cardiology Dept., Rotterdam, Netherlands*

Purpose: This study compares the incremental prognostic value of dobutamine stress echocardiography and dobutamine stress myocardial perfusion imaging in patients with diabetes mellitus.
Background: Dobutamine stress testing is a safe and feasible technique for the assessment of prognosis, especially in patients unable to perform an exercise test. However, the relative prognostic value of DSE and DSMPI in patients with diabetes mellitus has not been evaluated.
Methods: A total of 603 diabetic patients unable to perform an exercise test underwent DSE (396 patients) or DSMPI (207). Follow-up was successful in 597 of 603 (99%) patients. End-points during follow-up were hard cardiac events (cardiac death and nonfatal myocardial infarction) and all causes of mortality. An abnormal DSE was defined as the presence of wall motion abnormalities at rest or an ischemic response. An abnormal DSMPI was defined as the presence of fixed and/or reversible perfusion abnormalities.
Results: DSE was considered abnormal in 324 patients (82%). An abnormal DSMPI was present in 125 (64%) patients. A multivariable Cox proportional-hazard model demonstrated that both the presence of an abnormal DSE and an abnormal DSMPI provided incremental prognostic information to clinical data. Figure 1 compares hard cardiac event rates. Normal DSMPI vs abnormal DSMPI: $p<0.0005$. Normal vs abnormal DSE: $p<0.05$. Normal DSMPI vs normal DSE p=0.6. Abnormal DSMPI vs abnormal DSE p=0.4.



DSE versus DSMPI.

Conclusions: DSE and DSMPI are safe and useful methods for the prognostic stratification in patients with diabetes mellitus unable to perform an exercise test. Patients with normal DSE or DSMPI have a good prognosis, whereas patients with an abnormal test are at a high risk of cardiac events.

P999 Tumor necrosis factor-alpha impairs insulin-stimulated endothelium-dependent vasodilatation and glucose uptake in humans

H. Domínguez[1], C.R.M. Christian Rask-Madsen[2], N.I. Nikolaj Ihlemann[1], T.H. Thomas Hermann[1], L.K. Lars Køber[3], C.T.P. Christian Torp-Pedersen[1]. *[1]KAS Gentofte, Cardiology P, Hellerup, Denmark; [2]Harvard University, Joslin Diabetes Center, Boston, United States of America; [3]Rigshospitalet, Cardiology Laboratory B, Copenhagen, Denmark*

Aim: Tumor necrosis factor-alpha (TNF) is elevated in patients with type 2 diabetes and inhibits insulin-stimulated glucose uptake in animal models and in vitro. It may thus be a mediator of insulin resistance. The aim of this study was to examine whether TNF acutely inhibits insulin-stimulated endothelium-dependent vasodilatation and glucose uptake in humans. **Methods:** Lean healthy men were studied in the fasting state. Drugs were infused into the brachial artery measuring blood flow by venous occlusion plethysmography, expressed below in units of ml/[100 ml tissue]/min. Acetylcholine was used as endothelium-dependent agonist and nitroprusside as endothelium-independent agonist. Each study was based on three infusion series given the same day: infusing first the agonist alone, then co-infusing insulin and the agonist and finally co-infusing TNF, insulin and the agonist. TNF and insulin were infused at a constant rate of 17 ng/min and 0.05 mU/Kg/min. For control, TNF and insulin were replaced by their vehicle in separate groups of volunteers. Glucose uptake was measured as the product between the arterial-venous difference of plasma glucose and forearm blood flow and expressed in mM/Kg/min.
Results: During insulin infusion plasma insulin rose from 3.7±0.3 to 98.8±8.3 mU/L in venous effluent blood from the perfused arm and to 5.6±0.4 mU/L in samples from systemic blood. During TNF infusion, local and systemic plasma TNF rose from 1.4±0.5 to 134±36 and 6.5±1.4 ng/L respectively. The flow under maximal acetylcholine stimulation was 12.7±2.3. Insulin enhanced this flow by 22% (p=0.0007). When TNF was co-infused with insulin forearm flow decreased by 32% to 8.6±2.3 (p=0.002). Neither insulin nor TNF had an effect on the nitroprusside response (p=0.7). Insulin infusion increased glucose uptake by 1.0±0.1 (p=0.02) but in the presence of TNF, insulin had no effect on glucose uptake, which changed by -0.2±0.3 (p=0.5)
Conclusion: TNF blunts both insulin-stimulated endothelium-dependent vasodilatation and insulin-stimulated glucose uptake in the human forearm. This findings support the hypothesis of the involvement of TNF in diabetes-related atherosclerosis.

P1000 Effects of vitamin C on endothelial function in diabetic patients with coronary artery disease: a double blind placebo controlled study

D. Tousoulis[1], C. Antoniades[1], G. Goumas[1], C. Tountas[2], C. Tentolouris[1], C. Pitsavos[1], C. Stefanadis[1], P. Toutouzas[1]. *[1]Hippokration Hospital, Cardiology Unit, Athens University, Athens, Greece; [2]Hippokration Hospital, Diabetology Department, Athens, Greece*

Background: Oxidative stress plays a key role in the pathogenesis of endothelial dysfunction in coronary artery disease (CAD) and diabetes mellitus (DM). In this study we investigated whether treatment with the antioxidant vitamin C improves endothelial function in patients with CAD and DM of type I or II.
Methods: In a double-blind placebo-controlled study, 49 patients (42 males, 7 females, aged 64±1.2 years) with CAD and DM, were enrolled. 23 of them were of type I DM and 26 of type II. 19 diabetic patients (8 with type I DM (group A) and 11 with type II DM (group B)) were treated with vitamin C 2g/day for 4 weeks. The remaining (15 with type I DM (group C) and 15 with type II DM (group D)) received placebo for 4 weeks. Forearm blood flow was measured using venous occlusion strain-gauge plethysmography, at baseline and after treatment. Endothelium dependent flow mediated vasodilation (FMD) was expressed as the % change from baseline to post reactive hyperemia blood flow. Endothelium independent flow (NTG%) was expressed as the % change from baseline to post sublingual nitroglycerin administration flow.
Results: Basal blood pressure, heart rate, body weight, basal forearm blood flow and NTG% remained unchanged in all groups. All values are expressed as mean±SEM. FMD was similar between patients with type 1 (51.7±5.1%) and type 2 (54.7±8.1%, p=NS) DM. After treatment, FMD was significantly increased in groups A (from 56.5±6.5 to 81.4±9.2% $p<0.05$) and B (from 66.5±11.7 to 84.3±15.1% $p<0.05$) while remained unchanged in groups C (from 53.1±4.2 to 50.1±8.2% p=NS) and D (from 55.8±11.6 to 58.3±10.1% p=NS).
Conclusions: Chronic administration of vitamin C seems to improve endothelial function in patients with combined coronary artery disease and diabetes mellitus of type I or II. This finding indicates a possible beneficial role of vitamin C in these patients.

P1001 Does ramipril have influence on antioxidant profile in type 2 diabetics?

D. Trifunovic-Zamaklar[1], M. Zamaklar[2], S. Markovic[3], P.M. Seferovic[1]. *[1]Institute for cardiovascular diseases, Cardiology II, Belgrade, Yugoslavia; [2]Institute for Endocrinology, Diabetology, Belgarde, Yugoslavia; [3]University clinical center, Department for biochemistry, Belgrade, Yugoslavia*

Oxidative stress and free radical injury are important in initiation and progression of accelerated atherogenesis in diabetics. We previously shown that antioxidant profile in diabetics are strongly influenced by the quality of metabolic control and plasma lipid levels. Recent studies suggested that ramipril can delay the progression of atherosclerosis, cardiovascular morbidity and mortality in high-risk population independently of its antihypertensive effect.
The study was aimed to estimate antioxidant effects of ACE-inhibition (ACEI) in obese, Type 2, normotensive diabetics with no angiographically and no clinically manifest coronary artery disease. Baseline characteristics of the study group were: n= 20, sex ratio female/male=11/9, mean age 47.5±3.5 years and duration of diabetes 3.5±1.2 years. All patients were on antidiabetic diet and gliclaside therapy and metabolic control was satisfied in all (HbA1c<7.5%). Antioxidant profile was estimated by: Erythrocyte Superoxide Dismutase (E-SOD; U/gHb), Erythrocyte Glutathione Peroxidase (E-GPx; U/gHb) activity and Plasma Total Antioxidant Status (P-TAS; mmol/l). All parameters were determined by spectrophothometric methods. Plasma triglyceride (TG; mmol/l), total cholesterol (Tot-Ch; mmol/l) and HDL cholesterol (HDL-Ch; mmol/l) were measured by enzymatic methods. LDL cholesterol (LDL-Ch; mmol/l) and LDL/HDL ratio were calculated. Blood samples were taken before and one month after ACEI (ramipril, 5 mg bid).
Results: after ramipril therapy the metabolic control remain unchanged (HbA1c: 7.2±0.5 vs. 7.0±0.3), as well as TG (1.8±0.6 vs. 1.7±0.5, p> 0.05), Tot-Ch (6.5±0.4 vs. 6.0±0.6 p> 0.05), LDL-Ch (4.2±0.4 vs. 3.9±0.5, p>0.05) and HDL-Ch (male: 1.32±0.05 vs. 1.29±0.05, p>0.05; female: 1.55±0.03 vs. 1.45±0.03, p>0.05). In comparison with the initial values E-SOD activity was markedly increased by 41% (635±55.5 vs. 895±43.5, $p<0.05$), E-GPX was increased by 2.25% (26.7±6.75 vs. 27.3±5.23, p>0.05) and increment of P-TAS was 13.93% (1.22±0.25 vs.1.39±0.20, p>0.05).
Conclusion: In type 2 diabetics one month of ramipril therapy improved antioxidant status independently of the quality of metabolic control and plasma lipid levels. It can be consider that this effect might be associated with angiotensin II suppression and its influence on oxygen free radicals production.

P1002 Atorvastatin and micronized fenofibrate, alone and in combination, in type-2 diabetes mellitus with combined hyperlipidemia

V. Athyros, A.A. Papageorgiou, V.V. Athyrou, D.S. Demitriadis, A.G. Kontopoulos. *Hippocration, Internal Medicine, Thessaloniki, Greece*

Objective: The study evaluated the effect of the atorvastatin-fenofibrate combination on lipid profile, in comparison to each drug alone, in patients with type-2 diabetes mellitus (DM) and combined hyperlipidemia (CHL).
Research design and methods: One hundred and twenty consecutive patients, free of coronary artery disease (CAD) at entry, were studied for a period of 24 weeks. These were randomly assigned to atorvastatin (20 mg/day,n=40), micronized fenofibrate (200 mg/day,n=40) or combination of both (atorvastatin 20 mg/day plus fenofibrate 200 mg/day,n=40). The effect of treatment on low density lipoprotein cholesterol (LDL-C), triglycerides (TG), high density lipoprotein cholesterol (HDL-C), apolipoproteins A-I and B, lipoprotein (a), and plasma fibrinogen (PF) was recorded. Moreover, the percentage of patients that reached the American Diabetes Association (ADA) treatment goals and the estimated CAD risk status were calculated.
Results: No patient was withdrawn from the study because of side-effects. The atorvastatin-fenofibrate combination reduced total cholesterol by 37%, LDL-C by 46%, TG by 50% and PF by 20%, while it increased HDL-C by 22% ($p<0.0001$ for all). These changes were significantly better than those of both monotherapies. From patients on drug combination 97.5% reached the LDL-C treatment goal of <100 mg/dl, 100% the desirable TG levels of <200 mg/dl, and 60% the optimal HDL-C levels of >45 mg/dl. These rates were significantly higher than those of both monotherapies. Combined treatment reduced the 10-year probability for myocardial infarction from 21.6% to 4.2%.
Conclusions: The atorvastatin-fenofibrate combination has a highly beneficial effect on all lipid parameters and plasma fibrinogen in patients with type-2 DM and CHL. It improved patients' CAD risk status significantly more than each drug alone.

P1003 Perfusion abnormalities detected by SPECT imaging are closely related to carotid intima-media-thickness in asymptomatic diabetic patients

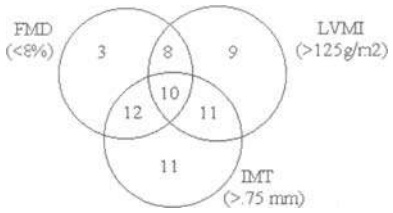
A. cerisier[1], B. Bouchet[2], V. Brulport-Cerisier[3], K. Bouchou[2], B. Estour[3], P. Cathebras[2], A. Da Costa[1], K. Isaaz[1]. [1]*Hopital nord, Service de Cardiologie, Saint Etienne, France;* [2]*Hopital Nord, Medecine interne, Saint Etienne, France;* [3]*Hopital Bellevue, Endocrinologie, Saint Etienne, France*

Background: Myocardial perfusion defect documented by stress SPECT imaging has been reported to be a long term prognosis marker in totally asymptomatic type 2 diabetic patients (TAD). The carotid intima-media thickness (CIMT) has been proposed recently as a new marker predictive of major cardiovascular events in high risk patients but no data exist in TAD patients. We evaluated the relation between CIMT and SPECT in a TAD population. Methods. From 01/00 to 12/00, CIMT was automatically measured by high resolution ultrasonography using a specific software in 52 TAD patients pts (mean age 60 years, range 49-75) without history of heart disease who underwent a rest Thallium 210/stress Tc-99m sestamibi SPECT imaging screening because of a diabetes duration > 10 years plus at least one additional risk factor. Results: 20 pts had had SPECT+, 32 SPECT-. They did not differ for age (62±8 vs 60±8, p=0.45) and duration of diabetes (14±6 versus (vs) 13±6; p=0.63); number of risk factor (2.6±8 vs 1.9±8; p=0.0046), male proportion (65% vs 34%; p=0.046) and CIMT (0.64±0.1 vs 0.55±0.09; p=0.0052)were higher in SPECT+ than SPECT-. Multivariate analysis using multiple logistic regression model showed that CIMT was the variable that best correlated with positive SPECT imaging: odd ratio 2.8, CI: [1.32;5.92], p=0.0074.
Conclusions: CIMT appears to be strongly correlated with positive SPECT imaging in high-risk diabetic asymptomatic patients and might represent an alternative screening test in this population.

P1004 The elusive link between insulin-resistance and ultrasonic indices of early cardiovascular damage in essential hypertensives

A. Zuccarelli[1], P. Rossi[2], A. Varga[1], E. Pacetti[1], N. Gruber[1], L. Venneri[1], E. Picano[1]. [1]*Institute of Clinical Physiology, PISA, Italy;* [2]*Fivizzano Hospital, Cardiology Division, Fivizzano, Italy*

Background: Insulin resistance has been proposed as the metabolic basis of atherogenesis. The association between hypertension, insulin resistance and early signs of cardiovascular damage is incompletely understood.
Aim: to determine the relationship between insulin-resistance and ultrasonically assessed early target organ damage in essential hypertensives.
Methods: 71 asymptomatic non diabetic essential hypertensives (36 females, age= 57 ± 11 years, weight: 81±15 kg) with negative maximal cardiac stress testing underwent, on different days and in random order: 1) Insulin-resistance calculation using the Homeostasis Model Assessment (HOMA); 2) an ultrasound study of carotid (intima-media thickness,IMT), cardiac (left ventricular mass index, LVMI), and brachial (% flow mediated dilation, FMD) district.
Results: IMT was 0.9.±0.30 mm; % FMD was 8.5±6.7; LVMI was 131±36 g/m^2. The mean HOMA was 2.29±1.19. HOMA was not significantly related to LVMI (r= -0.025, p= 0.8), FMD (r=-0.145,p=0.2) and IMT (r= - 0.09,p=0.4). %FMD was weakly correlated to LVMI (r=- 0.24,p=0.04) and carotid IMT (r=-.33,p=0.004),whereas no correlation existed between IMT and LVMI (r= 0.14, p=0.23). At individual patient analysis, an abnormality of at least 1 in % FMD (<8%), LVMI (>125 g/cm^2) and IMT (>.75 mm) was present in 64 patients (90%): Figure.



Patients with echographic abnormalities.

Conclusion: In clinically uncomplicated essential hypertensives, metabolic insulin resistance is not associated with left ventricular hypertrophy, brachial artery endothelial dysfunction and/or increased carotid intima-media thickness. Integrated noninvasive ultrasound evaluation provides an accurate identification of incipient atherosclerotic damage - otherwise missed by conventional clinical and metabolic assessment.

P1005 High dosage of atorvastatin strongly reduces CRP within four weeks in diabetes mellitus; less marked effect on other inflammatory markers

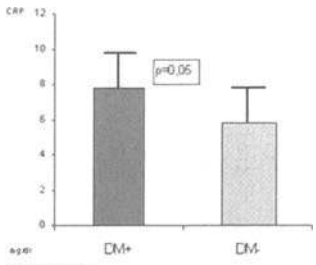
C. kluft[1], M.A. van de Ree[2], C.G. Schalkwijk[3], H.M.G. Princen[1], A.E. Meinders[2], M.V. Huisman[2] on behalf of the DALI Study Group. [1]*Gaubius laboratory, TNO-PG, Vascular and connective tissue researc, Leiden, Netherlands;* [2]*Leiden University Medical Center, Dept of General Internal Medicine, Leiden, Netherlands;* [3]*Free University Hospital, Department of Nephrology, Amsterdam, Netherlands*

Inflammation is thought to play a role in the development and progression of atherosclerosis.
Three strong acute phase proteins, high-sensitive CRP (hs-CRP), serum amyloid A (SAA), secretory phospholipase A2 (sPLA2) as well as the cytokines interleukin-6 (Il-6) and TNF-a have emerged as prognostic inflammation markers for cardiovascular disease. Statin therapy has repeatedly been shown to reduce hs-CRP levels; the effects on the other markers are less well documented.
In a placebo-controlled trial the effect of 10mg and 80mg atorvastatin on the inflammation markers hs CRP, SAA, sPLA2 and IL-6 was measured after 30 weeks of treatment in 196 patients with type 2 diabetes and without manifest cardiovascular disease. In addition the effect on hs-CRP was followed after 4, 10 and 20 weeks. Ten patients with a baseline or follow-up hs-CRP level over 15 mg/L were excluded. The levels of the markers before treatment were found to be high and to correlate mutually. The correlations with CRP showed r= 0.411-0.600; Spearman p< 0.001.
hs-CRP, SAA, sPLA2, Il-6 levels were reduced by 15% (p=0.012), 8% (n.s.), 3% (p=0.040), and 3% (n.s.) (medians, Mann-Whitney) respectively in patients randomized to 10mg atorvastatin, and by 47% (p<0.001), 18% (p=0.001), 10% (p= 0.004), and 10% (p=0.086) respectively in patients randomized to 80mg atorvastatin. Pretreatment levels of hs-CRP, SAA, sPLA2 and Il-6 were not related to the changes. The effects on hs-CRP were achieved in 4 weeks for low-dose and for > 75% for high-dose atorvastatin relative to the follow-up at 20 and 30 weeks. The effects on hs-CRP of 80mg atorvastatin were present with all continued antidiabetic co-medication.
It is concluded that the anti-inflammatory effect of 80mg atorvastatin is achieved rapidly and is predominantly targeted at CRP, suggesting a specific anti-inflammatory effect.

P1006 Do all classical cardiovascular risk factors have the same impact in C-reactive protein plasma concentration in acute coronary syndromes?

L. Bronze[1], A. Cândido[1], J. Monge[1], J. Galvão[1], A. Anão[1], C. Ferreira[1], J. Azevedo[2], A. Aleixo[1]. *[1]Hospital de São Francisco Xavier, UNICARD, Lisbon, Portugal; [2]Hospital São Francisco Xavier, Echocardiographic Laboratory, Lisbon, Portugal*

Elevated plasma concentration of C-reactive protein (CRP) is associated with increased global cardiovascular risk. We evaluated the influence of classical coronary heart disease risk factors (RF): hypertension (HT), smoking (SK), diabetes mellitus (DM), hypercholesterolemia (HC) and obesity (OB) in the level of CRP measured in acute myocardial infarction or unstable angina patients (pt). High-sensitivity CRP levels (Dade Behring test) were obtained upon entrance in 151 pts, 48 female, aged 65±12 years old, admitted within a 3-month period in the CCU. According to the presence of a single specific RF the whole of pts were divided in 2 groups: HT+ versus HT-, SK+ versus SK-, DM+ versus DM-, HC+ versus HC- and OB+ versus OB- and their CRP values compared (t-student and proportions comparison). The RF combination was also tested (RF<1 versus RF>2 up to RF<4 versus RF>5), in order to establish if the association of RF would impact on CRP and at wich level would it occur. HT+ was found in 64% of pts, SK+ in 25%, DM+ in 21%, HC+ in 34% and OB+ in 27%. CRP elevation was present in 83% of pts. A significant difference (p=0.05) was found only for pts with DM+ and DM-. In these subgroups, a significant difference was also found for the angiographic disease extension: multivessel disease in 89% of DM+ versus 46% in DM- (p=0.04) pts. We did not find a significant cut-off point for the association of RF. The presence of diabetes mellitus is associated with higher CRP serum levels in acute coronary syndromes.



CRP and DM.

This finding reflects the greater involvment of the coronary atherosclerotic process commonly associated with this metabolic condition. There was no association between this particular inflammatory marker, CRP, and any other RF or to their combination.

P1007 Silent myocardial ischaemia in diabetes mellitus: usefulness of adenosine ^{99m}Tc tetrofosmin myocardial SPECT

M. Feola[1], G. Magro[2], A. Biggi[3], A. Francini[1], G. Leonardi[1], M. Procopio[2], G. Borretta[2], E. Uslenghi[1]. *[1]Santa Croce Hospital, Cardiology Dept., Cuneo, Italy; [2]Ospedale Santa Croce, Endocrinology, Cuneo, Italy; [3]Ospedale S. Croce, Nuclear Medicine Dept., Cuneo, Italy*

Myocardial ischemia may not manifest symptoms in diabetic patients. The objective of this study was to evaluate if adenosine TC 99m tetrofosmin myocardial single photon emission tomography (SPECT) might detect silent myocardial ischemia in asymptomatic type 2 diabetic patients at high risk for coronary artery disease (CAD).

Methods: Fifty-seven patients (40 males, age 62,2 ys) with history of type 2 diabetes mellitus lasting more than 5 ys, unable to perform a standard stress test and presenting at least one of the following conditions (diabetic nephropathy or neuropathy, peripheral or carotid artery disease, elevated microalbuminuria) were enrolled in the study. All patients underwent adenosine-rest TC99 SPECT in a double-day protocol. Dividing the left ventricle in 20 segments, summed rest score (SRS), summed stress score (SSS) and summed difference score (SDS) were obtained with a 5-point scale (from 0=normal uptake to 4=absent uptake) by two operators. A gate-SPECT analysis was always provided. Silent myocardial ischemia was diagnosed when SDS>1; diabetic patients with extensive inducible ischemia (SDS>=3) underwent coronary angiography.

Results: In thirty-two (56.1%) subjects myocardial SPECT was normal; 25 (43.9%) showed silent ischemia, 16 (28.1%) of which had a SDS>=3. Coronary angiography was performed in all subjects with SDS>=3. A normal angiogram was found in 5 (31.2%), single-vessel disease in 2 (12.5%), two-vessel disease in 6 (37.5%) and three-vessel in 3 (18.8%). Three patients were treated with surgical revascularization and 3 with coronary angioplasty. At univariate analysis pts with more extensive silent ischemia had longer duration of diabetes (16.2±8.1 ys vs 11.8±5.8 ys, p=0.03), lower left ventricular ejection fraction (LVEF) at Gated acquisition after the adenosine infusion (44±11% vs 52.3±11.4%, p=0.03) and blunted reduction of diastolic blood pressure during the adenosine test (84.6±21.7 mmHg vs 75.3±7.2 mmHg; p=0.02). No differences were found in the metabolic control (glycosylated haemoglobin p=0.3, C peptide p=0.1) and lipid profile (triglycerides p=0.7; LDL cholesterol p=0.8).

Conclusion: adenosine TC99 tetrofosmin SPECT revealed myocardial ischemia in 43.9% totally asymptomatic diabetic pts. In pts with more extensive inducible ischemia angiography demonstrated CAD in 68.7%. The metabolic and lipid parameters were not different according to the degree of inducible ischemia.

P1008 How does the primary PTCA affects the long-term prognosis of diabetic patients?

S. Simek, M. Aschermann, J. Vojacek, F. Holm, J. Humhal, A. Linhart, L. Golan. *General Faculty Hospital,Charles Univ., IInd Med. Dep., Praha 2, Czech Republic*

Objectives: to investigate feasibility and safety of primary PTCA in diabetic patients.

Background: diabetic patients with acute myocardial infarction (AMI) have been shown to be at high risk for adverse clinical outcomes. Limited data is available on long term prognosis of diabetics treated with primary PTCA.

Methods: retrospective analysis and follow up of consecutive 67 diabetic patients and 211 non diabetic patients treated with primary PTCA from 1/95 to 12/99.

Results: The baseline characteristics were comparable in both groups. The mean age was 62 years in diabetic patients and 59 years in non diabetic patients. Hypertension (49% vs. 36% p=0,05), contraindications to trombolytic treatment (13,4% vs. 5,7%, p=0,037), cardiogenic shock (16,4% vs. 7,1%, p=0,023), multivessel disease (34%vs 23%, p=0,07) and longer time delay to treatment (240 vs. 180 min, p=0,05) were more often present in diabetic group. 47% of diabetic and 42% of nondiabetic patients received stents. The TIMI 2 and 3 flow rates were reached in 91% of diabetic patients and in 89,1% of nondiabetic patients, but TIMI 2 flow was found more often in diabetics (11,9% vs. 3,3%, p=0,06). Diabetics had lower need for cardiopulmonal resuscitation during PTCA (0% vs. 5,2%, p=0,05) and higher rate of bleeding complications leading to significant change in the blood count (7,5% vs 1,4%, p= 0,01). Acute and subacute closure of infarct related artery and nonfatal reinfarction occurred in 3% vs. 3,3%, 3 vs. 0,9% and 1,9% vs. 3% in diabetics and nondiabetics respectively. Left ventricle ejection fraction 3-5 days after AMI was 47% in both groups. Higher 30 day mortality (11,9% vs. 5,2%, p= 0,05) was observed in diabetic group. However when the shock patients were excluded from the analysis, the 30 day mortality was comparable in both groups (4,5% vs. 2,4%, p=0,369). During 38+12 month follow up of 259 acute phase survivors 24 patients died, mortality in diabetics and nondiabetics was 11,9% vs. 8,5%(p=0,43), nonfatal reinfarction rate was 11,9% vs. 4,5% (p=0,039) respectively.

Conclusion: Primary PTCA seems to be safe and effective treatment of diabetic patients presenting with AMI. The prognosis of this high risk population however remains serious. Higher rate of bleeding complications at puncture site after PTCA can be explained by the lower quality of vessel wall in diabetic patients.

P1009 C-reactive protein may have a different prognostic value in diabetics and in non-diabetics patients with unstable angina

L.M. Biasucci, G. Liuzzo, D.J. Angiolillo, V. Rizzello, A. Porto, G.G.L. Biondi-Zoccai, A. Abbate, F. Crea. *Catholic University, Cardiology Dept., Rome, Italy*

Background: Diabetes is a pro-atherosclerotic and potentially pro-inflammatory condition associated with increased cardiovascular risk, yet no study has so far assessed whether the prognostic role of C-Reactive Protein (CRP) is different in diabetic and non-diabetic patients.

Methods: We assessed the prognostic role of CRP for in hospital death and myocardial infarction in 253 consecutive pts admitted to our CCU with a diagnosis of unstable angina. In all pts CRP was measured on admission by a nephelometric method (Dade-Behring). The data were evaluated by CRP quintiles.

Results: 200 pts were diabetics, 53 non-diabetics, in the overall population we observed 21 events (death+infarction), that were significantly more frequent in the top quintile (>19.8 mg/L) of CRP (P for trend =0.0019). More events were observed in diabetics (13% vs 7.5%), although the difference was not significant, CRP levels on admission were similar between diabetics and non-diabetics (respectively 4.5 mg/L range 0.35-144 and 5.21, range 0.2-188 mg/L, P=ns). However the prognostic role of CRP was significantly different between diabetics and non diabetics. In non diabetics 71% of events were concentrated in top quintile (10/14, P for trend <0.0001) but no differences in event rate was observed among CRP quintiles in diabetics.

Conclusions: our data support the role of CRP as an important unfavourable short-term prognostic factor in pts with unstable angina. However, in our study the prognostic role of CRP seems to be confined to non-diabetic pts. Other mechanisms of instability, such as extent and severity of coronary atherosclerosis and a pro-thrombotic state, might obscure the prognostic role of CRP in diabetic patients with unstable angina.

P1010 Inhibition of the renin-angiotensin system regulates the anti-inflammatory response of statins and aspirin in coronary artery disease

B. Khan, W.B. Lauten, Q.A. Khan, S.T. Rahman, S. Parthasarathy. *Emory University, Division of Cardiology, Atlanta, United States of America*

Background: The therapeutic use of renin-angiotensin system (RAS) inhibitors results in a significant reduction of cardiovascular events in patients with coronary artery disease. Recent outcome studies demonstrate that these agents may have vascular benefits independent of blood pressure reduction. The addition of these agents to aspirin and statin therapy may provide additive or synergistic effects in reducing vascular pro-inflammatory and oxidative mechanisms.
Methods: We followed 124 normotensive patients with documented coronary atherosclerosis (pre-statin). These subjects were initiated on aspirin and atorvastatin to a low density lipoprotein (LDL) cholesterol of less than 100 mg/dl (post-statin) and then randomized to either the angiotensin converting enzyme inhibitor quinapril (QUI, 20 mg/day, n=69) or the angiotensin type 1 receptor antagonist irbesartan (IRB, 150 mg/day, n=55) for 8 weeks.
Results: In addition to the reduction of LDL cholesterol, atorvastatin reduced sP-selectin by 40 percent (0.57±0.08 to 0.38±0.06 ng/dl, $p<0.05$ from pre-statin), IL-6 by 18 percent (480±51 to 399±48 ng/dl, $p<0.05$ from pre-statin), and monocyte binding by 13 percent (90±11 to 76±18 percent of monocytes binding to the CD11b antibody, NS). The addition of either QUI or IRB further reduced sIL-6 (QUI, 330±51; IRB, 301±48 ng/dl, $p<0.05$ from pre- and post-statin). Furthermore, there was a profound decrease in monocyte binding in patients placed on either RAS inhibitor (QUI, 33±10; IRB, 27±6 percent of monocytes binding to the CD11b antibody, $p<0.05$ from pre- and post-statin). Both QUI and IRB were well-tolerated by the treatment groups and did not cause any significant hypotension in the normotensive population with coronary artery disease.
Conclusions: Our findings indicate that the addition of RAS inhibitors to aspirin and statin therapy differentially regulate markers of inflammation and oxidation in the vasculature and may demonstrate potential mechanisms by which these agents are effective in the secondary prevention of coronary atherosclerosis.

CARDIOVASCULAR CONTROL MECHANISMS IN HEALTH AND DISEASE

P1011 Effects of intensive resistance training on isotonic exercise Doppler indexes of left ventricular systolic function

E. Fisman[1], A. Pelliccia[2], A. Tenenbaum[1], I. Auerbach[1], A.G. Frank[1], M. Motro[1]. [1]*Chaim Sheba Medical Center, Cardiac Rehabilitation Institute, Ramat-Gan, Israel;* [2]*Italian National Olympic Committee, Institute of Sports Science, Rome, Italy*

Background: Endurance (isotonic) and resistance (isometric) training programs are known to induce different cardiovascular adaptations. It is still unclear whether resistance athletes may have an improved cardiocirculatory response to endurance exercise. The aim of this study was to evaluate Doppler-derived indexes of left ventricular (LV) systolic function during isotonic exercise in a highly trained population of resistance athletes, in comparison to age- and gender-matched endurance athletes and sedentary individuals.
Methods: Doppler echocardiography at rest and at supine symptom-limited isotonic exercise was performed in 120 male subjects: 40 weightlifters (mean age 29±4), 46 long-distance runners (mean age 29±6; p=NS) and 34 healthy sedentary men (mean age 30±5; p=NS).
Results: At peak exercise stroke volume increased by 65% above rest values in runners, by 77% in weightlifters ($p<0.05$) and by 37% in sedentary ($p<0.0001$ vs. athletes), associated with a parallel increase in end-diastolic volumes. The volumetric changes led to an increase in LV ejection fraction, from 64±7 to 92±7 in runners, 69±8 to 92±6 in weightlifters, and 67±7 to 86±6 in sedentary ($p<0.05$ vs. athletes). Peak flow velocity was 119±15 in runners, 114±12 in weightlifters, and 102±9 cm/s in sedentary ($p<0.05$ vs. athletes), increasing to 213±19, 203±16 and 160±14, respectively, at exercise ($p<0.0001$ vs. athletes). No significant rest or exercise differences were documented between both athletes groups. Mean acceleration values were higher for the runners and the weightlifters: 14.2±1.3 and 13.7±1.2 m/s/s, respectively, vs. 12.2±1.1 in sedentary ($p<0.01$). During exercise, a sharp increase to 39.3±5 and 37.3±4, respectively, was seen in the athletes (p=NS), and a less pronounced one to 25.4±2.5 in the sedentary ($p<0.0001$).
Conclusions: Two major findings can be drawn from the present study. First, resistance-trained athletes show an improved cardiovascular response to isotonic exercise, as reflected by Doppler-derived indexes of aortic flow (peak flow velocity and mean acceleration) compared to sedentary men, notwithstanding the fact that these athletes lacked of previous conditioning with this specific type of exercise. Second, the LV response to isotonic exercise in resistance athletes does not appear to be different than in endurance athletes.

P1012 Abnormalities in myocardial contractility, metabolism and perfusion reserve in non-stenotic coronary segments in heart failure patients

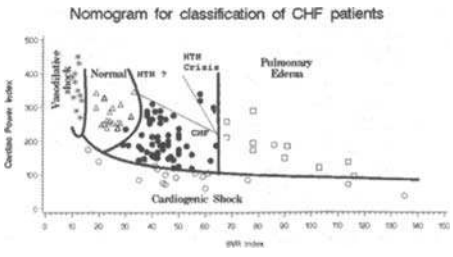
A.F.M. van den heuvel[1], J.J. Bax[2], P.K. Blanksma[1], W. Vaalburg[1], D.J. van Veldhuisen[1]. [1]*University hospital Groningen, cardiology, Groningen, Netherlands;* [2]*LUMC, Cardiology, Leiden, Netherlands*

Objective: Myocardial blood flow (MBF) reserve is impaired in congestive heart failure (CHF), while fluorine-18-deoxyglucose (18FDG) uptake is relatively preserved. To determine whether this mismatch could be interpreted as ischemia, we performed dobutamine stress echocardiography (DSE).
Methods: 12 males with coronary artery disease (CAD) and CHF were compared with 12 controls with similar CAD but normal left ventricular (LV) function. MBF in non infarct-related artery areas was assessed using N13-ammonia positron emission tomography (PET), at rest and after dipyridamole infusion and 18FDG-uptake was determined. DSE was performed with doses up to 40 μg/kg/min.
Results: In areas with non-stenotic arteries MBF-reserve was more impaired in CHF patients (1.6±0.6 vs. 2.2±0.5; CHF vs. normal LV resp. $p<0.05$). MBF-reserve was related to LV ejection fraction ($r=0.6$, $p<0.05$) and wall stress ($r=-0.72$, $p<0.05$). PET showed mismatch in 4±1% of the myocardium in normal LV, compared to 26±26% in CHF ($p<0.05$), coinciding with more ischemic wall motion abnormalities on DSE (21% vs 4%; CHF vs. normal LV resp, $p<0.05$).
Conclusions: In CHF, mismatch was found in areas supplied by non-stenotic coronary arteries. Correponding areas showed ischemic wall motions on DSE. These findings suggest that the condition of CHF may play a role in perpetuating myocardial failure by inducing myocardial ischemia. Follow-up studies to investigate the ischemia-CHF relationship in time would be needed.

P1013 The role of cardiac power and systemic vascular resistance in the pathophysiology and diagnosis of patients with acute congestive heart failure

G. Cotter[1], Y. Moshkovitz[1], E. Kaluski[1], O. Milovanov[1], Y. Nobikov[2], A. Schneeweiss[1], R. Krakover[1], Z. Vered[1]. [1]*Assaf-Harofeh Medical center, Cardiology, Zerifin, Israel;* [2]*Sheba Medical Center, Bio-Statistics, Tel-Hashomer, Israel*

Conventional hemodynamic indexes (cardiac index (CI), and pulmonary capillary wedge pressure) have previously demonstrated only limited value in the diagnosis and treatment of patients with acute congestive heart failure (CHF).
Methods: We have measured CI, wedge pressure, right atrial pressure (RAP) and mean arterial blood pressure (MAP) in 89 consecutive patients admitted due to acute CHF (exacerbated systolic CHF (n=56), hypertensive crisis (n=5), pulmonary edema (n=11) and cardiogenic shock (n=17)) and in two control groups: Eleven patients with septic shock and 20 healthy volunteers. Systemic vascular resistance index (SVRi) = (MAP-RAP)/CI. Cardiac contractility was estimated by the cardiac power index (Cpi), calculated as CI x MAP.
Result: We have found that CI < 2.7 Lit/min/M2 and wedge pressure > 12 mmHg are universally measured in patients with acute CHF. However these measures are often overlapping among patients with the above-mentioned different syndromes of acute CHF, while Cpi and SVRi are significantly different. Cpi was low in patients with exacerbated CHF and extremely low in patients with cardiogenic shock while SVRi was increased in patients with exacerbated systolic CHF and extremely high in patients with pulmonary edema. By using a two-dimensional presentation of Cpi versus SVRi we have found that these clinical syndromes can be accurately differentiated, as the paired measurements of each clinical group segregated into a specific region on the Cpi/SVRi normogram, that could be mathematically defined by a statistically significant line (Figure, Lambda=0.95).



Conclusion: Measurement of SVRi and Cpi and their two-dimensional graphic presentation enables accurate diagnosis and follow up of individual patients with acute CHF.

P1014 Intrapatient observations of autonomic nervous system activity during spontaneus and angioplasty coronary ischaemia

O. Manfrini, C. Pizzi, G. Morgagni, R. Bugiardini, N. Propato. *University of Bologna, Med. Intern., Cardioangiol., Epatol., Bologna, Italy*

Although autonomic sympatho-vagal balance has been reported to be abnormal in pts with anginal syndromes, it is still not known whether this abnormality may concur to the development of coronary occlusion in the natural history of the disease. Alternatively it could simply be an expression of the interaction between pain perception, coronary occlusion and neural reflexes.

Methods: To address this topic we studied 40 pts admitted to CCU for unstable angina, candidates to revascularization by PTCA in single vessel disease. All pts had > 75% stenosis of the left anterior descending coronary artery. ECG Holter monitoring was performed in all pts starting 2 to 6 hours before cardiac catheterization. Frequency domain measures of heart rate variability were assessed by power spectral analysis during spontaneous or balloon induced ischemia, and 1 to 5 min. before and after the ischemic episodes. Low (LF: 0.04-0.15 Hz) and high frequencies (HF:0.15-0.40 Hz) were assumed to be the expression of sympathetic and parasympathetic activity, respectively. LF/HF ratio was used to estimate the overall autonomic nervous system balance.

Results: Eight of the 40 pts experienced spontaneous ischemia during cardiac catheterization just before angioplasty. Angiography during spontaneous episodes showed transient total or subtotal coronary occlusion. Hundred episodes were analysed: 78 secondary to balloon obstruction and 22 spontaneously occurring. LF/HF ratio was dramatically reduced during balloon induced ischemia as compared to values recorded 5 min. before (0.5 ± 0.7 vs 3.7 ± 2.1, p< 0.01). The opposite occurred during spontaneous ischemia (12 ± 6.5 vs 4.3 ± 2.6, p<0.01). Spontaneous ischemic episodes were longer than those provoked by balloon angioplasty (180 ± 90 vs 120 ± 60 sec).

Conclusions: 1) A shift in the autonomic nervous system balance towards sympathetic activation may be a factor concurring to cause spontaneous coronary occlusion in unstable angina. 2) The hypothesis that neural reflexes originating by coronary occlusion itself, or by chest pain could trigger increased sympathetic activity during unstable angina, appears to be unlikely.

P1015 Adenosine and endogenous opioid sensitivity in patients with silent myocardial ischaemia and angina pectoris

B. Sadigh-Lindell, C. Sylvén, B. Eriksson. *Huddinge University Hospital, Department of Cardiology, Stockholm, Sweden*

Introduction: Different studies have shown that patients with silent myocardial ischemia (SMI) have the same prognosis as patients with angina pectoris (AP), despite this fact, they make much fewer primary and emergency visits. The aim of the present investigation was to study the differences in tolerability of the ischemic pain messenger, adenosine (ADO), in patients with AP, SMI and to healthy volunteers and study the effect of non-selective opioid antagonism on adenosine provoked pain.

Method: 13 patients with SMI (mean age 58±10 with BMI 25± 3) who underwent examination with exercise stress test or myocardial scintigraphy, with ECG ischemic changes and no pain during the test were compared with 10 patients with AP (mean age 57±9 with BMI 29±5) and positive test. Significant stenosis in one or several coronary vessels were shown during coronary angiography. Both groups were compared to a group of healthy volunteers (mean age 49±2 with BMI 26±4) n=10. The subjects received increasing doses of adenosine injected rapidly into antebrachial vein to estimate maximum tolerable dose (MTD). Initial dose was 2.5 mg, which was increased in steps of 2,5 mg. 1 minute after each dose of adenosine central chest pain was quantified using 0-10 point scale of Borg. When the MTD of adenosine was titrated, the subjects were given 4 doses (placebo, 1/3, 2/3, 3/3 of MTD) of ADO in double-blind random order. This was repeated double-blind after injection of a non-selective opioid antagonist (naloxone 0.4 mg/ml 1ml).

Results: Patients with SMI showed a higher pain threshold compared to the AP group (pain duration p=0,001), (pain area p=0,004), (Borg p=0,023) at 1/3 and 2/3 of MTD and this difference was abolished by naloxone. The same pattern of altered pain perception was seen in the SMI group compared to healthy volunteers without any effect after naloxone injection (pain duration p=0,027). There was an increase in pain within healthy and the SMI group after naloxone injection compared to before (p<0,05).

Conclusions: A decreased pain sensitivity to adenosine was evident in patients SMI compared to patients with AP. The lower pain in the SMI group disappeared after injection of naloxone. Naloxone decreased pain threshold in healthy and SMI group (p<0,05). Our results clearly suggest a role of peripheral endogenous opioid receptors in perception of pain, particulary in low grade pain among patients with SMI.

Key words: Silent myocardial ischemia, Angina pectoris, Adenosine, Maximal tolerable dose

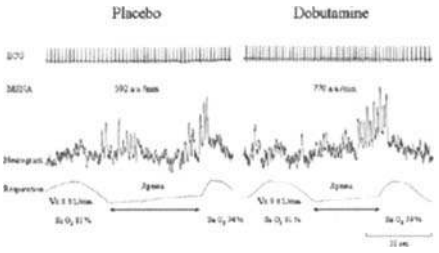
P1016 Optimal oxygenation is important in patients receiving dobutamine because this drug markedly enhances chemoreflex sensitivity to hypoxemia

S. Velez-Roa[1], A. Ciarka[2], M. Rhanama[1], B. Kojonazarov[1], M. Dagonnier[1], J.P. Degaute[1], P. van de Borne[1]. [1]*Erasme Hospital, Cardiology, Anderlecht, Belgium;* [2]*Warsaw Medical University, Physiology, Warsaw, Poland*

Background: There is evidence that beta-adrenergic mimetic agents may increase chemoreflex sensitivity to hypoxemia in humans. Whether this occurs also with the beta-1 adrenergic mimetic agent dobutamine, which is frequently administered to patients with heart failure, is not known.

Methods: We tested the hypothesis that dobutamine (5 μg/kg/min) increases chemoreflex sensitivity in 15 normal humans in a randomized, double-blinded, placebo-controlled study. We examined the effects of dobutamine on the respiratory, cardiovascular and sympathetic nerve activity (SNA, microneurographic technique) during normoxia, isocapnic hypoxia (10% O2 in 90% N2), maximal voluntary end-expiratory apnea and hyperoxia.

Results: Dobutamine markedly increased the ventilatory response (16.1±1.6 vs. 11.4±0.7 L/min at the 5th min of hypoxia, ANOVA p<0.0001) and the SNA response to isocapnic hypoxemia (403±94 vs. 222±5% at the 5th minute of hypoxia, ANOVA p<0.03). Peripheral chemoreflex deactivation by hyperoxia suppressed these effects (ventilation: 8.4±0.5 vs. 7.9±0.6 L/min, p=NS). Moreover, the apneas at the end of hypoxia which were performed with dobutamine were shorter than those under placebo (17±2 vs. 19±1 sec, p=0.01, Figure 1) and were accompanied by larger increases in SNA (501±107% vs. 291±38% with placebo, p<0.05) despite a lower reduction in oxygen saturation (81±2% with dobutamine vs. 77±1% with placebo, p<0.05).



Conclusions: Marked increases in the ventilatory and sympathetic response to hypoxemia reveal that dobutamine enhances peripheral chemoreflex sensitivity. Clinicians should be aware of this effect and attempt to maintain optimal oxygenation in patients with heart failure receiving dobutamine.

P1017 Vascular effects of L-NMMA are mediated via actions on eNOS not L-arginine transport

M.M. Parnell, D.M. Kaye. *Baker Medical Research Institute, Alfred Baker Medical Unit, Melbourne, Australia*

Background: Impaired endothelial function is well established in congestive heart failure (CHF), on the basis of decreased responses to both agonist-induced and shear stress stimuli. The downregulation of eNOS expression and activity has been proposed as a mechanism for this defect. We recently identified a decrease in L-arginine (L-arg) transport in the forearm, suggesting that substrate limitation may also contribute. To further investigate this abnormality, we determined the effect of L-NMMA on both blood flow and L-arg transport in control (C) and congestive heart failure (CHF) patients.

Methods and Results: Measures of L-arg transport ([3H]L-Arg clearance) and endothelial function (venous occlusion plethysmography) were performed in 19 male NYHA class II/III CHF pts (age 54 ± 3 years) and 17 healthy male volunteers (CON; age 53 ± 3 years). Forearm blood flow (FBF) responses to intra-arterial ACh infusions were attenuated in the CHF pts (37 μg/min, 6.26 ± 0.88 ml/min/100ml) when compared to the C group (37 μg/min, 11.6 ± 1.41 ml/min/100ml; p=0.01), while basal blood flow was similar between the two groups (p=ns). We next evaluated the effect of intra-arterial L-NMMA, an inhibitor of eNOS which also inhibits L-arg transport. L-NMMA reduced FBF in both C (4 μg/min, -1.43 ± 0.31 ml/min/100ml; p=0.003) and CHF pts (4 μg/min, -0.42 ± 0.13 ml/min/100ml; p=0.003), and the change in blood flow was significantly greater in C vs. CHF (p=0.001). At baseline, L-arg transport was greater in C (111.96 ± 9.77 ml/min) than CHF pts (84.27 ± 9.04 ml/min; p=0.05). L-arg transport was reduced to the same extent following L-NMMA infusions (C vs. CHF; -22.71 ± 5.33 vs -25.71 ± 6.22%; p=ns).

Conclusion: The present study confirms our earlier finding of reduced L-arg transport as a potential mediator of impaired endothelial function in CHF. Our observation that L-NMMA produces a greater blood flow reduction in C than in CHF, while exerting similar effects on L-arginine transport suggests that this agent acts principally to inhibit eNOS rather than L-arg transport.

INFLAMMATORY MECHANISMS OF CELL DAMAGE

P1018 Role for a novel integrin linked kinase in leukocyte recruitment

E.B. Friedrich[1], S. Sinha[1], L. Li[2], S. Dedhar[3], T. Force[4], A. Rosenzweig[2], R.E. Gerszten[1]. *[1]Massachusetts General Hospital/Harvard, CIID, Charlestown, United States of America; [2]CVRC, Massachusetts General Hospital/Harvard, Charlestown, United States of America; [3]University of British Columbia, Vancouver, Canada; [4]New England Medical Center/Tufts, Boston, United States of America*

Chemokines such as MCP-1 are potent monocyte agonists and a growing body of evidence from animal models and human specimens suggest a key role in the pathogenesis of atherosclerosis. Chemokines modulate monocyte integrin avidity to coordinate adhesion and subsequent transendothelial migration, though the sequential signaling pathways involved remain poorly characterized. Here we show that integrin linked kinase (ILK), a recently described 59-kDa serine-threonine protein kinase which interacts principally with beta1-integrins, is highly expressed in human mononuclear cells and has sustained activation by exposure of leukocytes to the chemokine MCP-1. Biochemical inhibitor studies show that chemokine-triggered activation of ILK is downstream of phosphoinositide 3-kinase (PI 3-K). In functional assays in a parallel plate laminar flow chamber (2,0 dynes/cm^2), overexpression of wild type ILK in human monocytic cells markedly diminishes beta1-integrin/vascular cell adhesion molecule-1 (VCAM-1)-dependent firm adhesion to human endothelial cells [13.2± 1.0 (Control transduced) vs. 2.6±1.1 (ILK transduced), $p<0.001$]. These data implicate ILK in the dynamic signaling events involved in the regulation of monocyte integrin avidity for endothelial substrates, potentially in the transition from stable arrest to subsequent migration. Identification of the signaling pathways responsible for monocyte recruitment could provide further insights into celluar mechanisms underlying human atherosclerosis and potentially identify new targets for therapeutic intervention.

P1019 High dose of aspirin inhibits NF-kB and protects against endorgn damage in rats with human renin and angiotensinogen genes

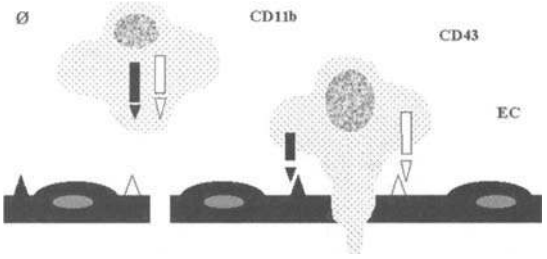
R. Dechend, D.N. Muller, F. Hampich, J.K. Park, F.C. Luft. *Franz Volhard Clinic, Cardiology, Berlin, Germany*

Recently, it was reported that aspirin (ASA) inhibits I-kB kinase beta in vitro. We previously showed that NF-kB activation and inflammation plays a crucial role in the pathogenesis of dTGR. We now tested the hypothesis that ASA inhibits NF-kB and ameliorates renal and cardiac end-organ damage. The dTGR feature hypertension, severe renal and cardiac damage. We treated rats chronically with ASA (600 and 25 mg/kg ip). Only apirin 600 prevented mortality, while untreated dTGR and ASA 25 showed mortality > 50% at 7 weeks. ASA 600 reduced cardiac hypertrophy (4.0±0.2 vs. 5.7±0.2 mg/g, $p<0.001$) compared to dTGR. Blood pressure levels in ASA 600 were slightly, but not significantly lower (158±8 vs. 182±8 mm Hg, p=0.2). In contrast, ASA 600 reduced albuminuria by 85% ($p<0.01$) and perivascular fibrosis. However, apirin 25 had no effect on cardiac and renal damage. ASA 600 inhibited renal I-kB kinase activity and NF-kB DNA binding activity, which was increased in dTGR. Immunohistochemical analysis shows increased expression of the activated p65 NF-kB subunit in the endothelium, smooth muscles cells, infiltrated cells, glomeruli, tubuli of dTGR, which was markedly reduced by ASA 600. ASA 600 also resulted in reduced immunostaining of NF-kB-regulated genes laminin, ICAM-1 and IL-6. Monocyte infiltration was increased in dTGR hearts and kidneys and reduced by ASA 600, and not by ASA 25. Thus, these results demonstrate that only high dose ASA inhibits NF-kB, suppresses inflammation and protects against ANG II-induced end-organ damage.

P1020 Evaluation of the phasic variation of monocyte membrane markers during acute coronary syndromes

A. Anão[1], J. Cortez[2], V. Azevedo[1], L. Bronze[1], I. Arroja[1], J. Azevedo[1], A. Aleixo[1], M.G. Morais[2]. *[1]Hospital São Francisco Xavier, Echocardiographic Laboratory, Lisbon, Portugal; [2]Faculdade de Ciências Médicas-UNL, Biochemistry Department, Lisbon, Portugal*

In acute coronary syndromes (ACS) an inflammatory response (IR) is associated with the instability of the coronary artery plaque related to the activity of the monocyte (M) type cell involved. Our aim was to analyse the time variability of several M cell membrane markers (MM) during the first days post ACS. We studied a group of 52 ACS pts, aged 65±12 yrs, 69% male, after CCU admission. Blood samples were collected in EDTA at day 1, 3, 5 and 10 post admission and after discharge. The absolute and relative M circulating levels (n-%/mm^3), and its relative % to blood white cells count (%M-%) were determined. After a selective M cell MM process, a quantitative flow citometry method was applied to assess the concentration of M MM/mm^3, ICAM and VCAM ligands such as CD11b and CD43 and its ratio CD11b/CD43. We also evaluated the levels of fibrinogen (FB-mg/dl), mioglobin (MG-U/L), C-reactive protein (CRP-mg/dl), troponin I (TI-μ/L), total CK (U/L) and CK-MB (U/L) isoenzyme. Between day 1 and 10 post ACS, the CD11b levels suffered a significant variation of +13.5% (130.6-148.3/mm^3) with a peak level at day 5, CD43 registered higher initials levels and a variation of +7.3% (39.5-24.1/mm^3) with a peak at day 3, and CD11b/CD43 ratio a variation of +31% (3.07-5.02; $p<0.01$) with a correspondent peak at day 5. The CD11b/CD43 ratio registered also significant correlations with the CRP levels (r=0.55; $p<0.01$), troponin I (r=0.37; p=0.02) and total CK (r=0.40; p=0.02), different from the other variables. The MM suffer a variation during the acute phase of the myocardial ischemic ACS process.



The phasic variation of these M cell MM reflect the intensity of the IR associated with plaque instability and may correspond to a cell index of the myocardial inflammation level in acute ischemiaMonocyte receptors

P1021 Atorvastatin decreases the upregulation of COX-2 and EP1 receptor induced by proinflammatory cytokines in cultured vascular smooth muscle cells

A. Gómez-Hernández[1], M. Ortego[1], J.L. Martín-Ventura[1], L.M. Blanco-Colio[1], J. Tuñón[1], C. Díaz[2], G. Hernández[2], J. Egido[1]. *[1]Fundación Jiménez Díaz., Vascular Research Lab, Madrid, Spain; [2]Medical Division Pfizer, R&D Department, Madrid, Spain*

Background: Inflammation constitutes a key factor in the initiation, progression and rupture of the atherosclerotic plaque. One enzyme implicated in the inflammation is cyclooxygenase 2 (COX-2), not constitutively expressed in normal vessels. COX-2 is responsible for the synthesis of proinflammatory prostaglandins (PGs) such as PGE2, which exerts a wide variety of actions through G protein –coupled receptors (EP 1- 4). Little is known, however about the regulation of the EPs in atherosclerosis. In addition, recent data have shown some antiinflammatory effects of HMG-CoA reductase inhibitors (statins). The aim of this work was to study the expression of COX-2 and of different PGE2 receptors in vascular smooth muscle cells (VSMC) induced by proinflammatory cytokines such as IL-1beta and TNF-alfa, as well as its modulation by atorvastatin (Atv).

Methods and Results: mRNA expression of COX-2, EP1, EP2 and EP-4 receptors induced by TNF-alfa and IL1-beta (100U/ml, each) was studied in rat VSMC by RT-PCR. Stimulation with cytokines elicited an increase of COX-2 expression (3.2±1 fold). EP-1 receptor expression was induced at 3h (2.3±2 fold), diminished at 6h, increased again at 8h (1.8±0.8 fold; and 4.1±5 fold, respectively) and kept constant until 24h. The expression of EP-4 receptor peaked at 8 h. However the expression of EP-2 and COX-1 remained invariable with the time. Since it has been suggested that Atv may have antiinflammatory effects, additional experiments were performed. Preincubation for 1 h with Atv (10^{-5} M) significantly reduced COX-2 expression at 8h (1.0±0.8 fold, 56%) coinciding with a reduction in the expression of EP1 (0.8±0.5 fold, 75%). Antiinflammatory compounds such as acetylsalicylic acid (100μM) and dexamethasone (1μM) significantly decreased the expression of COX-2 and EP1 at both 3 and 8h. Comparatively, the reduction obtained with Atv was slightly lower to that observed with the antiinflammatory drugs (76-91%). In addition, pyrrolidine dithiocarbamate (200μM), a known NF-kB inhibitor and antioxidant, diminished the COX-2 and EP1 mRNA expression, suggesting the implication of this nuclear factor.

Conclusions: In cultured VSMC, proinflammatory cytokines such as TNF-alfa and IL1-beta upregulate the expression of COX-2 and several PGE2 receptors. This effect was reduced by Atv in the range obtained by classical antiinflammatory drugs, probably via NF-kB. These data further support the antiinflammatory properties of Atv.

P1022 Application of TNF receptor ameliorates cardiac and renal end-organ damage in Ang II-dependent hypertension independent of blood pressure

R. Dechend, D.N. Muller, J.K. Park, A. Mulally, R. Dietz, F.C. Luft. *Franz Volhard Clinic, Cardiology, Berlin, Germany*

We recently reported that rats harboring both human renin and angiotensinogen genes (dTGR) feature moderate hypertension, severe renal and cardiac damage, and a 50% mortality at 7 weeks. We also showed that TNFa is increased in both hearts and kidney by western blot and immunohistochemisty in this model of angiotensin II (Ang II) induced end-organ failure. Rats over expressing TNFa develop chronic heart failure associated with severe leukocyte infiltration in both the atria and the ventricles. Moreover chronic treatment with a soluble TNFa receptor (sTNF-R) in patients with heart failure resulted in a significant dose-dependent improvement in LV structure and function and a trend toward improvement in patient functional status. Thus, we tested the hypothesis that TNF signaling is involved in Ang II-induced cardiac and renal damage. We treated rats chronically with sTNF- for 3 weeks. sTNF-R had no effect on blood pressure (211±8 vs. 194±7 mm Hg, Sprague Dawley rats (SD): 110±1 mm Hg), however cardiac hypertrophy index was reduced (5.64±0.13 vs. 4.75±0.09 mg/g, $p<0.05$, SD: 3.5±0.05 mg/g) compared to dTGR. sTNF-R reduced 24 h albuminuria by 50% (37.3±8.1 vs. 16.9±3.2 mg/d, $p<0.05$, SD: 0.2±0.02 mg/d). Vasculopathy and perivascular cardiac fibrosis were markedly ameliorated by sTNF-R. Immunohistochemical analysis showed increased infiltration of monocytes and T-cells in dTGR which was significantly reduced by sTNF-R. sTNF-R was only partially effective in the kidney. Electrophoretic mobility shift assay showed increased NF-kB and AP-1 DNA binding activity in heart and kidney of dTGR. The DNA-binding activity of both transcription factors was reduced by sTNF-R in heart and kidney. Immunohistochemical analysis shows increased expression of the p65 NF-kB subunit in dTGR that was reduced by sTNF-R treatment. Similarly, immunohistochemistry showed that the TNF-regulated adhesion molecule ICAM-1 was reduced in heart in the sTNF-R treated compared to untreated dTGR. These results demonstrate that TNF signaling is involved in Ang II-mediated end-organ damage in vivo. Blocking TNFa signaling does not reduce Ang II induced hypertension in vivo. sTNF-R reduced NF-kB and AP-1 DNA binding activity and reduced cardiac damage independent of blood pressure.

P1023 Low molecular weight dextran sulfate acts as an endothelial cell-protectant and prevents complement activation in xenotransplantation models

T. Laumonier[1], P.J. Mohacsi[1], E.Y. Korchagina[2], N.V. Bovin[2], R. Rieben[1]. [1]*Bern University Hospital, Cardiology, Bern, Switzerland;* [2]*Shemyakin Institute, Russian Academy of Sciences, Moscow, Russian Federation*

Introduction: The complement (C) system plays a critical role in the rejection of xenografted cells and organs as well as in the damage of endothelial cells (EC) as occurring e.g. during ischemia/reperfusion injury after myocardial infarction. Dextran sulfate of MW 5000 (DXS) is known to block C-activation and to regulate the coagulation cascade by potentiation of C1-inhibitor. Due to its negatively charged nature we hypothesized that DXS can bind to the endothelium and protect it from C-mediated damage.

Methods: A FACS assay using pig cells (PK15 as well as pig aortic EC) was developed to analyze C-deposition, DXS binding and cell survival. Pig cells were preincubated with DXS (0,04 to 25 mg/ml) for 30 minutes at 37°C, 5% CO2, followed by washing, and incubated with normal human serum (NHS) to induce C-mediated damage. The cellular localization of DXS was analyzed by confocal microscopy using a FITC labeled DXS (DXS-FITC) and also evaluated on more complex tissues like pieces of rat aorta in a setting of ischemia/reperfusion injury.

Results: DXS was able to inhibit human serum-mediated C deposition (C3c, C4c) on pig cells in a dose dependant manner (IC50 = 0,7 mg/ml). This cytoprotective effect was still present when the challenge with human serum was done up to 48 hours (IC50 = 18 mg/ml) after the 30 min incubation of the cells with DXS, followed by washing. Up to a concentration of 100 mg/ml, DXS had no toxic effects on the cells. By FACS analysis and confocal microscopy, we could show that cytoprotection was paralleled by binding of DXS-FITC, both to the cell surface and the nucleus.

Discussion: Our results indicate that DXS is able to bind to the endothelium and to protect it from C deposition mediated endothelial injury. These data suggest that DXS acts as an "endothelial cell protectant" with potential for clinical application to prevent ischemia/reperfusion injury after PTCA or cardiac surgery and heart transplantation.

IMAGING OF ATHEROSCLEROSIS

P1024 In vitro photodynamic diagnosis of atherosclerotic wall changes with use of mono-l-aspartyl chlorin e6

D. Bialy[1], A. Derkacz[1], M. Wawrzynska[1], A. Bednarkiewicz[2], P. Ziolkowski[3], H. Nowosad[1], W. Strek[2]. [1]*Cardiosurgery, Medical University of Wroclaw;* [2]*Polish Academy of Sciences, Institute for Structure Research, Wroclaw,* [3] *Pathomorfology, Medical University of Wroclaw, Wroclaw, Poland*

Background: Although there are several methods for atherosclerosis detection available, none of them seems to be accurate enough to solve the problem. Photosensizer Assisted Light Induced Fluorescence (PALIF) as a background for photodynamic diagnosis (PDD) and therapy (PDT) is a new method based on using photosensitizing drugs and light of appropriate wavelength needed for drug activation. The aim of this study was to asses in vitro the capability of PALIF with use of chlorin e6 as a PS to recognize different stages of atherosclerosis and its usefulness as a feedback system for photoangioplasty treatment.

Methods: 20 specimens of human aorta and 10 specimens of human coronary artery from eight patients were obtained at autopsy. The patients ranged in age 45 to 76 years. The specimens were soaked with mono-l-aspartyl chlorin e6 for 15 minutes and then washed out. The luminescence spectra using 440 nm wavelength light from a Mercury lamp were collected and analyzed. Subsequently all specimens were histologically examined and basing on the pathological changes occurring in intima and media classified into three groups: 1: normal artery wall 2: atherosclerotic noncalcified plaque and 3: calcified plaque

Results: Tissue fluorescence is seen as green light with three peaks at 490, 515 and 543 nm, chlorin e6 fluorescence is seen as a fourth peak at 660 nm. Compared with the spectrum obtained from normal artery wall, spectra collected from noncalcified and calcified plaque show the reduction of green fluorescence intensity, with strongly reduced green part of the spectrum collected from noncalcified samples. Moreover we noted a very strong red fluorescence of chlorin e6 originating from lipid reach, noncalcified samples. We established a quantitive factor which is the ratio Re6 of chlorin e6 red intensity in its 660 nm maximum compared to the area of green luminescence centered at 516 nm. The highest value of the ratio was reached at atheromatous samples, then calcified and normal ones (R=3.53, R=1.63, R=1.50 respectively, $p<0.05$).

Conclusions: PS assisted spectroscopy can be a comparable, quantitive method of identifying artery wall changes. It may be a specific tool for atheromatous and normal or calcified segments discrimination. Further animal and clinical trials must be performed to evaluate in vivo atheroma detection algorithm as a feedback system for photoangioplasty. The advantage of the above method is a possibility of a real time imaging followed by targeted therapy of various forms and stages of atherosclerosis

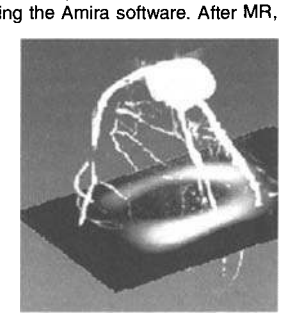
P1025 Fusion imaging in chronic coronary artery stenosis by magnetic resonance phosphorus spectroscopy and 3D coronary angiography

M. Nahrendorf[1], K-H. Hiller[1], T. Neuberger[1], A. Greiser[1], S. Köhler[1], K. Hu[2], G. Ertl[2], W.R. Bauer[2]. [1]*Universität Wuerzburg, EP5, Wuerzburg, Germany;* [2]*Universität Würzburg, Med. Klinik, Würzburg, Germany*

Aim of the study was to evaluate the concept of fusion imaging by magnetic resonance spectroscopy and imaging in the model of chronic coronary stenosis in the rat. 3D coronary angiograms were fused with ATP metabolite maps, which were acquired by 31P localized MR spectroscopy in the isolated rat heart.

Stenosis was induced by a ligation including a 300µm wire placed next to the left coronary artery. The wire was taken away imediately after the suture was closed. 2 weeks later localized 3D 31P Chemical Shift imaging was performed in 8 isolated perfused hearts on a Bruker 12 T AMX. (voxel size 4x4x6 mm). 1H gradient echo images were acquired to correlate position of the stenotic region in the metabolite maps and the angiography data, which was segmented and used for volume correction of spectroscopy. PCr/ATP was determined in a control and the ischemic region. MR angiography was performed with a flow weighted 3D gradient echo (TE 1.0ms, matrix 128±3). Metabolite maps of ATP were fused with the coronary angiogram using the Amira software. After MR, fraction of scarring within ischemic region was determined in histology. 3D MRA enabled detection of coronary stenosis. In the ischemic region, PCr/ATP was decreased when compared to control region (1.24 ± 0.38 vs 1.45 ± 0.49, $p < 0.05$). Fraction of fibrosis in histology was 12.81.4%, and correlated to ATP signal reduction in the ischemic region ($r = 0.71$, $p < 0.05$).

In future this kind of image fusion might be of help in fast characterisation of the severity of a stenosis and might aid decision making concerning revascularisation, because not only anatomy, but also metabolic information can be given at a glance.



Fusion image.

P1026 Non-invasive differentiation of plaque morphology using multi-slice computed tomography: experimental and post-mortem studies

S. Schroeder[1], A. Kuettner[2], M. Leitritz[1], A. Kopp[2], C. Herdeg[1], C. Burgstahler[1], M. Heuschmidt[2], C.D. Claussen[2]. [1]*University of Tuebingen, Med.Clinic III, Dept. of Cardiology, Tübingen, Germany;* [2]*University of Tuebingen, Division of Diagnostic Radiology, Tübingen, Germany*

Background: Initial clinical results indicate that multi-slice computed tomography (MSCT) might be used for the non-invasive differentiation of human coronary plaque morphology by measuring plaque density. Aim of the present studies was a) to determine the reliability of this new methodology in post-mortem studies, and b) to evaluate influence factors on the density measurements
Methods: a) 10 human hearts were scanned post mortem, focusing on the presence of atherosclerotic coronary plaques. Density measurements were performed within these plaques, which were furthermore histopathologically classified according to the Stary classification.
b) A coronary phantom model was developed, consisting of silicon tubes (lumen diameter 4 mm), with two plaques of known density inside, simulating soft and intermediate lesions (plaque 1: -39 Hounsfield Units [HU], plaque 2: 72 HU). Density measurement were conducted in 3 different contrast media concentrations ([CMC], 1:30, 1:40, 1:50) All MSCT scans were performed on a Somatom Volume Zoom™ (Siemens, Forchheim, Germany).
Results: a) 13 plaques were detected by MSCT (n=4 soft [Stary III/IV], n=5 intermediate [Stary V], n=4 calcified [Stary VII]). Soft plaques had a mean density of 41±17 Hounsfield units (HU), intermediate plaques of 73±20 HU, and calcified plaques of 772±330 HU.
b) Both Plaques (P1/2) could be differentiated from each other on all three CMC. Rising CMC lead to significant higher density values within the plaques ($p<0,001$).
Conclusions: The post-mortem results confirm that human coronary plaque morphology might be reliably evaluated by the use of MSCT. However, when determining tissue density levels within small anatomic structures such intracoronary atherosclerotic plaques, partial volume effects have to be taken into account, affecting precision of the measurements. Our data indicate, that standardization of methodology is required, before it can be reliably applied in the clinical setting.

TRANSOESOPHAGEAL ECHOCARDIOGRAPHY VALVULAR HEART DISEASE

P1027 Is TEE necessary after a transthoracic echo negative for left atrial thrombi in atrial fibrillation in presence of severe mitral regurgitation

N. Ozdemir[1], C. Kaymaz[2], M. Akçay[2], O. Karakaya[2], C. Çevik[2], M. Yüce[2], O. Özveren[2], M. Özkan[2]. [1]*Kosuyolu Heart & Research Hospital, Cardiology Clinic, Istanbul, Turkey;* [2]*Kosuyolu Heart & Research Hospital, Cardiology Clinic, Ýstanbul, Turkey*

Incidence of systemic embolism (SE) and thrombi (T) within the left atrium (LA) has been documented to be lower in pts with severe mitral regurgitation (MR) as compared to pts without MR despite comparable LA size and atrial fibrillation (AF). Although transesophageal echo(TTE) provides higher diagnostic performance than transthoracic echo(TTE) for LAT, indications of TEE for exclusion of LAT,and necessity of anticoagulation in pts with AF in presence of severe MR remain to be determined.We aimed to compare TTE and TEE in diagnosis of LAT in pts with AF associated with rheumatic mitral valve disease (RMVD),and to assess whether diagnostic performance of TTE for LAT relates to the presence of severe MR.The study group comprised 261 pts (M 176, F 85,mean age 41±16) with chronic AF and RMVD assessed by TTE and TEE before mitral valve surgery. Pure or predominant mitral stenosis (MS) was defined as mitral valve area <1.5 cm^2 and MR jet area <4 cm^2 (n= 91), severe MR was defined as jet area >8 cm^2 and/or jet area/ left atrial area $>40\%$ (n= 73), and MS concomitant with MR was defined as MS with MR jet area between 4 and 8 cm^2 (n=97). Echodensities mimicking LAT on 2D TTE study but remaining within the area of color flow MR jet were not accepted as LAT. Preop TTE and TEE diagnosed 15 and 44 out of the 46 LAT detected during operation, respectively. Incidence of LAT in pts with and without severe MR was 1.4% and 24% ($p<0.001$),respectively. For LAT, overall sensitivity of TTE and TEE was 34% and 95%, specificity was 96% and 94%, positive predictive value (PPV) was 80% and 89%, negative predictive value (NPV) was 75% and 97%, and diagnostic accuracy (DA) was 76% and 95%,respectively. In pts with and without severe MR, sensitivity of TTE was 100% and 33%, specificity was 98.5% and 95%, PPV was 50% and 85%, NPV was 100% and 64%, and DA was 97% and 67.5%, respectively. In pts with and without severe MR, sensitivity of TEE was 100% and 95%, specificity was 100% and 90%, PPV was 100% and 89%, NPV 100% and 96%, and DA was 100% and 92.5%,respectively.
Conclusions: Diagnostic performance of TTE for LAT in pts with rheumatic AF seems to be associated with type of RMVD,and color flow mapping on TTE study may be considered as reliable as TEE for exclusion of LAT in presence of severe MR.In a patient with TTE Doppler criteria of severe MR and negative for LAT, further TEE with this indication may not be necessary.

P1028 Importance of post-cardioversion transoesophageal echocardiography for the timing of anticoagulation in atrial fibrillation: a 1 year follow-up

I. De Luca, M. Sorino, B. Del Salvatore, P. Colonna, L. De Luca. *Azienda Policlinico, Division of Cardiology, Bari, Italy*

Background: In patients (pts) with atrial fibrillation (AF) recommended for electrical cardioversion (EC), the guided approach with transoesophageal echocardiography (TEE) permits the elimination of the three weeks pre-cardioversion anticoagulation therapy recommended by conventional strategy but,in accordance with non-controlled studies, still requires the prosecution of oral anticoagulation therapy for another 4 weeks due to the cardioversion-related thromboembolic risk. The aim is to verify whether the use of a 2nd TEE 7 days after EC could modify the post-EC therapeutic strategy. METHODS. Once informed consent was given, 101 pts (74 pts with non-valvular AF and 27 pts with flutter and a history of AF >48 hours) underwent a first TEE and, within 24 hours, an EC if there were not present any thrombi, aortic plaques or dense spontaneous echocontrast. Anticoagulation therapy was based on low molecular weight heparin(LMWH-enoxaparine 100 U antiXa/kgx2) for 7 days at which point a 2nd TEE was carried out. In the absence of any new thrombi,dense spontaneous echocontrast and/or low emptying velocity (<40cm/sec) of the left atrial appendage (LAA) the therapy with LMWH was terminated; if this was not the case, anticoagulation therapy, embricated with oral anticoagulation was continued for 4 weeks.Clinical follow-up was performed 1 month,6 months and 1 year post-EC. RESULTS. Sinus rhythm was restored in 71/101 pts after EC which resulted efficacious in 66 pts whilst in 5 restoration in sinus rhythm was spontaneous. After 7 days 55 pts remained in sinus rhythm. The 2nd TEE was refused by 2 pts and carried out in 53 pts. In the follow-up after one month post EC no thromboembolic events were recorded either in the pts at risk who had continued the anticoagulant therapy or in those who had suspended the therapy after 7 days. In the follow-up after 1 year no thromboembolic event was recorded in 87/101 pts with normal LAA velocity, whilst amongst the remaining 14 patients who had shown low LAA velocity, three had a stroke (0% vs 21%: $P<0.001$). In 8/14 low LAA velocity developed only after EC, as recorded by the 2nd TEE. CONCLUSIONS. The TEE 7 days post-EC, which is not to be found in the literature, could well define the timing of the post-EC anticoagulation therapy both for the low risk patients who could take advantage of an early suspension of the anticoagulation based on LMWH, as an alternative to oral anticoagulation, and for those thromboembolic risk patients who should continue oral anticoagulation until the signs of LAA dysfunction disappear.

P1029 Is transoesophageal echocardiography useful before atrial flutter cardioversion?

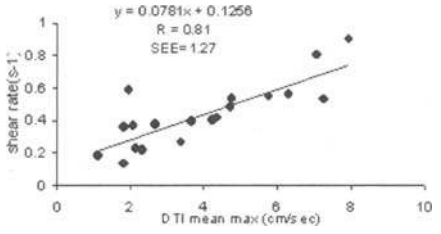
M.T. González-Alujas, C. Elorz, A. Evangelista Masip, G. Avegliano, H. García del Castillo, J. Soler-Soler. *Vall d'Hebron Hospital, Dept. of Cardiology, Barcelona, Spain*

The usefulness of TEE before atrial flutter (AFl) electrical cardioversion (EC) is currently controversial. The aim of our study was to assess the incidence of thromboembolism risk factors by TEE before AFl EC.
Methods: 96 AFl without rheumatic heart disease were studied immediately before EC: 18 had ischaemic heart disease, 18 hypertensive cardiopathy, 15 dilated cardiomyopathy, 37 other diseases and 8 idiopathic. Time of the arrhytmia ranged from 2 to 365 days (m:95±128), and could not be determined in 26. 22 patients were chronically anticoagulated. Ejection fraction (EF) and dimensions were quantified by transthoracic study and emptying velocity of left atrial appendage (LAAV) and thrombosis by TEE.
Results: A thrombus in the left atrial appendage was detected in 2 patients: one with AFl duration>1 year and the other with EF 40%. 7 patients had LAAV<25 cm/sec. 26 patients had EF<50%, 21 of these(81%) had LAAV>25 cm/sec and 5(19%)had LAAV<25 cm/sec. Time of the arrhytmia was more than 6 months in 12 patients, 10 of these (83%) had LAAV>25 cm/sec and 2 (17%) had LAAV<25 cm/sec. All 32 patients with EF>50% and arrhytmia duration < 6 months had LAAV >25 cm/sec.
Conclusion: Normal left ventricle function and arrhytmia duration <6 months identify a group of patients at low risk of atrial thrombosis, in whom precardioversion TEE does not appear to be indicated.

P1030 Tissue Doppler imaging and contrast echo for left atrial appendage spontaneous echo contrast quantification by transoesophageal echocardiography

E. Donal, A.L. Klein, M. Carneiro, Z.B. Popovic, R.D. Murray, J. Drinko, J.D. Thomas. *The Cleveland Clinic Foundation, Cardiology, cleveland, United States of America*

Background: Spontaneous echo contrast (SEC) in the left atrial appendage (LAA) of patients in atrial fibrillation (AF) is associated with thrombus formation and increased risk of thromboembolism. The qualitative operator-dependent appreciation is still the daily practice. Gray scale level quantification was proposed with a complex post-processing. Contrast-agent (CA) provides enhancement of endocardial border detection. Tissue Doppler Imaging (DTI) evaluation with CA has never been evaluated for SEC quantification in patients with AF.
Methods: We analyzed prospectively 20 patients with AF and LAA SEC (mild or severe). A CA (Optison) bolus injection (0.3 ml) was done during transesophageal echocardiography performed always according to the same methodology. The quantitative analysis was done off-line (HDI Lab, Philips). The mean (over 3 beats) maximal velocity of a region of interest (ROI=5x5 mm) was positioned at the LAA mouth. Shear rate was calculated as previously reported as an index of LLA function (2xV/LAA diameter/2).
Results: This DTI index (11.93±7.41cm/sec) was correlated with LAA emptying flow velocities (V) (r=0,72; p<0,001; 0.25±0.11cm/sec) and shear rate (r=0.81, p<0.001; 0.43±0.20 s-1). For the same ROI, normalized (by left ventricular cavity value) gray scale level information without contrast injection (2.37±1.53dB) was correlated with V (r=-0.72, p<0.001) and the shear rate (r=-0.62, p=0.006).



DTI-shear rate correlation.

Conclusions: This first experience of SEC quantification by DTI and contrast-echo is promising. SEC DTI velocities are well correlated with traditional risk factor of LAA thrombus formation. Additional studies will provide the prognosis significance of this new approach in a large number of patients.

P1031 Usefulness of transoesophageal echocardiography in stroke patients with normal transthoracic echoes

C.M. Schannwell, F.C. Schoebel, S.T. Perings, R. Marx, B.E. Strauer. *Duesseldorf, Germany*

Background: Embolism accounts for approximately 20% of strokes. Stroke patients in sinus rhythm with normal transthoracic echoes (TTE) continue to be referred for transesophageal echo (TEE) to rule out cardiac sources for systemic emboli. The aim of our study was to determine the potential clinical benefit of additional TEE information in stroke patients in sinus rhythm and normal TTE.
Methods: Patients with stroke undergoing TTE and TEE were evaluated. Patients with potential sources of embolism such as: atrial fibrillation, valvular disease including prosthetic valves and left ventricular dysfunction were excluded.
Results: 155 patients with stroke matched our inclusion criteria. The incidence of left atrial enlargement in TTE was 7.7% (n=12) versus TEE 11.6% (n=18) p=n.s., right atrial enlargement in TTE was 2.6% (n=4) versus TEE 3.8% (n=6), p=n.s.; vegetations on aortic/mitral valve in TTE 10,9% (n=17) versus TEE 14.2% (n=22) p=n.s.; patent formamen ovale in TTE 6.4% (n=10) versus TEE 10.3% (n=16); p=n.s., interatrial septal aneurysma TTE 1.3% (n=2) versus TEE 3.2% (n=5); p=n.s. and spontaneous contrast was 10.3% (n=16) in both. TEE however identified severe plaques in the ascending aorta in 15.4% (n=24) of patients. These plaques could not be detected by TTE.
Conclusion: There is no additional significant benefit of TEE in patients with normal TEE in sinus rhythm in identifying sources of embolization. However, TEE identified patients with severe ascending aortic plaques not seen in TTE.

P1032 Transoesophageal echocardiography for prolonged left atrial appendage dysfucntion after electric DC shock for atrial fibrillation

M. Sorino, B. Del Salvatore, P. Colonna, E. Fino, I. de Luca. *Azienda Ospedaliera Policlinico, Division of Cardiology, Bari, Italy*

Background: After electric DC shock (ES) for atrial fibrillation (AF) the sinus rhythm (SR) restoration is not always associated to a mechanical recovery of left atrial appendage (LAA) mechanical function. The aim of this study is to evaluate with transesophageal echocardiography (TEE) the left atrium (LA) and LAA functional behaviour 7 days after ES for AF.
Method: In 63 patients (pts) with non-valvular AF or atrial flutter lasting > 48 hours we performed a pre- cardioversion and a 7-days post-cardioversion TEE study. Left atrial dysfunction was considered when transmitral Doppler A wave velocity (LAv) was < 45 cm/sec (age corrected value) and when LAA emptying velocity (LAAv) was < 25 cm/sec.
Results: At TEE 7-days post-cardioversion we observed atrial and/or LAA dysfunction in 14 out of 63 pts; in 9 pts an isolated LAv reduction, in 3 pts an isolated LAAv reduction, and in 2 pts an associated LAv LAAv reduction. One of the 3 pts with isolated LAAv reduction showed a persistence of a fibrillation-type LAA flow profile, despite a SR restoration and a normal LAv. Serial TEE controls reported a LAA flow profile normalization 3 months after ES.

Cases of LAA or left atrial dysfunction

Patient	1, 2,	3, 4,	5, 6,	7, 8,	9, 10,	11, 12,	13, 14
LAv	38, 40,	40, 50,	45, 34,	71, 32	40, 41,	40, 40,	36, 48
LAAv	45, 40,	44, 25,	36, 43,	18, 38,	25, 20,	40, 44,	35, 15

Conclusion: It is, therefore, evident that in some patients undergoing ES for AF (4.7% of our cases) a persistent LAA isolated dysfunction may occur. Moreover, such dysfunction can last even for a prolonged period of time (3 months). This observation can importantly affect the therapeutic strategy in pts with AF undergoing ES.

P1033 Diagnosis of patent foramen ovale by transthoracic echocardiography using second harmonic imaging: comparison of three contrast agents

J. Lefevre[1], S. Lafitte[1], J.M. Perron[1], C. Jais[2], P. Coste[2], R. Roudaut[1]. [1]*hopital cardiologique Haut Leveque, echocardiographie, pessac, France;* [2]*Bordeaux, France*

Patent foramen ovale (PFO) diagnosis with atrial right to left shunt is of high importance in patients with an unexplained ischemic cerebral injury.We sought to evaluate whether transthoracic contrast echocardiography with harmonic imaging (TTE) is a diagnostic alternative to transesophageal contrast echocardiography (TEE) and whether the contrast agent composition is of consequence for the detection of patent foramen ovale (PFO) by TTE.
Methods: 121 patients referred for TEE underwent TTE and TEE explorations with one of three different and randomised contrast agents. Contrast agents injected in this study consisted of a mixture of dextrose and air (CA1), polygelatin molecule and air (CA2) and dextrose and blood and air (CA3). The severity of atrial shunting in the left atria was evaluated by two independent observers on TTE and TEE records, as well as the image quality by semiquantitative score. Intensity of contrast agent in the right atria was also assessed by 'off-line' videointensity measurements for CA1, CA2 and CA3.
Results: Total of 23 patients (19%) showed evidence of atrial right to left shunt by TEE. TTE allowed similarly the detection of 23 PFO with a positive and negative predictive values of 87% and 97% respectively. No significant difference was observed between the two techniques. Moreover, concerning the contrast agents comparison, no significant difference was observed between CA1, CA2 and CA3 in term of PFO detection during TTE and TEE. However, quantitative analysis of right atrial contrast showed a higher level of intensity with CA3 compared to CA1 and CA2 during TTE (p<0.05).
Conclusion: In combination with contrast agent injection, TEE and TTE have a comparable yield for the detection of PFO. Although the composition of contrast agent appears not to modify the PFO detection, the contrast quality in the right atria during TTE is the best with a blood, dextrose and air mixture.

P1034 A new screening method for the detection of patent foramen ovale in divers

M. Billinger, R. Vogel, S. Gerber, M. Schwerzmann, B. Meier, C. Seiler.
University Hospital, Cardiology, Bern, Switzerland

Background: Recent studies have shown a relation between patent foramen ovale (PFO) and paradoxical gas emboli in divers. A screening method for the detection of PFO is not available but would be very useful especially in the population of divers. High sensitivity and simple performance are important requirements for such a method. Right-to-left shunt through a PFO theoretically leads to a decrease in arterial oxygen saturation which may be detectable by peripheral oxygen saturation measurements (SO2, %). Therefore, the aim of this study was to assess the value of SO2 measurements to predict a PFO in divers.
Methods: In 71 divers peripheral SO2 was recorded 4 times at baseline as well as immediately after release of Valsalva maneuver in horizontal posture. Divers with a Valsalva induced absolute decrease in SO2 by more than 2% during 1 (criteria A) or at least 2 (criteria B) of the recordings were predicted to have a PFO. After SO2 measurements, contrast transesophageal echocardiography (TEE, reference method) for determination of PFO was performed by operators blinded to the SO2 results.
Results: In 23 of 71 (32%) divers, a PFO was found by TEE. In 19 of these divers PFO was also detected by SO2 measurements using criteria A (sensitivity 83%, specificity 56%). Using criteria B only 15 PFO were correctly detected (sensitivity 65%, specificity 71%)
Conclusion: Peripheral oxygen saturation measurements to detect PFO are easy to apply, harmless and reliable. Of importance for a screening method, the sensitivity for the detection of PFO by SO2 measurements can be improved by lowering the detection criteria, which is particularly useful in the population of divers.

P1035 Right atrial enlargement is an independent predictor for permanent non-valvular atrial fibrillation in the elderly: an echocardiographic study

M. Geist, M. Wolyvovics, M. Boaz, B. Tzur, Y. Rozenman, M. Wolyvovics, M. Geist, M. Boaz, B. Tzur, Y. Rozenman. *E. Wolfson Hospital, Cardiology, Holon, Israel*

Atrial fibrillation (AF) is the most common rhythm disturbance. Its prevalence increases with the age of the population. The relation between left atrial (LA) size and AF is well established in the literature. There is, however, very little data about right atrial (RA) size in non-valvular AF.
Methods: Echocardiographic data including LA area (LA-A) and RA area (RA-A), left ventricular ejection fraction (EF), estimated systolic pulmonary artery pressure (PAP), and the severity of mitral and tricuspid regurgitation (MR and TR), were determined in 286 elderly patients (age >70 years). 126 patients with AF and 160 controls in sinus rhythm. Patients with structural valvular or pericardial disease were excluded.
Results: As expected there was a highly significant correlation between LA-A, PAP, reduced EF ($p<0.0001$ for all comparisons). Patients with AF had more severe MR and TR ($p<0.0001$). RA-A was 16.3+7.3 cm^2 in patients with sinus rhythm as compared to 24.5+5.2 cm^2 in patients with AF ($P<0.0001$). Since RA-A was correlated to the other variables multiple logistic regression analysis was used. Even after controlling for age, gender, LA-A, PAP, EF, MR and TR, right atrial area significantly predicted AF. Each 1cm^2 increase in RA-A was associated with 67% increase in the odds of AF. Backward, stepwise approach from the full model was used with age and gender forced into the equation. In this model the odds ratio for AF increases by 4% with each 1% decrease in EF while each 1cm^2 increase in RA-A is associated with 85% increase in the odds of AF. Comparing patients with only one atrial chamber enlarged (above median) RA-A was much better predictor of AF. 7/49 patients with only LA-A (14%) had AF compared with 35/45 (78%) with RA-A only.
Conclusion: Right atrial size is associated with non-valvular AF in elderly patients.
RA-A is an independent predictor of AF. This association suggests a possible role for RA enlargement in the pathogenesis of AF in the elderly although enlargement of RA secondary to AF is another potential explanation for our findings.

P1036 Haemodynamic progression of aortic valve stenosis in patients with chronic renal failure: a long-term follow-up echocardiographic study

F. Antonini-Canterin, E. Cervesato, D. Schinella, A. Bolis, A. Ciavattone, A. Ruggiero, D. Pavan, G.L. Nicolosi. *Ospedale Civile, Cardiologia, Pordenone, Italy*

Background: It has been reported in the last years that elevated serum creatinine is a factor correlated with a more rapid hemodynamic progression of aortic stenosis. It is unclear, however, whether the progression of aortic stenosis is faster only in hemodialysis patients or even a mild-to-moderate increase of serum creatinine could play a role in the acceleration of the progression.
Methods: The adult echocardiographic laboratory database of our department was queried to identify patients with chronic renal failure (CRF) and with at least 2 studies separated by a minimum of 6 months and with an initial peak jet aortic velocity > 2 m/s. Patients with coexisting more than moderate aortic regurgitation were excluded. Inclusion criteria allowed to identify 28 chronic hemodialysis patients and 33 patients with mild-to-moderate CRF (serum creatinine: 2.4±1.1 mg/dl; range: 1.6-6.2). As control group 95 patients with aortic stenosis and normal serum creatinine were rendomly selected from the database. The mean follow-up in all patients was 4±3 years.
Results: Patients with mild-to-moderate CRF were older (71±8 years) of hemodialysis patients (63±10 years) and controls (64±11 years) ($p<0.01$). The first peak aortic jet velocity was 2.7±0.7 m/s in hemodialysis patients, 3.2±0.8 m/s in patients with mild-to-moderate CRF and 3.0±0.7 m/s in controls ($p<0.05$). A pattern of rapid progression, defined as increase of aortic jet velocity > 0.3 m/s per year, was found in 46.4% of hemodialysis patients, in 21.2% of patients with mild-to-moderate CRF and in 20.0% of controls ($p<0.05$). The annual rate of increase in peak jet velocity was 0.39±0.45 m/s per year in hemodialysis patients, 0.16±0.24 m/s per year in patients with mild-to-moderate CRF and 0.17±0.21 m/s per year in the control group ($p<0.001$). The annual rate of reduction in aortic valve area was 0.17±0.18 cm^2 per year in hemodialysis patients, 0.05±0.05 cm^2 per year in patients with mild-to-moderate CRF and 0.06±0.08 cm^2 per year in the controls ($p<0.001$).
Conclusions: Our results confirm that end-stage renal disease and hemodialysis are important predictors of rapid hemodynamic progression of aortic stenosis. On the contrary, patients with mild-to-moderate CRF, despite a higher age, seem to be not significantly different in the progression of the disease as compared with patients with normal serum creatinine.

P1037 ACE I/D polymorphism modifies left ventricular remodelling in pressure overload due to aortic stenosis in men but not in women

J. Bartunek[1], E. van Schuerbeeck[2], B. Heyndrickx[2], L. Mortier[2], B. Roelandt[2], M. Vanderheyden[2], G.R. Heyndrickx[2], B. De Bruyne[2].
[1]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium;*
[2]*O.L.V.-Ziekenhuis, Cardiovascular Center, Aalst, Belgium*

Both gender and cardiac renin angiotensin system (RAS) modify LV remodeling in response to persistent pressure overload. Furthermore, both cardiac and systemic angiotensin levels appear to be related also to the ACE genotype. We tested the hypothesis that the effects of ACE I/D polymorphism on the LV remodeling and function in response to pressure overload due to aortic stenosis (AS) are gender dependent. Accordingly, ACE genotype and levels were prospectively determined in 82 consecutive pts (37 men, 45 women) with pure AS (area <0.8 cm^2). Pts on ACE/angiotensin II receptor inhibitors were excluded from the study. At echo-Doppler study, LV mass and relative wall thickness (RWT = 2 x posterior wall (PW)/LV end-diastolic diameter [EDD]), an index of LV concentric remodeling, were calculated.
Results: *$p<0.05$ vs II using ANOVA, + $p<0.05$ vs Men
DD pts had higher ACE levels than II or ID pts, but respective ACE levels were similar between men and women. In both genders, there were no difference in the AS severity and age (data not shown) and LV mass. In men, the RWT was higher in DD pts vs ID and II pts. In contrast, in women, the RWT was similar in all groups. Furthermore, II women had higher RWT as compared to II men.

ACV genotype		ACE levels (U/L)		RWT (mm/mm)		LV mass (gm)	
Men	Women	Men	Women	Men	Women	Men	Women
II (n=10)	II (n=10)	24±16	23±6	0.29±0.09	0.37±0.07+	224±96	193±53
ID (n=16)	ID (n=20)	33±16	29±13	0.35±0.07	0.36±0.10	193±82	172±81
DD (n=11)	DD (n=15)	44±22*	35±12*	0.45±0.14*	0.44±0.11	232±50	174±40

Conclusion: Thus, despite the similar systemic ACE levels the ACE I/D polymorphism modifies LV remodeling due to aortic stenosis in men but not in women. This suggests that effects of ACE I/D polymorphism on the molecular mechanisms of LV remodeling in pressure-overload hypertrophy are gender dependent.

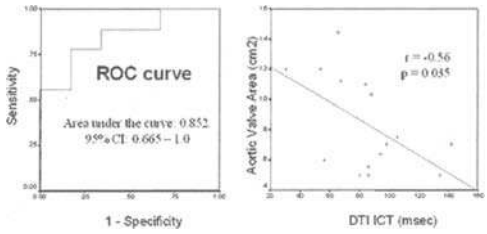
P1038 Evaluation of isovolumic contraction time by pulsed-wave Doppler tissue imaging. Is it useful in the detection of severe aortic stenosis?

R. Moreno, J. Zamorano, C. Almeria, J.L. Rodrigo, V. Serra, L. Alvarez, E. De Marco, L. Sánchez-Harguindey. *Hospital Clinico San Carlos, Cardiology Dept., Madrid, Spain*

The potential usefulness of pulsed-waved Doppler tissue imaging (DTI) has been mainly evaluated in coronary artery disease and some cardiomyopathies. In patients with aortic stenosis (AS), a delayed left ventricular myocardial contraction has been described. Aim of the study was to evaluate the possible role of DTI in the assessment of AS severity by measuring the isovolumic contraction time (ICT)

We studied 30 patients: 15 with AS (9 severe) and 15 control subjects. Patients were studied by DTI (ICT) and conventional echocardiography, measuring the aortic valve area by the continuity equation. The following was evaluated: 1) Differences in ICT between patients with vs without AS; 2) Relationship between ICT and aortic valve area and gradients in AS patients; 3) Diagnostic value of DTI in the diagnosis of severe AS.

Results: ICT by conventional Doppler was similar in both groups of patients, but DIT ICT was significantly longer in patients with severe AS (98±27 vs. 65±21, p = 0.024). There was a significant correlation between DTI ICT and aortic valve area (r = -0.56; p = 0.035) (see figure). Figure also shows the ROC curve for the diagnosis of severe AS among patients with AS (Area under the curve 0.852; 95% CI: 0.665-1.0). The two best cut-points were a DTI ICT > 73 msec (89% sensitivity, 77% specificity) and > 85 msec (78% sensitivity, 83% specificity).



Relation between ICT and aortic valve.

Thus, ICT as measured by DTI is significantly increased in patients with severe AS, showing a high sensitivity and specificity in the detection of severe AS. These data suggest a new potential clinical application of DTI.

P1039 The unsolved issue of symptoms in severe aortic stenosis: is there a role for the Total Ejection Isovolume Index?

F. Antonini-Canterin, G.Q. Huang, E. Cervesato, D. Pavan, R. Piazza, F. Marcianò, F. Macor, G.L. Nicolosi. *Ospedale Civile, Cardiologia, Pordenone, Italy*

Background: A Doppler-derived time interval index has been recently proposed: the total ejection isovolume index (TEI index), defined as the sum of isovolumetric contraction and relaxation time divided by ejection time. The value of this index, that combines both systolic and diastolic performance of the left ventricle, has been observed particularly in patients with myocardial infarction and dilated cardiomyopathy. There is however little information about the additional clinical usefulness of TEI index in patients with severe aortic stenosis.

Methods: Ninety-two patients with severe aortic stenosis, defined as continuity equation aortic valve area < 1.0 cm^2, in sinus rhythm underwent echo-Doppler examination (53 males, 39 females; mean age 66±9 years). According to clinical symptoms, patients were classified into two groups: A) Asymptomatic or mildly symptomatic (NYHA I/II): 63 patients; B) More severely symptomatic (NYHA III/IV): 29 patients.

Results: A TEI index >0.45 was found in 14/63 (22.2%) patients in group A and in 23/29 (79.3%) in group B (p<0.001). Aortic valve area was 0.73±0.21 in group A and 0.78±0.21 in group B (p=ns). Maximum Doppler velocity was 4.69±0.75 m/s in group A and 4.66±0.71 m/s in group B (p=ns). There were not significant differences in ejection fraction (60±8% in group A and 57±7% in group B), E/A ratio (0.94±0.77 in group A and 0.88±0.47 in group B), deceleration time (162±71 msec in group A and 163±70 in group B). On the contrary, TEI index was significantly higher in more symptomatic patients (0.40±0.08 in group A, 0.64±0.26 in group B; p<0.001).

Conclusion: In patients with aortic stenosis, the prevalence of a TEI index >0.45 is significantly higher in patients with more severe clinical symptoms. This global performance index seems to be superior to the commonly used systolic and diastolic echocardiographic parameters in identifying patients with worse symptoms. TEI index could help to explain why some patients with severe aortic stenosis have important symptoms while other patients are asymptomatic. This index could then provide a useful tool for the clinical decision making in patients with aortic stenosis.

P1040 The effect of heart rate on the color M-mode Doppler flow propagation velocity and pressure half time in aortic insufficiency

A. onbasili, T. Tekten, C. Ceyhan, E. Ercan, T. Piskin. *Adnan Menderes University, Cardiology, AYDIN, Turkey*

It has been shown that increased heart rate may improve the hemodynmic condition of patients with aortic regurgitation. Color M-mode Doppler flow propagation velocity (FPV) was introduced as a method to assess the severity of aortic regurgitation. The purpose of this study was to evaluate the effect of heart rate on the color M-mode Doppler flow propagation velocity and pressure half time in aortic insufficiency

Method: Seventeen patients (7 male, 10 female, mean age 52±15 yrs) who had isolated aortic regurgitation of various degrees were included. Color M-mode Doppler was used in FPV while continuous wave Doppler was used in PHT measurements, both in the apical 5-chamber view. Atropin sulfate was titrated in all patients to reach a 20 increase in the heart rate. FPV and PHT of aortic regurgitation were measured before and after the increase of the heart rate.

Results: Increased heart rate resulted in significant decrease in FPV (49.5±14.4 vs 42.1±12.6 cm/sec; p<0.001) and it shortened PHT (476±177 to 376±116 msec; p<0.001).

Conclusion: The FPV and PHT of the aortic regurgitation are rate dependent. The influence of heart rate should be considered in evaluating changes of such parameters in the serial follow-up evaluation of patients with aortic regurgitation.

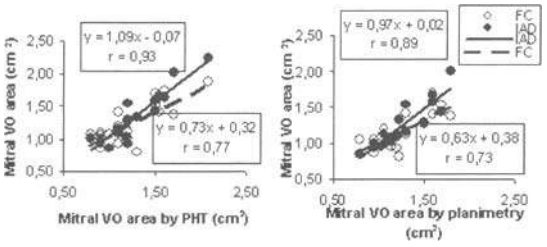
P1041 Interaliasing distance of the flow convergence surface for determining valvular orifice area in mitral stenosis: initial clinical experience

M. Sitges[1], T. Shiota[2], M. Azqueta[1], J.X. Qin[2], M.J. Garcia[2], J.D. Thomas[2], C. Paré[1]. [1]*Hospital Clinic, Cardiovascular Institute, Barcelona, Spain;* [2]*The Cleveland Clinic Foundation, Cardiovascular Imaging Center, Cleveland, United States of America*

The PISA or flow convergence (FC) method is an alternative to estimate valvular orifice (VO) area in mitral stenosis (MS) when accuracy of pressure half-time (PHT) or planimetry is not warranted. Recently, a new FC method which avoids locating the orifice by measuring the interaliasing distance (IAD) of the FC zone, was validated to quantify mitral regurgitation. Our aim was to evaluate the accuracy of the IAD method to estimate VO area in patients with MS.

Methods: 19 patients with MS were studied with 2D echo. Color Doppler M-Mode images along the centerline of the accelerating flow towards the VO were obtained. The distance between the two first aliasing boundaries proximal to the VO was measured and the FC radius was mathematically derived by the continuity equation (FC radius = IAD*3.41). The conventional FC radius was also measured. VO area was calculated according to the FC method using both IAD and conventional FC radius. Reference standard VO area was obtained by the PHT method and planimetry.

Results: Both mitral VO area calculated from IAD and conventional FC correlated well with VO area by PHT (r=0.93, SEE 0.15 cm^2 and r=0.77, SEE 0.20 cm^2, respectively, n=19)and by planimetry (r=0.89, SEE 0.14 cm^2 and r=0.73, SEE 0.18 cm^2, respectively, n=16)(Graph). There was a trend for a stronger correlation (p=0.07) and a smaller absolute error in favour of IAD (0.18±0.12 vs 0.12±0.10 cm^2, p=0.10).



Conclusion: Good correlation and agreement were observed between IAD-derived mitral VO and two reference methods, and similar to the ones observed with the conventional FC. However,the IAD method does not require spatial localization of the orifice. These data suggest that the IAD method is feasible and accurate to estimate mitral VO in patients with MS.

P1042 TDE reveals insufficient contractile reserve recruitment during exercise-echo in patients with mitral valve prolapse and thick mitral valve

A. Karavidas, J. Zampoulakis, E. Matsakas, G. Lazaros, J. Fotiadis, M. Foukarakis, F. Panou, A. Zacharoulis. *Athens General Hospital, Cardiology Dept., Athens, Greece*

Mitral valve prolapse (MVP) and thick mitral valve (TMV) have been associated with posterior-inferior wall motion abnormalities. Tissue Doppler echocardiography (TDE) is a promising technique for studying myocardial velocities. The aim of this study was to evaluate the tissue velocities at the basal-inferior wall, during symptom limited exercise echocardiography (EE), in patients (pts) with MVP and TMV.

Methods: Sixteen pts with typical MVP (aged 40±12 years, 20 pts with TMV, all of whom otherwise healthy, and 20 healthy subjects (HS), were studied. All individuals in the aforementioned groups were matched for age and sex. All pts underwent complete baseline echocardiographic study and EE. Peak systolic velocities (S) at the basal-inferior wall were measured by TDE at rest and immediately after the peak of the exercise. Mitral regurgitation (MR) was assessed by color Doppler. Statistical analysis was made with t-test, x2 and multivariate analysis which was performed with Cox regression.

Results: Baseline and peak exercise heart rate and blood pressure did not differ among MVP pts, TMV pts and HS. No wall motion abnormalities (either at rest or at the peak of the exercise) or significant changes in MR were observed in our study population. MVP pts developed in an earlier stage fatigue and dyspnea during the exercise test as compared with the other groups of pts. At rest S was greater in MVP pts (S=12.3±3cm/sec) compared with both, TMV pts (S=10.5±2cm/sec, $p<0.01$) and HS (S=9.5±1cm/sec, $p<0.0004$). During exercise the increase in S was significantly lower for MVP pts (S=17.3±5cm/sec, p=0.0008) and TMV pts (S=15.5±2.1cm/sec, p=0.0007) compared to HS (S=19.8±4cm/sec, p=0.0001).

Conclusions: i) No evidence of wall motion abnormalities was found with 2D echocardiography in MVP and TMV pts. ii) Systolic velocities at the basal-inferior wall in the aforementioned pts did not increase in response to exercise, suggesting insufficient contractile reserve recruitment. iii) The above velocities were higher in the resting state, probably due to the augmented adrenergic tone.

P1043 One-year echocardiographic follow-up of left-sided valvular disease in carcinoid syndrome

F. Digne, N. Mansencal, J.F. Forissier, T. Joseph, G. Jondeau, P. Rougier, P. Lacombe, O. Dubourg. *Hôpital Ambroise Paré, Service de Cardiologie, Boulogne Cedex, France*

Background: Right-sided valvular disease is well known in carcinoid syndrome but little is known about the left-sided valvular disease. The aim of our study was to assess the incidence of both right and left-sided valvular diseases and to determine the role of patent foramen ovale (PFO) with this left-sided valvular disease.

Methods: Forty-six consecutive trans-thoracic echocardiographies (TTE) have been performed in 23 pts (mean age 60 ± 8 years, 52% women) presenting with carcinoid syndrome, at control and at one-year follow-up. The echocardiographic following parameters were assessed: 1) right-sided valvular disease, 2) left-sided valvular disease, 3) right to left shunting through a patent foramen ovale (PFO +) using contrast echocardiography at rest and after cough test or Vasalva maneuver.

Results: At control, TTE revealed 6 pts (26%) with right-sided valvular carcinoid disease (RVCD), 3 pts (13%) with left-sided valvular carcinoid disease (LVCD) and 8 PFO + (35%). At one year, the incidence of RVCD, LVCD and PFO + was 30% (7 pts), 23% (5 pts) and 39% (9 pts) respectively. All patients with RVCD and PFO + exhibited progression or new appearance of left-sided valvular disease.

Conclusion: According to follow-up, our data suggest that the incidence of left-sided valvular injury is higher than previous studies in carcinoid syndrome. PFO + resulting in right to left shunting seems to be a major factor of left-sided valvular injury and should be systematically researched in carcinoid syndrome.

P1044 Aortic valve calcification in hypertensive patients: prevalence, risk factors and association with transvalvular flow velocity

A. Tenenbaum, E. Fisman, E. Schwammenthal, Y. Adler, J. Shemesh, V. Boyko, M. Motro. *Sheba Medical Center, Tel Hashomer, Ramat Gan, Israel*

Background: The important role of the "nonobstructive" aortic valve calcification (AVC) in cardiovascular morbidity and mortality has recently been emphasized. Data regarding the factors determining the extent of AVC and its interrelationship with flow velocity across the aortic valve are scarce and discordant. The present work had two goals: 1) To analyze the prevalence and the factors determining the extent of AVC in hypertensive patients; 2) To investigate a possible association between the extent of AVC and flow velocity across the aortic valve in patients without established aortic stenosis.

Methods: It was a prospective comparative crossectional study performed in a cardiology department in a general hospital. The study sample consisted of 263 consecutive patients (139 men and 124 women, aged 52-79 years, mean 65±6), who underwent echo-Doppler. A calcified deposit of <2 mm in its highest thickness was defined as minimal, a deposit ranging from 2 to 5 mm as mild and a calcified deposit of more or equal than 5 mm, as significant. Advanced AVC was defined as follows: a) Presence of at least one significant calcified deposit or b) Presence of 2 or more mild calcified deposits. There were 31(12%) patients in the advanced AVC group and 122 (46%) patients without any calcified deposits (the No AVC group). The remaining 110 (42%) patients who did not meet criteria of the advanced AVC comprised the Trivial AVC group.

Results: The upper quartile of peak flow velocity across the aortic valve (>130 mm/sec in our population) was defined as augmented flow velocity. Peak flow velocity across the aortic valve was significantly higher in patients with advanced versus trivial AVC and no AVC groups: 135±45, 116±23 and 113±23 mm/sec, respectively; p=0.0002. Prevalence of augmented transvalvular aortic flow was significantly higher (p=0.01) among patients with advanced AVC (41.9%) versus trivial (20.9%) and no AVC (29.5%). Multivariate analyses identified age as the only independent variable associated with advanced AVC [OR 1.6 (CI 1.2-2.3), 5 years increment] and any AVC [OR 1.5 (CI 1.2-1.9)]. Advanced AVC and female gender were identified as independent variables for augmented transvalvular aortic flow with OR 2.9 (CI 1.3-6.4) and 2.5 (CI 1.4-4.6), respectively.

Conclusions: Prevalence of AVC among hypertensive patients is high and clearly age-related. Advanced (but not trivial) AVC is associated with augmented aortic transvalvular peak flow velocity despite unrestricted opening of the valve leaflets.

P1045 Influence of postoperative anemia on valve gradient measurement by Doppler echocardiography

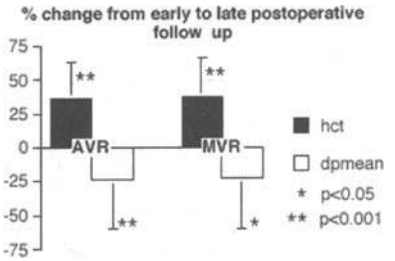
L. Haegeli[1], P A. Kaufmann[2], R. Jenni[1]. [1]*Cardiovasc. Center, Echocardiography, Zurich, Switzerland;* [2]*Cardiovascular Center, Nuclear Cardiology, Zurich, Switzerland*

Background: The accuracy of early postoperative Doppler echocardiographic gradient measurements after valve replacement may be affected by postoperative anemia.

Purpose: To assess the influence of the postoperative recovery of hematocrit (hct) and hemoglobin values on the Doppler measurements of valve gradients.

Methods: Transthoracic Doppler echocardiography was used to assess postoperative valve function.

Results: In 38 patients maximal instantaneous (dpmax) and mean (dpmean) pressure gradient was assessed 10+5 days and 268+318 days after aortic valve replacement (AVR). In 12 patients dpmean and pressure half time (p/2-time) was assessed 10+5 and 306+311 days after mitral valve replacement (MVR). In AVR dpmax decreased from 26+12 to 20+9 mmHg ($p<0.005$) and dpmean from 14+8 to 11+6 mmHg ($p<0.005$). In MVR p/2-time remained unchanged (76+18 vs 76+14 ms) but dpmean decreased significantly (5+1 vs 4+2 mmHg, $p<0.05$). This was paralleled by an increase in hct (28+4% to 38+6%, $p<0.0001$) and hemoglobin (9.2+11.4 g/dl to 12.3+2.0 g/dl, $p<0.0001$) in AVR aswell as in MVR (28+4% to 37+5%; $p<0.0001$ and 8.9+1.4 to 12.2+1.8 g/dl; $p<0.0001$). See figure.



Conclusions: Early postoperative Doppler echocardiographic routine gradient measurements after valve replacement should not be used as baseline characterization for future follow up because they may provide misleading results due to the hyperdynamic state induced by postoperative anemia.

P1046 Cardiac involvement in pulmonary sarcoidosis. An echocardiographic evaluation study

L. Sargento[1], C. David[2], A. Almeida[2], A.C. Mendes[3], J. Vyscaio[3], S. Furtado[3], A. Bugalho de Almeida[3], M. Celeste Vagueiro[2]. [1]*LUIS SARGENTO, OEIRAS, Portugal;* [2]*H.Sta Maria, Cardiologia, Lisboa, Portugal;* [3]*H. Sta Maria, Pneumologia, Lisboa, Portugal*

Background: Sarcoidosis is a multisystem disorder of unknown aetiology characterised by infiltration of several organ system by caseating granulomes. The aim of this study was to identify the presence and patterns of cardiac involvement in patients (pts) with pulmonary sarcoidosis.
Methods: We studied 53 consecutive pts with pulmonary sarcoidosis (45 women, age 49 ±13 years), without cardiac disease, followed in an ambulatory specialised clinic. Clinical data: NYHA functional class; sarcoidosis stage (0 to 3); disease duration, RFT and corticotherapy. Echocardiographic study included the analysis of cavities dimensions, left ventricle (LV) walls hyperechogenicity, systolic LV function and Doppler measurements of mitral and tricuspid flows (E/A ratio, desacceleration time, A wave duration); pulmonary venous flow (s, d and a waves, a wave duration), systolic tricuspid flow (in patients with tricuspid regurgitation) and pulmonary valve flow (acceleration and ejection times).
Results: Half of the pts had at least one echocardiographic abnormality. In 21 (33%) there was hyperechogenicity of the ventricular septum, suggestive of possible myocardial infiltration, in 20 (36%) there was right ventricular enlargement, in 20 (36%) pulmonary valve flow had criteria for pulmonary hypertension. Left ventricle diastolic dysfunction (LVDD) pattern found in 14 subjects, 12 with impaired relaxation and 2 with restrictive physiology. In twelve pts, the tricuspid flow desaceleration was above 210 ms.
Association with clinical data: (1) Septum hyperechogenicity: was less frequent in pts who had been previously treated with corticosteroids (35% vs. 64%; $p<0,05$); was associated with lesser tricuspid valve inflow velocity ($r= -0.55$ $p<0.01$) however was associated with the pulmonary artery systolic pressure ($r= 0.55$ $p<0.05$); (2) Longer the disease duration higher the incidence of LVDD ($p<0.01$). Pts with disease duration lesser than 5 years did not have LVDD.
Conclusions: Echocardiographic abnormalities are frequent in subjects with pulmonary sarcoidosis and there is a possible relationship between the valvular Döppler flow patterns, pts clinics and corticotherapy.

P1047 Impact of Transoesophageal Echocardiography (TEE) in the diagnosis and outcome of patients with infected pacemaker and defibrillator leads

T. Padder[1], B. Kantharia[1], F. Padder[1], A. Ivanov[1], G. Panjrath[2], V. Patel[2], C. Saari[1], S.P Kutalek[1]. [1]*Hahnemann University Hospital, Cardiac Electyrophysiology, Philadelphia, United States of America;* [2]*Hahnemann University Hospital, Nuclear Cardiology, Philadelphia, United States of America*

Background: Infection is one of the most important indications for pacemaker and ICD lead extraction as infection rate of these devices ranges from 4-7%. Ten years ago the morbidity and mortality from infection of these devices without explantation was around 60%. This emphasizes the importance of rapid and accurate diagnosis of infection leading to the removal of the entire system as soon as possible The clinical manifestation of infection are multiple: fever, local inflammation, erosion, endocarditis and vegetation. With the use of echocardiography especially Transesophageal Echocardiography (TEE), clinicians can make accurate and fast diagnosis of infection thereby helping in the diagnosis and management of this devastating problem.
Purpose: Assessment of the impact of TEE on the planning, performance and outcome of pacemaker and defibrillator lead extraction.
Method: Prospective data analysis was done on all patients treated at Hahnemann University Hospital from Jan.1991- Nov.2001 for lead extraction. Only patients who had TEE done before or after lead extraction were included.
Results: 100 patients with 250 leads were dignosed with device related infection with the help of serial blood cultures and TEE. TEE confirmed the device infection in 2 patients with negative blood cultures. During pre-operative TEE, vegetation was found in 22 patients. Vegetation ranged in size from 0.2 to 3 cm in largest dimension. Infection was caused by Staphylococcus in 82% patients, Enterobacter 5%, Pseudomonas 5%, Streptococcus 5% and 1% each by Candida, Citrobacter, Cornybacterium, and Propionibacterium. Complete device removal was achieved in 95% patients. Postoperative TEE was performed in all patients with vegetation. Reimplantation of a new device was performed in 84% patients after negative blood culture and negative TEE. No TEE related complications were noted.
Conclusion: We conclude that TEE is the diagnostic tool of choice in the patients with clinical suspicion of lead infection. TEE monitoring during lead extraction provides real time information enabling the operator to better plan the procedure and rapidly diagnose complications. TEE also provides guidelines about the time frame of reimplantation of new device.

P1048 Biventricular pacemaker/ICD-implantation in the operating room: guidance of coronary sinus intubation by transoesophageal echocardiography

R. Schimpf[1], C. Wolpert[2], H. Omran[1], B. Esmailzadeh[3], S. Herwig[1], K-M. Jeong[1], O. Balta[1], B. Lüderitz[1]. [1]*University of Bonn, Dept. of Cardiology, Bonn, Germany;* [2]*Universitätsklinikum Mannheim, 2. Medizinische Klinik, Mannheim, Germany;* [3]*University of Bonn, Dept. of Cardiac Surgery, Bonn, Germany*

Biventricular pacing has been introduced to improve quality of life and cardiopulmonary performance in patients with advanced congestive heart failure. Location and implantation of the additional left ventricular electrode via the coronary sinus (CS) in cardiac veins is significantly prolonging the duration of surgery as the crucial point of the procedure. In the setting of anteroposterior fluoroscopy technique in the operating room additional transesophageal echocardiography (TEE) was used to guide proper lead placement and verification of lead location and for immediate hemodynamic monitoring.
Patients and methods: 25 patients with severe congestive heart failure (NYHA class 3.2 mean) were enclosed in the study. Underlying heart disease was coronary heart disease (n=9) and dilated cardiomyopathy (n=16). The patients received a biventricular pacemaker or ICD (Medtronic InSync, Guidant Contak CD/TR). During the procedure additional intraoperative echocardiography was applied. Guidance of CS-intubation, final electrode position, mean QRS-width, NYHA-class, exercise capacity and ejection fraction, were analysed during follow up. Results: CS intubation could be guided in all cases by TEE. The mean ejection fraction, NYHA-class increased significantly (24%±8.2% vs 34,2±8.7% and 3.1±0.16 vs 2.2±0.54), QRS-width decreased significantly (168± 22ms vs 135±15 ms) ($p<0.05$).
Conclusions: 1. In the absence of intraoperative biplane fluoroscopy technique transesophageal echocardiography improves coronary sinus intubation and time for lead placement. 2. Biventricular stimulation established significant benefit for the patient in this implantation setting.

P1049 The association between aortic atheroma and ischaemic cardiomyopathy

S. Maraj[1], N. Wongpraparut[1], S. Apiyasawat[2], T.A. Malik[1], L.E. Jacobs[1], M.N. Kotler[1]. [1]*Albert Einstein Medical Center, Department of Cardiology-Klein 363, Philadelphia, United States of America;* [2]*Albert Einstein Medical Center, Department of Medicine, Philadelphia, United States of America*

Objective: The association between the pathogenesis of aortic atheroma (AA) and ischemic cardiomyopathy (ICM) has not been established. We studied the correlation between the presence and degree of AA with the presence or absence of coronary artery disease (CAD).
Method: We studied 81 patients (pts) with a diagnosis of cardiomyopathy who had undergone both transesophageal echocardiography (TEE) and cardiac catheterization (CC) between 1996 and 2002. A luminal diameter narrowing of > 70% in one or more epicardial arteries was considered significant for CAD. Pts were classified into a non-ICM group (normal coronary arteries) and an ICM group (presence of one or more epicardial CAD). We documented the presence, location and degree of significant AA (plaque grade > 3). Clinical, TEE and CC parameters were analyzed. Statistical analysis was performed by ANOVA t-test and Spearman's correlation test.
Results: 29 (60.4%) pts in the ICM group had significant atherosclerosis of the ascending aorta and aortic arch compared to 2 (6.1%) pts in the non-ICM group ($p<0.0001$). Multivariate analysis showed hypertension (HT), smoking and diabetes mellitus (DM) to be more common in the ICM group than in the non-ICM group (Table 1). A close association was observed between the presence of CAD and the severity of the plaque in the ascending aorta ($p< 0.0001$), aortic arch ($p< 0.0001$), and descending aorta ($p< 0.0001$). Multivariate analysis of other clinical variables such as age, sex, history of alcohol abuse, stroke, history of viral myocarditis, hyperlipidemia, medications and other TEE and CC variables were not significant.

Risk Factors	ICM (n=48)	N-ICM (n=33)	p-value	RR (95% CI)
Smoking	42 (87.5%)	4 (12.9%)	0.0001	24.5 (7-85.2)
HT	41 (85.4%)	9 (31%)	0.0001	13.7 (4.5-41.9)
DM	19 (39.6%)	4 (12.9%)	0.009	4.6 (1.4-15.2)
Significant AA	29 (60.4%)	2 (6.1%)	0.0001	23.7 (5.1-110.6)

Clinical and echocardiographic predictors of ischemic cardiomyopathy (RR=relative risk, CI=confidence interval)

Conclusion: As expected, traditional risk factors such as smoking, HT, and DM are associated with ICM. In addition, the presence and severity of AA is strongly associated with ICM. Conversely, the absence of significant AA has a high negative predictive value for excluding ICM (93.9%).

P1050 Fibrinolysis and thrombosis of mechanical prosthetic valve: risk stratification by TEE

R. Roudaut, S. Lafitte, J.M. Perron, C. Jaïs, P. Coste. *Hôpital Cardiologique, PESSAC, France*

Fribrinolysis treatment in prosthetic valve thrombosis appears to be an attractive alternative to surgery but is still controversial because of the well-known embolic risk. The objective of this study was to assess the impact of TEE upon the risk stratification.
Methods: We analyzed 49 patients with a prosthetic valve thrombosis confirmed by TEE and subsequently treated by fibrinolysis. The involved prosthetic valves were mitral for 37, aortic for 11 and tricuspid for 1. We observed 11 non obstructed thrombosis (NOT) and 37 obstructed (OT). Clinical events and fibrinolytic treatment efficacy were studied related to the criteria of valve obstruction and to the thrombus size < 10 mm (n = 33) or superior or equal to 10 mm (n = 16).
Results: Complete recovery of the normal prosthetic motion was achieved by the fibrinolysis regimen in 34 patients (69.4%). In term of complications, we observed 2 early cerebral haemorrhages (4.1%) one in the NOT group and one in the OT group, 6 peripheral embolisms (12.2%) (one in the NOT group). No significant statistical association was found between thrombus size and embolic event rate. However, the risk of treatment failure and/or complications (embolism) was related to the thrombus size (full success when thrombus size < 10 mm: 82% versus 35% when thrombus size is superior or equal to 10 mm, $p < 0.05$). Conclusion: TEE is of major interest in the management of prosthetic valve thrombosis. As far as FT is considered it will be safer and more effective when thrombus formation is small.

P1051 Co-relation of flow sample curves in Coronary Sinus with the Pathophysiology coronary circulation analyzed by transoesophageal echocardiography

J. Ramos[1], J. Ramires[2], M. Turina[3], M. Lachat[3], M. Macedo[1], D. Martins[1]. [1]*University Sao Franscisco, Cardiology, Bragança Pailista, Brazil;* [2]*University of Sao Paulo, Heart Institute (Incor), Sao Paulo, Brazil;* [3]*Universitätsspital Zürich, Klinik für Herz und Gefässchirurgie, Zürich, Switzerland*

Background: Thansoesophageal echocardiography (TEE) has proved to be a useful method to evaluate coronary flow velocity analysis in coronary sinus (CS) using Doppler measurement during continuous infusion of adenosine.
Objective: Our study had the propose to evaluate systolic velocity (SV), diastolic velocity (DV) and flow sample curves morphology within CS in healthy volunteers and Patients with obstructive coronary arteries lesions before and after Coronary Artery Bypass Graftings (CABG) with intravenous adenosine infusion.
Methods: Through TEE with adenosine infusion in a dose of (140ug/Kg/min for 4 min) adequate flow velocity and morphology curves were evaluated within CS in 10 healthy volunteers (mean age 37 ± 8 years; 5 women) and 23 patients (mean age of 68 ± 14 years; 17 men) with multiarterial obstructive lesions (>70% luminal diameter narrowing) before and 52 ± 16 days after CABG.
Results: Flow velocities in healthy volunteers and patients before and after CABG are shown in table 01. CFR in the control group was (3,5 ± 0,33 4°min) and in patients pre and post bypass surgery (1,7 ± 0,27 4°min, 3,1 ± 14 4°min) respectively. Differences pre and post procedures were considered significant when P<0,05.

Table 1: Systolic Flow Velocity in CS

Condition	Normal SV	pre-CABG SV	post-CABG SV
basal	39±8 cm/s	32±6 cm/s	39±5 cm/s
Aden 1 min.	68±18 cm/s	38±6 cm/s	50±8 cm/s
Aden 2 min.	88±20 cm/s	41±9 cm/s	58±13 cm/s
Aden 3 min.	106±22 cm/s	53±7 cm/s	73±15 cm/s
Aden 4 min.	111±19 cm/s	58±10 cm/s	80±17 cm/s

Abbreviations:CS=coronary sinus; Aden=adenosine; min=Minute; SV=systolic velocity; CABG= coronary arteries bypass graftings.

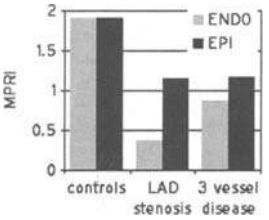
Conclusion: Flow velocities (SV and DV) and CFR in CS increased during adenosine infusion in healthy volunteers and patients before and after procedures, but in patients without reaching the level of the normal flow velocities.

MAGNETIC RESONANCE IMAGING: WHAT'S NEW?

P1052 Assessment of stress induced reduction of subendocardial bloodflow in patients with coronary artery disease with magnetic resonance imaging

E. Nagel, I. Paetsch, E. Fleck. *German Heart Institute, Cardiology - CMR, Berlin, Germany*

Subendocardial perfusion is highly sensitive for the detection of myocardial ischemia, however, current methods, such as SPECT and PET lack sufficient spatial resolution to discriminate between different layer. MR perfusion measurements offer sufficient spatial resolution. Our aim was to assess, whether separate analysis of subendo- (ENDO) and subepicardial (EPI) perfusion increases diagnostic accuracy for the detection of significant coronary artery disease (CAD).
Methods: 47 patients (pts) (30 male, age 62±7 yrs) with previous invasive angiography were included. 17 pts had single vessel CAD, 20 three-vessel disease, and 10 no significant CAD. Pts were examined with a 1.5 T MR scanner (Philips ACS NT) at rest and during adenosine stimulation (140µg/kg bw) and the first pass of a contrast agent (Gd-DTPA 0.025mmol/kg bw) injected as a peripheral bolus was visualized in 5 short axis views (TFEPI, TE/TR/flip 3.3/12/30, spatial resolution 1.7x2.2 mm). The myocardium was divided into 6 endo- and epicardial segments per slice (60 segments total) and the max. upslope of the myocardial signal intensity time curves was determined. Myocardial perfusion reserve index (MPRI) was calculated as the upslope at stress divided by the upslope at rest.
Results: A close correlation between ENDO and EPI was found (r^2=0.85) with a 35% higher ENDO perfusion in comparison to EPI. At rest, MPRI was similar for ENDO and EPI. At stress, ENDO perfusion was reduced to a higher extent, than EPI. Diagnostic accuracy improved from 89% (transmural) to 94% (ENDO).



Conclusions: MR perfusion measurements allow the differentiation of subendo- and subepicardial blood flow. Subendocardial perfusion is more sensitive to ischemia, than subepicardial perfusion resulting in an improvement of diagnostic accuracy.

P1053 Rapid evaluation of myocardial viability by contrast-enhanced MRI using a three-dimensional inversion-recovery (IR) sequence

H.P. Kühl[1], T. Papavasiliu[2], A.M. Beek[2], M.B.M. Hofman[3], A.C. van Rossum[2]. [1]*University Hospital, Medical Clinic I, Aachen, Germany;* [2]*VU University Medical Center, Department of Cardiology, Amsterdam, Netherlands;* [3]*VU University Medical Center, Dep of Medical Physics and Informatics, Amsterdam, Netherlands*

Delayed contrast-enhanced magnetic resonance imaging (DCE-MRI) allows assessment of myocardial viability in patient with ischemic heart disease. The current approach requires multiple breath-holds to generate a set of images covering the left ventricle which is time-consuming and may introduce misregistration of slices. We evaluated a novel approach using a 3D sequence which allows complete data acquisition within one breath-hold.
Methods: 10 patients with chronic coronary artery disease (62±12 years, 3 females) underwent DCE-MRI on a 1.5T MR scanner (Sonata, Siemens, Erlangen, Germany) for viability assessment 15 minutes after 0.2 mmol/kg Gadolinium-DTPA. For the standard approach we used a 2D segmented IR gradient-echo sequence (25 segments, TR/TE 9.6/4.4, FA 25°, TI 250-300 ms, matrix 208x256, resolution 1.3x1.6x5mm) with data acquisition every other heartbeat. For the 3D approach we used a segmented IR gradient-echo sequence (77 segments, TR/TE 2.8/1.1, FA 25°, TI 200-230 ms, matrix 256x208x12, resolution 1.4x1.4mm, slice thickness 8.3mm reconstructed to 5mm) with data acquisition every heart beat. Double oblique short-axis views covering the left ventricle were acquired with identical orientation using both sequences. In matched images total myocardial areas and DCE areas for both techniques were assessed and the signal to noise ratio (SNR) for DCE myocardium as well as contrast to noise ratios (CNR) for DCE vs. non-DCE myocardium and blood was calculated. The accuracy of the 3D sequence to detect the presence of DCE compared to the 2D sequence was evaluated in 8 sectors per slice in each patient. Observer agreement for the presence and the transmurality of DCE was evaluated in a randomized, blinded fashion.
Results: Imaging was successful in all patients. Myocardial areas and DCE areas were not different between the 2D and 3D sequence (p=ns). The accuracy of the 3D sequence to detect the presence of DCE was 92%. SNR and CNR were 3 to 4-fold larger for the 3D sequence compared to the 2D sequence. Agreement between two observers was 95% for the presence of DCE (Kappa=0.90) and 88% for the transmurality of DCE (Kappa=0.77).
Conclusions: Detection of DCE using the 3D sequence is feasible in one single breath-hold and accurate compared to the standard 2D sequence. The improved SNR and CNR facilitate recognition of the DCE area. This fast sequence should be used for rapid screening for the presence of DCE. Acquisition of selected images using the 2D sequence can be added for accurate quantification of the transmural extent of DCE.

P1054 Assessment of perioperative myocardial infarction associated to coronary artery bypass surgery using contrast-enhanced magnetic resonance imaging

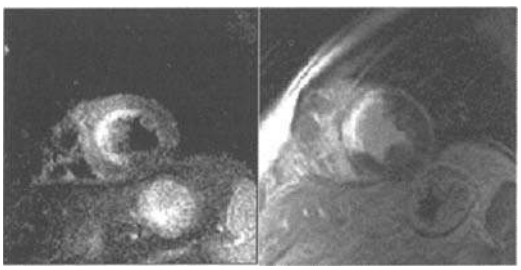
M. Regenfus[1], H. Mahrholdt[2], A. Wagner[2], C. Schlundt[1], J. von Erffa[1], R.M. Judd[2], R.J. Kim[2], W.G. Daniel[1]. *[1]FAU Erlangen-Nürnberg, Medical Clinic II, Erlangen, Germany; [2]Feinberg CV Research Institute, Northwestern University, Chicago, United States of America*

Background: It is unknown whether routine, successful coronary artery bypass surgery (CABG) is associated with perioperative myonecrosis. Contrast-enhanced MRI (ceMRI) is able to visualize both transmural and subendocardial myocardial infarction (MI). Hereby, MI is represented by hyperenhancement (HE).
Methods: 48 patients (pts) underwent cine and ceMRI before and after CABG on a 1,5 T scanner (SONATA, Siemens). The pattern of hyperenhancement (HE) and regional myocardial function was compared using a 72-segment model. The amount of new hyperenhancement (HE) after CABG and ejection fraction (EF) was quantified by planimetry. ECGs were analyzed as to presence of Q-waves using the Minnesota-Code.
Results: Before CABG, 18 pts (38%) had electrocardiographic Q-waves but 38 (79%) had evidence of prior MI (HE present). After CABG, only 6 pts (10%) had new Q-waves but 20 (48%) had new areas of HE. The median mass of perioperative myonecrosis based on the volume of new HE was 5.4 gm (0.3-48.9) or 2.1% (0.1-33.0%) of left ventricular mass. EF increased 7.1+9.5 points and the level of improvement was not different between pts with and without new HE (P=0.66). Regional contractility, however, showed significantly more improvement after CABG in patients without new HE ($p<0.0001$).
Conclusions: Perioperative myocardial damage is common following routine, successful CABG. The rate of new MI is significantly underestimated by electrocardiographic criteria but the volume of necrosis is small and appears to have minimal impact on the level of contractile improvement following CABG. Improvement of regional function, however, is impaired in patients with new MI.

P1055 The sensitivity of heavily T2-weighted MRI to detect acute myocardial infarction – Relation to "delayed enhancement"

M.G. Friedrich, H. Abdel-Aty, J. Schulz-Menger, R. Dietz. *Franz-Volhard-Klinik, Cardiology, Charite Campus Buch, Berlin, Germany*

Background: Heavily T2-weighted magnetic resonance imaging (MRI) is suitable for the detection of the tissue edema. Newer techniques such as triple-inversion-recovery-based SE sequences show a reproducibly high image quality with an excellent contrast-to-noise in detecting tissue edema. Especially the sensitivity of this technique in acute myocardial infarction, however, is unknown.
Patients and Methods: We have studied 51 patients (age 59±13y.) 3±1 days after acute myocardial infarction, as defined by clinical means, typical ECG patterns, elevated troponine T, and invasively confirmed related coronary occlusion or stenosis. In a 1.5 T MRI scanner using a body coil and a short-TI-inversion-recovery sequence (STIR, TE 64ms, TR 2 RR intervals, TI 140ms, acquisition time 16 to 20 sec) in 3 short axis views. Results were compared to contrast-enhanced inversion-prepared gradient-echo images ("delayed enhancement", TI 220 to 250msec) in the same slice position. A blinded analysis was performed.
Results: Image quality was adequate to excellent for the diagnosis in all cases. In all patients, the infarct-related region revealed a bright signal intensity (sensitivity 100%). Fig. 1 shows infarct-related edema (left panel) and delayed enhancement (right panel) of an anteroseptal infarction. The edematous area tended to slightly extend that of the area of "delayed enhancement". An intraluminal high-intensity signal area was also observed (see fig. 1).



Conclusion: Heavily T2-weighted MRI allows the confirmation of suspected acute myocardial infarction with an excellent sensitivity. Thus, in a clinical setting, contrast-enhanced MRI may only be necessary for more chronic infarctions. However, an overestimation of the infarct size may occur.

P1056 Plaque-targeted MRI contrast media; introducing a novel SPIO contrast media for magnetic resonance imaging of macrophage infiltration in vulnerable plaque

M. Azadpour[1], D. Chan[2], M. Madjid[1], C. Jagannath[3], M. Naghavi[1], W. Casscells[1], J.T. Willerson[1]. *[1]Center for Vulnerable Plaque Research, Univ. of Tex-Houston and Tex Heart Ist., Houston, United States of America; [2]University of Colorado Health Science, Department of Oncology, Houston, United States of America; [3]Univ of Texas-Houston Health Sc Cent, Department of Molecular Pathology, Houston, United States of America*

SPIO (super paramagnetic iron oxide) is a MRI blood pool contrast media in the form of nano-particles consisting of a central core of iron oxide traditionally coated by colloidal polysaccharide mainly dextran. We have shown that dextran-coated SPIO including the commercially available SPIO (Feridex) is taken up by macrophages in atherosclerotic plaques of Apo E K/O mice and Watanabe rabbits. However, their uptake was followed by a significant rise in intracellular oxidative enzyme activity mainly due to respiratory burst associated with the digestion of dextran in macrophages. Also we needed to increase macrophage uptake in lipid rich plaques. Here we report a novel liposomal SPIO. We hypothesize that lipid-coated SPIO particles enter macrophages through a different pathway allowing more uptake with less oxidative stress.
Methods: Mouse peritoneal macrophages were isolated in the culture medium and incubated with different SPIOs for 4 hrs and then washed. After 24 hrs, production of NO was measured in supernatant by Greiss reagent. In a second series of experiments fluorescent-labeled SPIO (FL-SPIO) was added to macrophages in the presence of two inhibitors of mannose receptor: dextran and mannan. Intracellular retention of FL-SPIO was measured after 2 hrs in 4 groups of macrophages with SPIO, SPIO and dextran, SPIO and mannan and no SPIO as control.
Results: See Figure 1 ($p<0.05$). Also FL-SPIO studies showed that mannan a known inhibitor of mannose receptor significantly inhibited macrophage uptake of dextran coated SPIO but not lipid coated SPIO.

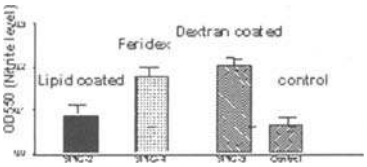


Fig. 1: NO production by dextran coated vs. lipid coated SPIO particles in macrophages 24 h.

Conclusion: Liposomal SPIO is a promising candidate for contrast-enhanced MR imaging of macrophage infiltration in vulnerable plaque. Receptor-targeted liposomal SPIO may further improve plaque-targeted MR imaging.

P1057 Prognostic value of a residual false lumen in aortic dissection submitted to surgery. A magnetic resonance prospective study

A G. Almeida[1], M. Pacheco[2], J. Fancony[3], L. Beja[3], J. Cravino[3], M.C. Vagueiro[2]. [1]*Hospital Santa Maria, Cardiology Piso 8, Lisbon, Portugal;* [2]*Hospital Santa Maria, Cardiology Piso 8, Lisbon, Portugal;* [3]*Cardiothoracic Surgery Service, Hospital Santa Maria, Lisbon, Portugal*

Patients (pts) with aortic dissection submitted to surgery remain at risk of long-term complications. The aim of this study was to assess the prognostic influence of the presence and permeability of a residual false lumen, in pts operated for aortic dissection with involvement of ascending aorta.

Methods: We studied 43 pts, 23 men, with a mean age 53.8±1.7, operated for Stanford type A aortic dissection (ascending aorta replacement in 22 pts, with valve resuspention in 7, with aortic valve prosthesis in 9 and Bentall procedure in 5). All pts were submitted to a magnetic resonance study (MRI) at two months after surgery and, afterwards, annually, for three years. MRI study included: fast spin echo, in axial, coronal and oblique sagital planes; fast gradient-echo in axial plane; cine MR in selected planes, for flow evaluation and aortic valve function. For analysis, aorta was classified in four segments: ascending (proximal to the aortic graft), arch, descending thoracic and abdominal. Endpoints: aneurysm (thoracic segments > 49 mm and abdominal > 39 mm), pseudoaneurysm or aortic valve regurgitation development.

Results: Total follow-up time was 39.1±2.7 months. At initial evaluation, no pt had aneurysm and none had more than mild aortic valve regurgitation. During follow-up, aneurysms were detected in 31/167 segments of 19 pts (41.9%) and moderate or severe aortic regurgitation developed in 12 (42.9%). A residual false lumen was present in 73 segments of 24 pts (in 19 involved all distal aorta), which remained present during follow-up. There was persistent patency of false lumen in 63 segments (86.3%), thrombosis in 2 (2.7%) and variable patency in 6 (8.2%). A false lumen in arch was associated with a 6.6 relative risk (RR) for aneurysm in the same segment (95% c.i.,1.8-23.8, p=0.001), while in descending thoracic with a 2.3 RR (95% c.i.,0.9-6.8, p=0.01) and in abdominal with a 2.3 RR (95%c.i.,0.7-8.6, p=0.01). Patency patterns weren't associated to increased risk of aneurysm. False lumen presence and patency didn't have influence on aortic regurgitation.

Conclusions: In this prospective MRI study, patients operated for aortic dissection with ascending segment involvement had high incidence of long-term complications. The presence of a residual aortic false lumen was associated with increased risk of aneurysm development.

P1058 Simultaneous assessment of wall motion and perfusion during high-dose dobutamine-atropine stress MRI improves diagnosis of ischaemia

A. Wahl, S. Roethemeyer, I. Paetsch, S. Huehns, C. Klein, E. Fleck, E. Nagel. *German Heart Institute Berlin, Cardiology, Berlin, Germany*

Introduction: With MR, both the assessment of wall motion during high dose dobutamine stress (DSMR), and of myocardial perfusion during adenosine stress are highly accurate. Since high-dose dobutamine has been shown to fully exhaust myocardial resistance, like the direct coronary vasodilator adenosine, we investigated whether a simultaneous assessment of wall motion and myocardial perfusion reserve during the same DSMR examination improves diagnosis of ischemia.

Methods: 80 consecutive pts (59±8 yrs; prior myocardial infarction 50%; prior percutaneous or surgical revascularization in 83% and 20%) underwent DSMR (1.5 T Philips), prior to clinically indicated invasive coronary angiography. DSMR images were acquired at rest and during a standardized high-dose dobutamine-atropine protocol in 3 short-axis, a 4- and a 2-chamber view (single-slice segmented GRE; TR/TE/flip 5.6/1.9/25; spatial res<1.5x2.5x8 mm; temporal res<30 ms). Regional wall motion was assessed by consensus between 2 blinded observers using a multiple screen format (MASS 4.2, Medis), a 16 segment model and a four-point scoring system. DSMR was defined as positive for ischemia in the presence of a new or worsening wall motion abnormality in >=1 segment. During the same stress test (only at rest and 20 μg.kg-1.min-1), myocardial perfusion was assessed during the first pass of a gadolinium-DTPA bolus from 60 dynamic images acquired every heartbeat (3 identical short axis views; single shot TFE-EPI hybrid sequence with saturation prepulse; pp-delay 200 ms; TR/TE/flip 3.6/12/30; spatial res<2.4x2.4x8 mm). Myocardial perfusion reserve was calculated from the alterations of the upslope of the signal intensity time-curve (MASS) and segments were classified as ischemic or normal according to a previously determined threshold.

Results: Significant CAD (>=50% diameter stenoses by QCA) was found in 57 pts (71%). Wall motion analysis was non-diagnostic in 8 pts (10%, target heart rate not reached) and perfusion measurements in 26 pts (33%, poor image quality). Sensitivity and specificity of wall motion analysis for detection of significant CAD were 86% and 81%, as compared with 92% and 53% for perfusion analysis, and 87% and 78% for a combined analysis, with only 4% non diagnostic examinations.

Conclusions: A simultaneous assessment of wall motion and myocardial perfusion reserve during DSMR is safe and feasible in pts with known CAD. Compared with wall motion analysis alone, diagnostic yield is improved. However, the diagnostic accuracy of perfusion measurements alone is relatively low with the stress scheme applied.

P1059 Measurement of vasodilator reserve in coronary grafts using magnetic resonance tomography

N. Abegunewardene[1], T. Voigtlander[1], K.F. Kreitner[2], S.E. Petersen[1], T. Wittlinger[1], G. Horstick[1], M. Thelen[2], J. Meyer[1]. [1]*University Hospital Mainz, II. Medical Clinic, Mainz, Germany;* [2]*University Hospital Mainz, Department of Radiology, Mainz, Germany*

Introduction: Atherosclerosis of coronary grafts is a common clinical problem. MR vasodilator reserve measurement using adenosine is used for noninvasive hemodynamic assessment of coronary grafts, whereas most noninvasive imaging modalities can only provide information about their patency. The aim of the study was to evaluate the potential of this method to discriminate stenosed from patent coronary grafts.

Methods: MR measurements were performed on a 1.5 T system (Siemens, Vision) using a body array coil in 36 patients with a total of 51 coronary grafts (14/51 IMA-LAD, 16/51 vein grafts LAD, 21 vein grafts RCA/CX). MR provides adenosine vasodilator reserves for blood velocity and flow measurements using a breathhold phase change technique (TR/TE: 24/5 ms, VENC 75 cm/sec). During the cardiac cycle 5-6 image pairs were acquired and mean flow and mean velocity were measured integrating the data over the cardiac cycle.

Coronary grafts were imaged by conventional invasive angiography within 48 hours of MR measurement. Graft stenosis was measured quantitatively by AWOS System (Siemens).

MRI HASTE imaging was used to visualize the course of the grafts. Perpendicular to the course the first MR flow measurement in breath-hold technique was planned. Afterwards adenosine infusion was started and a second flow measurement was performed.

Target parameters were the vasodilator reserves for mean flow, mean velocity and peak velocity.

Results: In 3 patients and 3 grafts the imaging quality was insufficient. The results of 33 patients and 48 grafts were included in the final results. Angiographically no atherosclerosis was present in 36 grafts. In 11 grafts invasive angiography showed a significant stenosis > 50% (QCA: 83 ±15% diameter stenosis).

MR measurement of normal vs. stenosed grafts differed significantly between the two groups for mean flow reserve 3.33 ± 0.38 vs. 1.26 ± 0.16 (p<0.001), mean velocity reserve 2.95 ± 0.31 vs. 1.13 ± 0.15 (p<0.001) and peak velocity reserve 1.77 ± 0.11 vs. 1.24 ± 0.19 (p<0.05).

Conclusions: MR breath hold flow measurement provides hemodynamic assessment of coronary grafts. Using adenosine flow and velocity reserves can be calculated. These noninvasively derived values are reliable in discriminating diseased from patent grafts.

RESTENOSIS AND GENETICS

P1060 Platelet glycoprotein IIIa polymorphism is not associated with increased percutaneous coronary intervention risk

G. Weisz, G. Dangas, R. Mehran, D. Ashby, S. Polena, G.W. Stone, J.W. Moses, M.B. Leon. *Lenox Hill Hospital, Interventional Cardiology, New York, United States of America*

Background: Platelet aggregation has a role in the emergence of complications after PCI. Genetic polymorphism (PlA2) of the IIIa protein is associated with increased risk of endovascular thrombosis, stroke, and myocardial infarction. The role of this type of genetic heterogeneity in ischemic events during and after PCI has not been investigated.
Patients and Methods: Patients undergoing PCI (n=200) were enrolled. PCI was performed blinded to PlA2 status. The use of IIb/IIIa inhibitors was left to operator choice. Presence of polymorphism was correlated with baseline and events after PCI.
Results (table): The normal (A1A1), heterozygote (A1A2) and homozygote (A2A2) variants were found in 144 (72%), 55 (27.5%), and 1 (0.5%) respectively.

	A1A1 (n=144)	A1A2 (n=55)
Patients and PCI Characteristics		
Acute coronary syndrome	98 (68%)	36 (66%)
Platelet count (X1000/mm^3)	212±73	220±84
Heparin (IU)	5556±1580	6160±2511
Maximal ACT (sec)	266±60	281±58

Base-line platelet aggregation units	166±44	174±50
Adverse Events		
No flow/thrombus	2 (1%)	0 (0%)
Any CPK-MB elevation (>X1)	56 (39%)	21 (38%)
CPK-MB elevation (>X3)	25 (17%)	7 (13%)
CPK-MB elevation (>X5)	14 (10%)	6 (11%)
MACE (death, MI, TVR) at 30 days	5 (3.9%)	0 (0%)

p=non-significant for all variables

One-year follow-up will be available.
Conclusions: In the present study: 1. The IIIa protein genetic heterozygote polymorphism (PlA2) is frequent (30%) in patients undergoing PCI, but the homozygote variant was very infrequent (0.5%). 2. The presence of PlA2 genetic polymorphism has no influence on clinical and angiographic presentations. 3. The presence of PlA2 genetic polymorphism has no influence on procedural outcomes, occurrence of complications, or 30-day events.

P1061 Apolipoprotein E genotype predicts the clinical outcome after coronary artery stenting

W. Koch[1], W. Latz[2], N. von Beckerath[2], K. Griesser[2], J. Mehilli[2], A. Schömig[2], A. Kastrati[2]. [1]*Deutsches Herzzentrum München, München, Germany;* [2]*Deutsches Herzzentrum München, München, Germany*

Background: The T allele of the -219G/T polymorphism and the epsilon 4 allele of the gene encoding apolipoprotein E were found to be associated with an increased risk of coronary artery disease. We examined whether these alleles were also related to adverse clinical and angiographic outcomes after coronary artery stenting.
Methods: In 1850 consecutive patients, the occurrence of myocardial infarction (MI), target vessel revascularization (TVR), and the combined incidence of death, MI, or TVR (= MACE; major adverse clinical events) were evaluated over 1 year after stenting. Repeat angiography at six months was achieved in 84.1% of the patients; angiographic restenosis was defined as a 50% or greater diameter stenosis at follow-up.
Results: The incidences of MI, TVR and MACE were significantly lower among carriers of the -219T allele, with patients of genotype TT having the lowest risk (Table). In contrast, the risk of MI, TLR or MACE was not related to the presence or absence of the epsilon 4 allele (Table). The rate of angiographic restenosis was equally distributed between the carriers of genotype -219GG (35.0%), GT (32.5%) and TT (31.6%) (P=0.6) and between carriers of allele epsilon 4 (34.1%) and patients not carrying allele epsilon 4 (29.7%) (P=0.1).

	-219GG	-219GT	-219TT	P value	epsilon 4	not epsilon 4	P value
MI (%)	3.2	1.5	1.1	0.03	2.1	1.2	0.24
TVR (%)	24.3	20.2	16.2	0.008	21.0	18.5	0.24
MACE (%)	27.2	24.6	19.6	0.02	23.6	20.3	0.14

Clinical outcome 1 year after coronary artery stenting

Conclusions: Contrary to our expectations, the -219T allele of the apolipoprotein E gene was associated with lower degrees of MI, TVR, and MACE after coronary stent placement. The epsilon 4 allele was not significantly related to the clinical and angiographic outcome after stenting.

P1062 Oestrogen receptor-α polymorphisms and angiografic outcome after stented angioplasty: a comparison between postmenopausal women and men

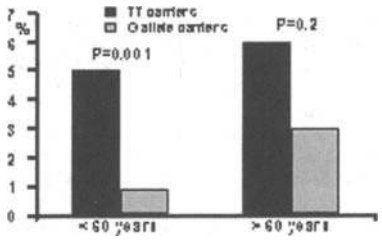
V. Ferrero[1], F. Ribichini[1], G. Matullo[2], S. Carturan[2], S. Guarrera[2], A. Piazza[2], E. Uslenghi[1]. [1]*Ospedale S. Croce, Cardiology Dept., Cuneo, Italy;* [2]*University, Department of Genetic, Torino, Italy*

The angiographic outcome after coronary stenting seems to be similar between genders. Most women undergoing percutaneous coronary intervention are postmenopausal and older than men. Female hormones play a role in the occurrence of coronary disease in women, but the effects in males are less known. Estrogens activity is mediated by the interaction with specific receptors located in various organs and tissues such as endothelial and vascular smooth muscle cells of both, women and men. In this study we have tested the role of two alfa-estrogen receptor (ER) gene polymorphisms, PVU and Xba, in the occurrence of in-stent restenosis (ISR).
Methods and Results: The 6-month angiographic outcome of 719 stented lesions was assessed in 136 PM-women (PMW) and 510 men. PMW were older (65±8 vs 61±9, p=0.001), showed a worse risk profile (diabetes p=0.0001, hypertension p=0.0001 and hypercholesterolemia, p=0.02) and had smaller vessel diameters (2.75±0.5 vs 2.9±0.5 mm, p=0.001). The global restenosis rate was 28.1%. A higher incidence of ISR was observed in PMW compared to men (35.6% vs 26.1%, p=0.02).
The restenosis rate for women and men according to the PVU-ER polymorphisms were: PVU-C/C= 32 vs 20.7%, p=0.2; PVU-C/T= 32.5 vs 27.2%, p=0.3; PVU-T/T= 43.9 vs 28.2%, p=0.05. Analysis of restenosis for the Xba polymorphism in PMW and men was: Xba-1/1= 41.2 vs 21.3%, p=0.09; Xba-1/2= 33.3 vs 27.2%, p=0.3; Xba-2/2= 37 vs 27.8%, p=0.1.
Although PMW tended to higher ISR rates for each genotype, the highest ISR rate was associated with the T/T polymorphism of the PVU genotype in females compared to males.
Conclusion: Common risk factors such as diabetes and hypertension together with the smaller vessel size may account for a higher incidence of ISR in our series of PMW compared to men. While ISR was similarly distributed according to the ER polymorphism among men, ISR in TT homozygous women was higher, suggesting that ISR may be in part modulated by this polymorphism in women but not in men.

P1063 Age dependent impact of the 894 TT genotype of the endothelial nitric oxide synthase on the outcome of men following coronary stent placement

O. Gorchakova[1], W. Koch[2], N. von Beckerath[2], J. Mehilli[2], A. Ehrenhaft[2], A. Schömig[2], A. Kastrati[2]. [1]*1 Med. Klinik rechts der Isar, Deutsches Herzzentrum, Munich, Germany;* [2]*1 Med. Klinik rechts der Isar, Deutsches Herzzentrum, Munich, Munich, Germany*

Background: The functional 894G/T endothelial nitric oxide synthase (eNOS) polymorphism has been found to be clinically relevant, with the TT genotype as a risk factor. Since the relative contribution of genetic factors may decrease with age and may be more pronounced among younger men, we performed a specific analysis for male patients with coronary artery disease undergoing coronary stenting.
Methods: We analysed 1459 consecutive men, there were 620 patients < 60 years and 839 patients > 60 years. One-year mortality was the primary endpoint of the study. The combined incidence of death and myocardial infarction (MI) during the first year was also assessed. Odds ratios (OR) and respective 95% confidence intervals associated with the carriage of the 894TT e NOS genotype are shown.
Results: The 894TT eNOS genotype was associated with a significant risk increase for death within 1 year only among younger patients (figure). In patients < 60 years, the mortality was 5.7% in TT-carriers vs 0.9% in G-allele carriers (OR, 6.4 [2.1 to 20.1], P=0.001.) The difference was much less evident in patients > 60 years, with a mortality of 6% in TT-carriers and 3% in G-allele carriers (OR, 1.9 [0.77 to 5.10], P=0.2). It remained also true for the combined 1-year incidence of death and MI: it was 8.6% vs 2.6% (P=0.007) for younger men and 7.2% vs 4.3% for older men (P=0.3), among TT-carriers and G-allele carriers, respectively.



1 year mortality after coronary stenting.

Conclusions: The 894TT genotype can serve as a prognostic marker of an unfavourable outcome after coronary stenting, especially among young men.

P1064 Endothelial nitric oxide synthase E298D gene polymorphism and restenosis after percutaneous coronary intervention

J. Korinek[1], M. Aschermann[1], A. Linhart[1], M. Jachymova[1], V. Reznicek[1], L. Golan[1], K. Horky[1], P. Martasek[2]. [1]*General University Hospital, 2nd Department of Internal Medicine, Prague, Czech Republic;* [2]*General University Hospital, Department of Pediatrics, Prague, Czech Republic*

Background: Nitric oxide (NO) is a potent vasodilator and has important antiproliferative effects. Some endothelial NO synthase gene polymorphisms may influence plasmatic and intramural NO concentrations. Thus, they may play an important role in pathogenesis of coronary atherosclerosis and in restenosis.
Aim OF THE STUDY: To assess the occurrence of restenosis and loss of lumen diameter after percutaneous coronary intervention (PCI) according to the genotype of E298D polymorphism (Glu-298-Asp) in exon 7 of endothelial NO-synthase gene in patients with coronary artery disease (CAD).
Methods: We studied 96 patients with CAD (age 36-79 years, average 57±9), who had repeated coronary angiography for suspected clinical restenosis and signed informed consent for DNA analysis. Restenosis was evaluated by quantitative coronary angiography (QCA) by using GE OEC CRS-PC software in corresponding views. Restenosis was considered as 50% or more severe stenosis of reference lumen within the site of intervention. In addition, absolute and relative late loss of lumen diameter were evaluated by comparison with QCA result obtained immediately after the procedure.
Results: Genotype frequency was 7%, 51%, and 42% for DD, ED, and EE genotypes, respectively. The restenosis rate was 71% in DD genotype, 37% in ED genotype and 25% in EE genotype ($p < 0.05$). In addition, the absolute and relative late loss were also significantly higher in DD homozygotes (1,3±0.9 mm, 46,5±37,0%), as compared to ED heterozygotes (0,8±0,7 mm, 31,2±30,0%) and EE homozygotes (0,5±0,4 mm, 17,7±22,1%) ($p < 0,05$). The results were also significant when EE homozygotes were compared to other genotypes.
Conclusions: The D allele homozygotes of E298D polymorphism of NO synthase gene have significantly higher frequency of restenosis and, more importantly, late lumen loss as compared to heterozygotes and E allele homozygotes. The lowest restenosis rate and late loss were associated with EE genotype. These pilot study results need to be validated by larger series of patients.

P1065 β2-Adrenergic receptor polymorphism THR164ILE is an independent predictor of severe coronary artery disease

G. Galasso[1], G. Iaccarino[2], F. Piscione[1], E. Barbato[1], G. Marrazzo[1], G. De Luca[1], B. Trimarco[2], M. Chiariello[1]. [1]*Federico II University, Cardiology, Naples, Italy;* [2]*Federico II University, Internal Medicine, Naples, Italy*

Background: Beta2-adrenergic receptor (b2AR) polymorphism (poly) determines functional cardiac responses to catecholamines and adversely affects the outcome in patients (pts) with congestive heart failure. Furthermore, several studies showed that b2AR poly affects bAR mediated vasodilation. Therefore, we studied two poly of the b2AR, the GLN27GLU and the THR164ILE, that impair cardiovascular responses, in pts with severe coronary artery disease (CAD) undergoing percutaneous coronary interventions (PCI).
Methods: Study group consisted of 200 consecutive pts (CAD pts) (166 men; 60±11 years) undergoing PCI in our Cath Lab. The control population consisted of 100 healthy volunteers blood donors. All clinical, echocardiographic and angiographic characteristics of study group were determined. At time of PCI, peripheral blood was drawn to determine b2AR genotype by restriction fragment length poly. One hundred forty seven pts completed at least 6 months follow-up period (7±2 months) and any major adverse cardiac event (MACE) (including cardiac death, new acute myocardial infarction, re-PCI of target vessel or CABG involving treated segment) was checked and recorded in a database.
Results: There were no differences in the frequency of the b2AR 27 poly compared to our control population. However in CAD pts the frequency of heterozygous THR164ILE (164 HET) was threefolds higher than the control group (14% vs 3% respectively, $p<0.001$). No homozygous for ILE 164 were found. We did not observe any difference in terms of clinical, biochemical, echocardiographic and angiographic parameters of the 164 HET pts that could be major causative for CAD. The Kaplan-Mayer curves for event free survival showed a significant higher risk for 164 HET pts of combined death and new acute myocardial infarction ($p=0.0193$) and total MACE ($p=0.039$). Furthermore, at a Cox regression analysis the 164 HET was an independent predicting factor for total MACE ($B=1.185$, $p=0.015$) and there was no interaction noted for this relationship considering age, risk factors, number of vessel treated, and b2AR 27 poly.
Conclusion: We conclude that polymorphism of the b2AR in position THR164ILE is an independent predictor of adverse clinical outcome in CAD pts.

P1066 Interleukin-10 and tumor necrosis factor gene polymorphisms and thrombotic and restenotic events after coronary stenting

K. Tiroch, W. Koch, N. von Beckerath, J. Mehilli, A. Ehrenhaft, A. Schömig, A. Kastrati. *Deutsches Herzzentrum München, Cardiology, Munich, Germany*

Background: Inflammatory mechanisms have been shown to play an important role in the process of restenosis after percutaneous coronary interventions. Cytokines IL-10 and TNF-alpha exert opposite effects in inflammatory reaction. Functional single nucleotide polymorphisms located inside or close to the genes of IL-10, or TNF-alpha, and TNF-beta have an influence on gene expression and plasma levels of IL-10 or TNF-alpha, respectively. In this study we assessed the influence of IL-10, TNF-alpha and TNF-beta polymorphisms on restenotic and thrombotic events.
Methods: In a population of 1850 consecutive patients, we assessed the incidence of death, myocardial infarction (MI), clinical restenosis (target vessel revascularisation) and angiographic restenosis (>=50% diameter narrowing at follow-up angiography performed in 84% of patients) over 1 year after coronary stenting. Genotyping was performed with techniques based on the polymerase chain reaction.
Results: The polymorphisms in the IL-10 promotor (-1082G/A, -819C/T, and -592C/A), in the TNF-alpha promotor (-863C/A and -308G/A) and TNF-beta intron 1 (252G/A) were neither associated with the incidence of angiographic restenosis nor thrombotic events. We further analysed three IL-10 haplotypes (-1082/-819/-592 - ACC, ATA, GCC) and four TNF haplotypes (-308/-863/252 - ACG, GAA, GCA, GCG). No relevant relationship was observed between the studied IL-10 and TNF haplotypes and the incidence of adverse events (see Table).

TNF and IL-10 haplotypes

	TNF					IL-10			
Haplotypes	ACG	GAA	GCA	GCG	p	ACC	ATA	GCG	p
Angiographic restenosis	32%	33%	34%	31%	0,24	33%	33%	33%	0,88
Clinical restenosis	20%	18%	21%	19%	0,08	20%	21%	20%	0,75
Death or MI	5%	3%	5%	3%	0,13	4%	4%	5%	0,14

Incidence of adverse events and TNF and IL-10 haplotypes

Conclusion: These findings suggest that six functionally relevant polymorphisms of IL-10, TNF-alpha and TNF-beta are neither separately nor in combination associated with the risk of restenotic and thrombotic events after coronary stenting.

P1067 The endothelial nitric oxide synthase (eNOS) gene polymorphism (Glu298Asp) is associated with coronary in-stent restenosis

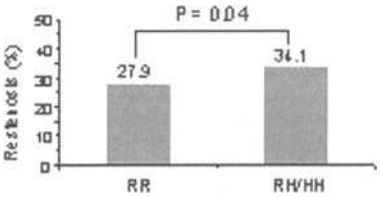
A. Gomma[1], M.A. Elrayess[2], E. Hawe[2], S.E. Humphries[2], K.M. Fox[1]. [1]*Royal Brompton Hospital, Cardiology, LONDON, United Kingdom;* [2]*University College London, Centre for Cardiovascular Genetics, London, United Kingdom*

Background: The biological effects of endothelium-derived Nitric oxide (NO) include vasodilation, inhibition of vascular smooth muscle cell growth, antiatherogenic property, prevention of platelet aggregation and adhesion of white cells to the blood vessel wall. Reduced or impaired synthesis of NO promotes vascular smooth muscle cells proliferation and thus may induce neointimal hyperplasia leading to coronary in-stent restenosis. The Glu298Asp variant of eNOS gene is functional with the Asp allele being associated with hypertension, myocardial infarction, coronary spasm and atherosclerosis. In this study, we have examined the effect of this allele on risk for in-stent restenosis.
Methods: 226 consecutive patients who underwent elective coronary artery stenting to de novo lesions in native coronary arteries were prospectively studied. Patients were restudied with coronary angiogram at 6 months and the stented lesions were assessed with automated quantitative angiography system. Coronary in-stent restenosis was categorically defined with the classic criterion of >50% diameter stenosis at follow up. Genotype was determined by PCR and restriction enzyme digestion with DpnII.
Results: In the 206 (91.15%) patients who were restudied angiographically at 6 months the binary restenosis rate was 30.1%. Overall, genotype distribution was in Hardy-Weinberg equilibrium and the frequency of the Asp allele was 0. 33 (95%CI: 0.28-0.38). Compared to 298Glu homozygotes, carriers of the 298Asp allele showed a higher frequency of restenosis with odds ratio of 2.0 (95% CI: 1.08-3.73, p= 0.026).
Conclusion: In coronary artery disease patients, the possession of 298Asp allele is a risk factor for coronary in-stent restenosis, demonstrating the importance of the NOS system in restenosis.

P1068 FcgammaRIIa-R-H131 polymorphism is associated with the formation of restenosis after coronary stenting

N. von Beckerath, W. Koch, A. Ehrenhaft, H.P. Wittmann, O. Gorchakova, J. Mehilli, A. Kastrati, A. Schömig. *Deutsches Herzzentrum München, München, Germany*

Background: IgG Fc receptor FcgammaRIIa-R-H131 polymorphism has a significant influence on human IgG2 binding to this receptor. A single nucleotide substitution (G507A) causes the amino acid exchange, Arg (R)-His (H) at position 131. FcgammaRIIa-H/H131 interacts well with human IgG2 whereas FcgammaRIIa-R/R131 binds IgG2 poorly. Conversely, the opposite affinities are true for binding of C-reactive protein (CRP). Inflammation is thought to play a role in the formation of neointima.
Methods: FcgammaRIIa-R-H131 genotypes were determined with polymerase chain reaction and allele-specific probes (Taq Man). Due to differences in nucleotide sequence between the FcgammaRII genes A, B and C in proximity to the polymorphic base it was possible to construct allele and gene (gene A) specific probes. Consecutive patients (n=1850) that underwent coronary stent implantation due to symptomatic coronary artery disease were included in the study. Six-month follow-up angiography was performed in 84% of the patients.
Results: The genotype distribution of the patients was 18.3% (R/R), 47.2% (R/H), 34.5% (H/H) and complied with Hardy-Weinberg equilibrium. The incidence of restenosis was 34.1% for H carriers vs. 27.9% for RR patients which results in a significant increase (by 34%) of the risk of restenosis for H allele carriers (Fig. 1).

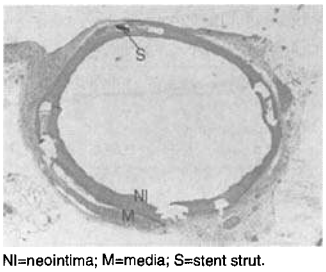


Conclusions: Homo-and heterozygous carriers of FcgammaRIIaH131 have an increased risk of restenosis following coronary stenting. This new finding provides additional cues on the role of inflammation and immunomodulation in the process of restenosis.

P1069 Rat aortic stenting: a simple model of in-stent restenosis

L.J. Wagenaar[1], A.J.M. Roks[2], H. Bartels[2], R.A. Tio[1], H. Buikema[2], A.J. van Boven[1], W.H. van Gilst[2]. [1]*Academisch Ziekenhuis Groningen, Thoraxcentrum, Groningen, Netherlands;* [2]*University of Groningen, Dept of Clinical Pharmacology, Groningen, Netherlands*

Background - In-stent restenosis (ISR) occurs in 10-21% of the patients who have undergone a percutaneous coronary intervention with placement of a stent. Several drugs are being investigated in animal models to test their efficacy for treatment of ISR. The currently available models are limited in number, elaborate and expensive.
We have developed a simple and inexpensive rat model, in which new therapies for ISR can be easily tested.
Methods: Male Wistar rats (400 to 425 grams) were anaesthetised with the use of N2O, O2, and isoflurane gas narcosis. The lower 2.5 cm-segment of the abdominal aorta was prepared free very carefully from the vena cava. Two vascular clips were placed to isolate a 2 cm-segment. A small incision was made and the isolated aortic segment was stented with a human coronary stent (Medtronic beStent, 2.5 x 10 mm). The incision was closed with a 9-0 suture, and the clips were removed. Rats were killed after 14, 21, or 56 days, and the consequences of stent placement were studied.
Results: After 14 days, neointima formation was minimal and only partial, but after 21 and 56 days a prominent, concentric neointima had been formed. On the luminal side of the neointima, histological patterns that are typical for cell division were seen in all three groups.
Conclusion: Placement of a human coronary stent in the rat abdominal aorta results in a clear and fulminent in-stent restenosis within one month. In accordance with the pig coronary stenting model, cell division is still observed even after 8 weeks. Therefore, the new rat abdominal aorta model is a simple, promising method to investigate the efficacy of oral drugs or drug-eluting stents for treatment of ISR.



NI=neointima; M=media; S=stent strut.

P1070 Smoking and restenosis after coronary artery stenting: the artefact of smoker's paradox

J. Mehilli[1], H. Bollwein[1], J. Pache[2], G. Pogatsa-Murray[1], F. Dotzer[3], A. Kastrati[1], A. Schömig[1]. [1]*Deutsches Herzzentrum München, Cardiology, Munich, Germany;* [2]*Rechts Der Isar, 1. Med. Klinik, Munich, Germany;* [3]*Klinikum Garmisch-Partenkirchen, Medizinische Klinik I, Garmisch-Partenkirchen, Germany*

Background: Cigarette smoking is a strong risk factor for heart disease. Some previous studies showed a lower incidence of adverse events and restenosis after percutaneous coronary interventions (PCI) in smokers which has since been called the "smoker's paradox". We investigated the influence of smoking on restenosis after stenting. Methods: A consecutive series of 6911 patients who underwent coronary artery stenting was analysed. The follow-up protocol included 6-month angiography (performed in 80% of the patients) and a contact of 12 months after the procedure. Primary endpoint of the study was angiographic restenosis defined as a > 50% diameter stenosis at follow-up. Other endpoints were the combined rate of death and myocardial infarction and the need for reinterventions at 1 year. Results: As shown in the table, the risk profile of the smokers is significantly different from that of non-smokers. Apparently, smokers have a lower risk of restenosis. However, the risk reduction disappears after adjustment for baseline characteristics: adjusted odds ratio, 0.94 [95% CI, 0.81-1.09]. More importantly, smokers showed a significantly increased risk of death or myocardial infarction (adjusted hazard ratio, 1.29 [95% CI, 1.03-1.61].

Univariate Analysis

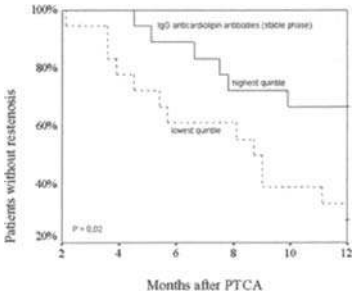
	Smokers (n=1848)	Nonsmokers (n=5063)	p
Age, years	59 ± 11	67 ± 10	<0.001
Women, %	16	27	<0.001
Diabetes, %	15	22	<0.001
Multivessel disease, %	67	75	<0.001
Vessel size, mm	3.06 ± 0.51	3.00 ± 0.54	<0.001
Angiographic restenosis, %	28	31	0.04
Reinterventions, %	17	19	0.13
Death or MI, %	6.4	6.9	0.54

Conclusions: The apparent relation between smoking and a lower restenosis rate after PCI is the consequence of more favourable baseline characteristics. Smoking itself has an unfavourable influence on the outcome after stenting by increasing the risk of most dreadful events.

P1071 Circulating IgM and IgG cardiolipin antibodies in restenosis after balloon angioplasty and their interference with prothrombotic pathways

A. Niessner, S. Graf, M. Nikfardjam, W. Speidl, B. Richter, G. Maurer, J. Wojta, K. Huber. *General Hospital Vienna, Internal Medicine II/Cardiology, Vienna, Austria*

It was our aim to show the possible role of circulating IgM and IgG anticardiolipin (aCL) antibodies for the development of restenosis. Furthermore, we were interested in the interference of aCl antibodies with parameters of different prothrombotic pathways.
We investigated 145 patients with stable coronary artery disease after a successful angioplasty for their plasma levels of IgG and IgM aCL antibodies. Sixty-six patients (45%) developed angiographically proven restenosis, seventeen of them (12%) developed more than one episode of restenosis.
ACL IgM antibodies in the upper quartile at baseline (before angioplasty) predicted a higher risk to suffer from recurrent restenosis compared to the lowest quartile (R= 0,04) and were positively correlated with Lipoprotein (a) (P=0,04). In contrast, also aCL IgG antibody levels in the lowest quintile at baseline conditions in chronic stable disease were a risk factor for restenosis (P=0,01). Adjusting for cardiovascular risk factors, low aCL IgG antibodies represented an independent risk factor for restenosis (P= 0,036). Kaplan-Meier survival analysis showed a higher event rate in patients with low aCL IgG antibodies (P= 0,02; Fig. 1). ACL IgG antibodies were further correlated with PAI-1 activity after angioplasty (P= 0,021).
In conclusion, high aCL IgM antibodies seem to be a risk factor for a more complicated course of disease with a tendency to recurrent restenosis after PTCA whereas low aCL IgG antibodies are more likely an independent risk predictor indicating a protective effect against the development of restenosis. Associations of aCL IgM antibodies with Lipoprotein (a) and with aCL IgG antibodies with PAI-1 activity might further explain their suspected role in thromboembolic diseases.



P1072 Doxycycline-therapy reduces angiographic restenosis rate after percutaneous coronary intervention in non-diabetic smoking males

J. Haase[1], M. Kannengießer[1], W. Stille[2], H. Störger[1], M. Kaltenbach[1]. [1]*Red Cross Hospital Cardiology Center, Frankfurt, Germany;* [2]*Johann Wolfgang Goethe University, Frankfurt, Germany*

The potential role of Chlamydia Pneumoniae in the pathogenesis of coronary artery disease remains to be a matter of controversial discussion. Goal of this study was to test the influence of antibiotic therapy on clinical outcome and restenosis rate (RR) after percutaneous coronary intervention (PCI).

Methods: We followed 1.019 patients with consecutive PCI at Red Cross Hospital Cardiology Center. The treatment group (TG) consisted of 541 consecutive patients (7/98 to 10/98) receiving doxycycline (100mg/day) for 50 days after PCI; the control group (CG) consisted of 478 patients with standard treatment (250 consecutive patients, 5/98 to 7/98; 228 consecutive patients, 10/98 to 11/98). Baseline demographics were equally distributed: mean age (TG: median 65 years; 25th percentile (P), 58 years; 75th P, 72 years versus CG: median 64 years; 25th P, 56 years; 75th P, 71 years), smoking (20.8% vs 20.9%), diabetes (22.9% vs 22.0%), dyslipidaemia (52.2% vs 51.2%), and hypertension (46.0% vs 41.2%). The percentage of women was higher in TG (TG, 30.1% vs CG, 22.6%; $p<0.01$). Clinical follow-up (FU) was assessed equally after 7 months (median, 237 days; 25th P, 223 days; 75th P, 272 days) and obtained in 614 patients (60.3%). Angiographic FU was higher in TG (64.5% vs 56.0%). This carried the risk of underestimating RR of TG relative to CG, thus favoring the acceptance of the antibiotic hypothesis. To exclude this potential error, RR was calculated as the ratio of restenotic patients to all patients.

Results: No difference between TG and CG was found in adverse event rates (respectively, MI: 0.7% vs 1.3%; Re-PCI: 24% vs 20.9%; coronary artery bypass graft: 5% vs 3.9%, death at 6 months 3.5% vs 2.1%) and RR (21.6% vs 23.4%). Subgroup analysis of smoking nondiabetic males (TG, n=59; CG, n=55) showed a significantly lower RR in TG (10.9% vs 30.5%; $p<0.02$) without differences in clinical outcomes.

Conclusions: Treatment with 100mg doxycycline over 50 days after PCI does not appear to influence clinical results and over all restenosis rate. The observed reduction in RR among doxycycline-treated nondiabetic male smokers deserves further investigation.

P1073 C-reactive protein stimulates smooth muscle cell proliferation but does not affect endothelial tissue factor activity or endothelin-1 release

A. Sethi, D.M. Lees, E.G. Wood, R. Corder. *William Harvey Research Institute, Experimental Therapeutics, London, United Kingdom*

Background: Increased levels of C-reactive protein (CRP) are predictive of adverse coronary events in stable and unstable angina. Furthermore, elevated levels of CRP are predictive of both early and late complications, including restenosis, after coronary angioplasty and stent implantation. The mechanisms responsible for these complications are not clear but involve endothelial injury and smooth muscle cell proliferation. CRP has been found within atherosclerotic plaques and has been shown to increase the expression of adhesion molecules and the production of chemokines from endothelial cells. We therefore investigated the effect of CRP on vascular cells.

Methods and Results: Human recombinant CRP and human serum high purity CRP was tested on human internal mammary artery smooth muscle cell (HIMASMC) proliferation and also on tissue factor (TF) activity and endothelin-1 (ET-1) release from bovine aortic endothelial cells (BAEC). All experiments were performed on 2 or 3 separate occasions. Incubation for 96h with 100μg/ml CRP increased HIMASMC proliferation by 42% (n=6, $p<0.01$). This effect on HIMASMC proliferation was also present at 10μg/ml CRP (n=9, $p<0.01$), with a concentration-dependent increase up to 100μg/ml. At 5μg/ml CRP, there was no significant increase in HIMASMC proliferation. Incubation with 10μg/ml CRP and 10ng/ml recombinant tumor necrosis factor alpha showed no additional increase in HIMASMC proliferation. There was no effect of 100μg/ml CRP on TF activity or ET-1 release from BAEC incubated for up to 24h, with or without serum.

Conclusions: These results show for the first time that CRP stimulates HIMASMC proliferation and elucidates a possible role for CRP in the pathogenesis of restenosis. In this study, CRP did not affect endothelial function as assessed by TF activity and ET-1 release.

P1074 Inhibition of smooth muscle proliferation by glycoprotein IIb-IIIa antagonists in vitro: eptifibatide more effective than abciximab or tirofiban

J. Froehlich, C. Kaun, K. Huber, J. Wojta, G. Christ. *University of Vienna, Dept. of Cardiology, Vienna, Austria*

Background: Recent data suggest that among the platelet glycoprotein (GP) IIb-IIIa (alpha IIbeta,beta3) integrin antagonists not only abciximab (ReoPro®, a chimeric monoclonal antibody), but also eptifibatide (Integrilin®, a cyclic heptapeptide) is able to bind to integrin-receptors of the alpha nu subunit family, whereas the affinity of tirofiban (Aggrastat®, a peptidomimetic) is restricted to alpha IIbeta,beta3. We were interested whether these differences in integrin specificity might influence human smooth muscle cell (SMC) migration and/or proliferation in vitro.

Methods: A two-dimensional assay system for determination of SMC migration/ proliferation was used. Sterilized steel supports were inserted into gelatine coated six well plates. Human umbilical artery SMC were seeded into the middle hole of each support. At confluency, inserts were removed and after 24 hours of serum deprivation, GP IIb-IIIa antagonists were added in culture media with 10% calf serum. After 20 days cell-layers were stained, digitally quantified (Scion Image) and in parallel cells counted.

Results: No GP IIb-IIIa antagonist influenced SMC area significantly at therapeutic plasma concentrations (abciximab: 200 ng/ml; eptifibatide: 2 μg/ml, tirofiban: 40 ng/ml). At 10x conc. eptifibatide reduced SMC area significantly by 30% ($p=0.01$) and at 30x conc. by 41% ($p=0.001$), whereas abciximab and tirofiban showed no significant influence. This effect was paralleled by a decrease in cell counts (30x conc.: 43% reduction, $p=0.005$), reflecting an inhibition of cell proliferation.

Conclusions: Among the currently available GP IIb-IIIa antagonists, only eptifibatide showed a dose-dependent inhibition of SMC proliferation in our in vitro assay system. Abciximab and tirofiban exerted no significant effects. As these findings might be due to eptifibatides broader range of integrin specificity (alpha IIbeta,beta3 and various alpha nu subunit integrins), compared to abciximab (alpha IIbeta,beta3 and alpha nu,beta3) or tirofiban (only alpha IIbeta,beta3) we hypothesize that inhibition of SMC proliferation requires simultaneous blockade of several integrin receptors. The clinical relevance of this phenomenon, with reduction of late restenosis after percutaneous coronary interventions needs to be proven.

P1075 Intracoronary paclitaxel added to contrast media inhibits in-stent restenosis of porcine coronary arteries

B. Scheller[1], U. Speck[2], H.P. Stoll[1], M. Böhm[1], G. Nickenig[1]. [1]*University of Saarland, Internal Medicine III, Homburg/Saar, Germany;* [2]*Department of Radiology, Charite, Berlin, Germany*

Objective: Coronary arteries are coated with contrast media forming a thin film on the endothelium during catheterization. In a prior study, we demonstrated that a taxane dissolved in a contrast medium can inhibit in-stent restenosis at subtoxic systemic taxane levels. The present study was designed to test the efficacy of different formulations of Paclitaxel added to the contrast agent Iopromide in a porcine stent model.

Methods: 34 stents were implanted into LAD and CX coronary arteries of 17 pigs using an 1.2 to 1 overstretch ratio. Iopromide-370 was used in group I (control), the treatment groups were injected with 80 ml intravenous Iopromide plus 12.8 mg Paclitaxel (group II), 80 ml intracoronary Iopromide plus 6.4 mg Paclitaxel (group III), and 80 ml intracoronary Iopromide plus 12.8 mg Paclitaxel respectively (group IV). Quantitative coronary analysis (QCA) was used to evaluate measures of restenosis (reference diameter, minimal lumen diameter, diameter stenosis) from the pre-sacrifice angiography at 28-day follow-up.

Results: QCA documented no differences between the baseline parameters of the four groups. At follow-up, however, there was a marked reduction of all parameters relevant to in-stent restenosis in favor of the intracoronary Iopromide-Paclitaxel administration (see table).

Quantitative coronary angiography

	group I	group II	group III	group IV	p
# of pigs	6	3	4	4	
# of stented vessels	12	6	8	8	
reference diameter	2.8±0.2 mm	2.7±0.2 mm	2.7±0.5 mm	2.7±0.2 mm	0.976
minimal lumen diameter	1.1±0.3 mm	1.3±0.5 mm	1.7±0.8 mm	2.0±0.5 mm	0.004
diameter stenosis	59±9%	55±15%	38±19%	29±13%	0.001

Conclusion: This study provides evidence that intracoronary application of a taxane dissolved in a contrast medium can prevent in-stent restenosis. The novel drug delivery mechanism is efficient at subtoxic systemic levels of Paclitaxel. Thus, this simple and inexpensive approach is potentially suited for prevention of restenosis in a broad spectrum of interventional cardiology.

PAEDIATRIC CARDIOLOGY, OTHERS

P1076 Ventricular septal defect – A review

M. kelmendi[1], F. Shllaku[2], R. Bejiqi[3], N. Gashi[3], M. Avdiu[3], N. Zeka[3], A. Batalli[3]. [1]*Children's Hospital, cardiology, prishtina, Albania;* [2]*Faculty of Dentistry, Prishtina, Kosova, Albania;* [3]*Children's Hospital, Cardiology, Prishtina, Albania*

Ventricular septal defect(VSD) is the most commonly encountered congenital heart lession, occurring in more than 20% of CHD.
Objective: to determine the frequency of VSD in our cardiology patients, including clinical forms, haemodynamic profiles as well as the outcome.
Materials and methods: Using non-invasive techniques (history, clinical examination, chest X-ray, ECG and Doppler echocardiography, the CHD diagnosis has been established in patients examined in University Children's Hospital, including in and outpatients.
Results: Of 665 children with CHD,247 (37%)had VSD: 206 (30.9%) as a solitary lession, 27 (4.0%) in combination with other defects, mainly with ASD and 14 (2.1%) as a part of complex congenital heart disease.VSD was found slightly more frequently in females (53.5%) as compared to males 946.5%). VSD was the most common CHD in the majority of chromosomal syndromes (21-trisomy).
Clinical forms, haemodynamic changes and the outcome are prescribed below:

– muscular VSD	21 (8.6%)
– restrictive	115 (46.5%)
– nonrestrictive	66 (26.7%)
– in spontaneous closure	28 (11.3%)
– in pulmonary hypertension	17 (6.9%)
Total	247 (100%)

All children were followed-up by cardiologists and, when needed, have given adequate, anticongestive therapy including digoxin, furosemide, ACE inhibitors, spironolactone.
They also followed AHA recommendations for the prevention of infective endocarditis. However,in one, five yrs old child with small, restrictive VSD severe infective endocarditis occurred including severe tricuspid regurgitation.
This child was born abroad and since the VSD was small the decision was made to don't be operated but to be in a continuous infective endocarditis prophylaxis.
After her comming back, 1 mo after a dental procedure (no prophylaxis was used) she got endocarditis which was very refractare to antibiotic therapy.
From at least 83 pts with VSD who require cardio-surgery treatment, only 17 have been operated abroad, since our region has no cardio-surgery center.
Conclusion: In our region echocardiography as a very precise diagnostic tool is mainly sufficient for the diagnosis of CHD. The big problem is lack of cardio-surgery; so a certain number of patients with operable VSD is older then 10 years.On the other hand infective endocarditis is also a problem in cases with restrictive VSD.

P1077 Dimensions of the pulmonary arteries and some cardiovascular structures in children and young adults with tetralogy of Fallot

M. Shehu[1], F. Meksi[1], A. Baboci[1], B. Xhaxho[1], V. Zogu[1], S. Xhepa[2]. [1]*University Hospital Center Tirana, Cardiology, Tirana, Albania;* [2]*University Hospital Center Tirana, Vascular Surgery, Tirana, Albania*

The results of complete correction of tetralogy of Fallot are closely related with its anatomy. Our study is undertaken to obtain new information for the anatomy of the childrens and young adults with tetralogy of Fallot.
Methods: Diastolic diameters of the right and left pulmonary arteries and their lower lobe arteries, descending thoracic aorta, right ventricular infundibulum, pulmonary valve anulus, pulmonary trunkus were estimated from angiograms in 22 children and young adults with tetralogy of Fallot and correlated with BSA and for each of them Mc.Goon and the Ratio, (the sum of the diameters of the lower lobe arteries divided with the diameter of aorta descendens)is calculated.
Results: Compared with normal subjects patients with tetralogy of Fallot have smaller diameters of the above cardiovascular structures and different growth patterns. The median values of the diameters of the right ventricular infundibulum, pulmonary trunk, pulmonary annulus were 50% of the normal ones. The right pulmonary prebranching diameter and the right lower lobe artery is greater than the left but not significantly. Mc.Goon median value is 1,7 and Ratio value 1,2.
There is a strong correlation between aorta descendens and BSA, but there is no correlation between right ventricular infundibulum, pulmonary valve anulus, pulmonary trunkus right and left pulmonary arteries their lower lobe arteries with BSA and aorta descendens suggesting different growth patern.
Conclusion: Tetralogy of Fallot is a complicated congenital disease and the growth of the cardiovascular structures is different from normal subjects. There is severe obstruction at the level of the right ventricular outflow tract. The pulmonary arteries are good developed but even these are smaller then normal subjects. The new Index can be a more appropriate measure of pulmonary artery development, ignoring the mistakes rsulting by stenoses or dilatation of the main branches.

P1078 Degree of atherosclerotic involvement of primary congenital coronary anomalies

B. Balci, O. Yesildag. *Ondokuz Mayis University, Department of Cardiology, Samsun, Turkey*

There is no consensus about the subject that the coronary anomalies may cause the predisposition for atherosclerosis. In this study, it was determined whether the atherosclerotic involvement in patients with coronary anomalies was different from the patient group which the frequency of anomalies was investigated or not. The angiographic repots of the consecutive 2119 patients were screened and 15 patients with coronary anomalies were detected. The angiographic and ventriculographic data of the patients with coronary anomalies were compared witf the data of the patients without coronary anomalies. A numeric value was given to each segment of the vessel according to the decrease in percentage of the luminal diameter as taing into consideration of the 29 segment coding system of ACC/AHA. The coronary atherosclerosis score of that artery was found with the addition of the numerical values in the related coronary artery. Total coronary atherosclerosis score was obtained with the addition of the atherosclerosis scores of three coronary arteries. Total coronary atherosclerosis score (104±131 v 108±122), total LAD score (42±50 v 47±50), total Cx score (20±44 v 41±51), total RCA score (41±66 v 30±52) were not different statistically between groups. These data suggest that there was not any difference between the patients with coronary anomalies and the patients without coronary anomalies according to atherosclerosis development.

P1079 Ventilatory efficiency during exercise in patients with cyanotic congenital heart disease is related to the clinical outcome after surgery

T. Reybrouck[1], D. Boshoff[2], M. Gewillig[2]. [1]*University Hospital Gasthuisberg, Cardiology, Leuven, Belgium;* [2]*University Hospital Gasthuisberg, Pediatric Cardiology, 3000 Leuven, Belgium*

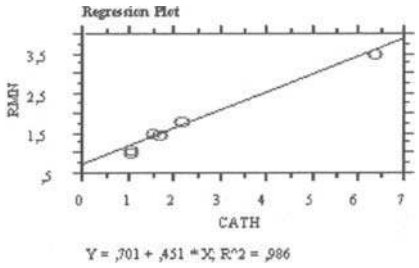
Most patients (pts) who underwent surgical repair for cyanotic congenital heart disease (CCHD) are clinically well when examined at rest, but a considerable number may complain of exercise intolerance at heavy exercise. The aim of the present study was to analyse ventilatory efficiency during exercise and correlate with the clinical outcome after surgery.
Methods: 78 pts with surgical repair of CCHD (mean age: 12.6 ± 2.3 years) were studied. 3 subgroups of pts formed the study group: 32 pts with repair for tetralogy of Fallot (TF), 23 pts after Senning operation for transposition of great arteries (S) and 23 pts with Fontan operation for functionally univentricular hearts (F). Pts were compared to 27 age-matched controls. Exercise testing was performed on a treadmill. Gas exhange was measured on a breath-by-breath basis with mass spectrometry. To assess the efficiency of ventilatory gas exchange during exercise, alveolar ventilation (VA) was calculated and subtracted from total ventilation (VE). The difference which reflects the physiological dead space ventilation (VD) was used as an estimate of the ventilatory efficiency.
Results: During exercise, VE, VA and VD were significantly ($P = 0.01$) elevated in the 3 pts groups compared to normal contols. VD was abnormally elevated in 47% of TF, 65% of TGA and 62% of F. This was associated with a steeper slope of VE vs VCO2. This correlated with hemodynamic sequels after surgery such as pulmonary regurgitation, residual pulmonary stenosis and cardiomegaly after TF repair, severe right ventricular dilatation, tricuspid incompetence after S operation and atrioventricular valve insufficiency in F.
Conclusion: Assessment of ventilatory efficiency during exercise gives useful complementary information to other clinical tools to assess the functional outcome after surgery, since abnormal values correlated with hemodynamic sequels after surgery.

P1080 QP/QS ratio evaluation by phase veloecity cine magnetic resonance imaging in patients with left to right shunt

G. festa[1], D. Chiappino[1], A. Cerillo[1], S. Redaelli[1], S. Costa[1], F. Amoretti[1], M. Lombardi[2]. *[1]CNR, Clinical Physiology Institute, Paediatric Cardiology, Massa, Italy; [2]CNR, Clinical Physiology Institute, MRI Laboratory, Pisa, Italy*

Objectives: : PVC-MRI is a powerful noninvasive technique to quantitate and analyze blood flow. Our purpose is to correlate QP/QS ratio evaluated by PVC-MRI and by cardiac cateterization (CC) in pts with septal defects or patent foramen ovale.
Methods: 7 pts with Atrial Septal Defect (3 pts), Ventricular Septal Defect (1 pt), Atrial Septal Defect + Anomalous Partial Pulmonary Venous Return (1 pt), Patent Foramen Ovale (1 pt), and suspected residual shunt in status/post closure of ASD by Ampatzer device (1 pt) have been evaluated by MRI and CC in order to calculate QP/QS ratio. 2 other pts have been excluded by the study because their turbolent flow at pulmonary artery level. The QP/QS ratio has been calculated by the oximetric method at CC, and measuring flows in pulmonary artery and aorta by PVC-MRI. Results have been analysed by means of a statistical-dedicated software (statwiew 4.5 for Mac).
Results: Linear regression analysis showed a high correlation between the two methods:

$y = 0.701 + 0.451*x$; $R^2 = 0.986$. p (ANOVA) < 0.0001.



Conclusions: Calculation of QP/QS ratio by PVC-MRI has a linear correlation with the oximetric method. Therefore PVC-MRI is an accurate, robust, and safe technique for obtaining in vivo blood flow information. Moreover PVC-MRI may be easily integrated into a comprehensive cardiac MRI evaluation that provide extensive diagnostic anatomical and functional information.

P1081 Plasma homocysteine levels and their reduction with folic acid/vitamin B6 in a cohort of apparently healthy young men in polish population

R. Olszewski, R. Grabysa, J. Warmiński, T. Makowski, R. Szczechowicz, W. Piechota, J. Adamus. *School of Military Medical Academy, Cardiology, Warsaw, Poland*

Several cross-sectional and prospective studies have indicated that increased levels of total plasma homocysteine (tHCY) are an independent risk factor for cardiovascular disease.
The purposes of this study were to determine serum levels of tHCY and their associations with traditional risk factors of atherosclerosis and to assess the degree of tHCY reduction after two weeks administration of standard multivitamin tablets (containing folic acid and vitamin B6) in population of young, healthy Polish men.
In 150 men (mean age 20,5 ± 1,24 yrs) we evaluated clinical, anthropometric and biochemical measurements (tHCY, total cholesterol, HDL-cholesterol, LDL-cholesterol, triglycerides, uric acid, apolipoproteins A and B). tHCY was determined with IMx analyzer and Abbot IMx TM Homocysteine Assay. 75 men (randomly assigned) started taking 1 tablet of Panvitan® for men (Bayer,USA) containing 0,2mg of folic acid and 3mg of vitamin B6 on the enrollment day. Concentrations of tHCY were measured at baseline and at two weeks in all subjects.
Mean concentration of tHCY in the studied group was 10,04 μmol/L (SD ±2,26 μmol/L). tHCY correlated with diastolic blood pressure values (r=0,208; p<0,03) and with uric acid concentrations (r=0,217; p<0,02). In the group administered with Panvitan® there was a reduction of mean tHCY level by 1,40 μmol/L (13,7%; p<0,01) compared with 0.61 μmol/L (6,2%, p<0,01) reduction in group with no supplementation. The reaction to Panvitan® was more pronounced in men with tHCY concentrations above 10 μmol/L.
Conclusion: Our data support the view that lowering homocysteine levels through dietary supplementation with folic acid and vitamin B6 may play an important role in reducing of cardiovascular risk.

P1082 Incubating arrhythmogenic right venticular cardiomyopathy in Naxos disease of childhood

A. Tsatsopoulou[1], C. Basso[2], N. Protonotarios[1], A. Anastasakis[3], G. Papadopoulos[4], C. Spiliopoulou[5], G. Thiene[2]. *[1]Yannis Protonotarios Medical Center, Cardiology, Naxos, Greece; [2]University of Padua, Cardiovascular Pathology, Padova, Italy; [3]University of Athens, Cardiology, Athens, Greece; [4]Agia Sofia Children's Hospital, Paediatric Cardiology, Athens, Greece; [5]University of Athens, Forensic Medicine and Toxicology, Athens, Greece*

Background Arrhythmogenic right ventricular cardiomyopathy (ARVC) causes ventricular arrhythmias due to fibrofatty replacement of right ventricular (RV) myocardium. A deletion in plakoglobin (cell adhesion protein) in homozygous state results to ARVC (Naxos disease) 100% penetrant by adolescence. A study of homozygotes in childhood might elucidate the incubating period of ARVC.
Methods An affected family with 11 members was studied clinically and genetically. Three homozygous carriers for plakoglobin mutation were identified; two siblings (a brother, 13 years old and a sister, 5 years old) and their grandmother (58 years old). Cardiac biopsies were available in the two affected siblings.
Results ARVC was fully penetrant on ECG and echocardiography in the 13-year-old boy and his grandmother (2 major and 2 minor criteria). Endomyocardial biopsy of the boy revealed significant fibrofatty replacement of RV myocardium. The 5-year-old girl had complex ventricular extrasystoles mainly of RV origin (>10000/24h) without ECG or echocardiographic abnormalities. She died in severely progressive myelodysplasia 2,5 years later without developing any significant cardiac alteration. Postmortem gross pathology did not show any overt abnormality, but histology revealed tiny fibrosis with rare adipocytes in the subepicardial layers of RV free wall. Moreover there was diffuse subendocardial fibrosis. There was no inflammatory infiltration or leukemia infiltration.
Conclusions In this young child, ventricular arrhythmia was a striking feature although the ARVC pathological substrate appeared very mild. The early arrhythmogenicity might be attributed to the primary dysfunction of cell-cell adhesion.

P1083 Changes in aortic elasticity in non-operated Marfan patients after three years of follow-up

G.J. Nollen[1], L.J. Meijboom[1], M. Groenink[2], J. Timmermans[3], H. Lamb[4], J. Stoker[5], E.E. van der Wall[6], B.J.M Mulder[2]. *[1]Academic Medical Center, Cardiology Dept., Amsterdam, Netherlands; [2]Academic Medical Center, Cardiology Dept., Amsterdam, Netherlands; [3]University Medical Center St Radboud, Cardiology, Nijmegen, Netherlands; [4]Leiden University Medical Center, Radiology Dept., Leiden, Netherlands; [5]Academic Medical Center, Radiology Dept., Amsterdam, Netherlands; [6]Leiden University Medical Center, Cardiology Dept., Leiden, Netherlands*

Objective- Aortic elasticity is related to aortic rupture behavior and may serve as an additional risk factor. Aortic elasticity can be expressed in terms of distensibility and flow wave velocity, and is decreased in Marfan patients. The aim of this study was to determine changes in aortic elasticity assessed with MR imaging in non-operated Marfan patients.
Design and patients- In 2000, 19 consecutive non-operated Marfan patients (mean age 34 (8) years, 13 men and 6 women), who had undergone magnetic resonance (MR) imaging in 1996-1997, underwent second MR imaging. MR flow mapping was assessed at four levels (1: ascending aorta beyond the aortic root, 2: thoracic descending aorta, 3: descending aorta at the level of the diaphragm and 4: abdominal descending aorta) in the aorta. Distensibility and diameter at each level, and flow wave velocity (FWV) between levels were calculated.
Results- Mean time after first MR imaging was 38 (4) months (range, 34-49 months). No significant change in aortic diameter at any of the 4 levels was shown. Distensibility at second MR imaging at the ascending aorta (level 1) was significantly decreased (1.8 (1.0) 10-3 mmHg-1) compared to first MR imaging (2.7 (0.9) 10-3 mmHg-1, p<0.01). Accordingly, FWV in the aortic arch tended to be increased at second MR imaging (5.0 (1.2) m/s vs. 4.4 (1.0) m/s, p=0.10, respectively). At all other levels no changes in aortic elasticity were shown.
Conclusion- After 3 years of follow-up in non-operated Marfan patients elasticity in the ascending aorta was significantly decreased without changes in diameter. This finding could indicate that changes in aortic elasticity precede changes in aortic diameter in Marfan patients.

P1084 Correlation of plasma neurohormones and functional status in patients with right ventricular pressure and/or volume overload

I.I. Tulevski[1], J.W.M. Mulder[1], A. Dodge-Khatami[2], E.E. van der Wall[3], M. Groenink[1], D.J. van Veldhuisen[4], B.J.M. Mulder[2]. [1]*Academic Medical Center, Cardiology B 2 239, Amsterdam, Netherlands;* [2]*Academic Medical Center (AMC), Cardiology room B2 223, Amsterdam, Netherlands;* [3]*Leiden University Medical Center, Cardiology, Leiden, Netherlands;* [4]*University Hospital Groningen, Cardiology Dept., Groningen, Netherlands*

Objective: To examine the relation between plasma neurohormones Brain Natriuretic Peptide (BNP) and Atrial Natriuretic Peptide (ANP), and NYHA functional status classification, in patients with chronic right ventricular (RV) pressure and/or volume overload.
Methods: BNP and ANP levels were measured in 67 patients (age 30(12)) and 12 matched healthy volunteers (age 31(10)). Patients with congenitally corrected transposition of the great arteries (CCTGA, n=12), surgically corrected TGA (n=18), and subpulmonary pressure/volume overloaded RV (n=37), were classified in NYHA functional classes I - IV. Exclusion criteria included renal impairment, atrial arrhythmias and left ventricular dysfunction.
Results: Plasma BNP levels in asymptomatic patients (NYHA I) were significantly higher compared to healthy volunteers (5.0±4.0 vs 2.4±1.8 pmol/L, p=0.03). There was no significant difference in both BNP and ANP plasma levels between patients with functional class NYHA I vs NYHA II (BNP 5.0±4.0 vs 5.1±2.2 pmol/L; p=ns, and ANP 6.5±5.3 vs 5.9±3.2 pmol/L; p=ns). BNP and ANP plasma levels were significantly higher in patients with NYHA III compared to NYHA II (BNP 22.1±8.6 vs 5.1±2.2 pmol/L, p=0.0001 and ANP 17.8±10.2 vs 5.9±3.2 pmol/L, p=0.001) and NYHA IV compared to NYHA III, respectively (BNP 115.7±57.88 vs 22.1±8.6 pmol/L, p=0.005 and ANP 57±31.7 vs 17.8±10.2, p=0.02).
Conclusion: A strong relationship exists between the NYHA functional class and plasma neurohormonal levels. Plasma neurohormones and in particular BNP may be used for quantitative follow-up in patients with chronic RV pressure and/or volume overload.

P1085 Validation of four risk scores in patients undergoing off-pump coronary surgery: a United Kingdom multi-centre analysis of 2,223 patients

S. Al-Ruzzeh, G. Asimakopoulos, G. Ambler, R. Omar, R. Hasan, B. Fabri, K. Taylor, M. Amrani. *LONDON, United Kingdom*

Objective: Various risk stratification systems have been developed based mainly on patients undergoing cardiac surgery with Cardiopulmonary Bypass (CPB). This report attempts to assess the validity and applicability of the Parsonnet score, the EuroSCORE, the ACC/AHA system and UK CABG Bayes model in patients undergoing Off-Pump Coronary Artery Bypass (OPCAB) surgery in the United Kingdom (UK).
Methods: Data on 2,223 patients who underwent OPCAB in eight UK cardiac surgical centres were collected. Predicted mortality risk scores were calculated using the four systems and compared to the actual observed mortality. Calibration was assessed by Hosmer-Lemeshow (HL) test. Discrimination was assessed by calculating the Receiver-Operating-Characteristic (ROC) curve area.
Results: Out of 2,223 patients 30 (1.3%) died in hospital. For the Parsonnet score the HL test was significant ($P<0.001$) and the ROC area was 0.74. For the EuroSCORE the HL test was also significant ($P<0.01$) and the ROC area was 0.74. For the ACC/AHA system the HL test was non-significant (P=0.73) and the ROC area was 0.75. For the UK CABG Bayes model the HL test was also non-significant (P=0.87) and the ROC area was 0.81.
Conclusion: This study shows that the UK CABG Bayes model is well calibrated and provides good discrimination when applied to OPCAB patients in the UK. Amongst the other three systems, the ACC/AHA system is also well calibrated but its discrimination power was less than that of the UK CABG Bayes model. These data suggest that the UK CABG Bayes model is an appropriate risk stratification system to use for patients undergoing OPCAB in the UK.

P1086 Ebstein's anomaly and isolated tricuspid valve dysplasia: prenatal diagnosis, management and outcome

L.A. Lisowski[1], P.M. Verheijen[2], G.W.B.E. Bennink[2], P.H. Stoutenbeek[3], E.J. Meijboom[2]. [1]*Wilhelmina Children's Hospital, Pediatric Cardiology, Utrecht, Netherlands;* [2]*Wilhelmina Children's hospital, Pediatric Cardiology, Utrecht, Netherlands;* [3]*Wilhelmina Children's hospital, Obstetrics and Gynaecology, Utrecht, Netherlands*

Objective: A meta-ananlysis of the literature and a comparison with the results of a tertiary referral centre for paediatric cardiology and cardiac surgery. Included is a review of the diagnosis, management and outcome in cases of tricuspid valve dysplasia.
Patients: The diagnosis tricuspid valve anomaly was made 14 fetuses. Isolated Ebstein's anomaly occurred in 4 patients. One patient had Ebstein's anomaly associated with discordance of the great arteries, congenitally corrected transposition of the great arteries. Tricuspid valve dysplasia was encountered in 10 fetuses.
Results: In the group with Ebstein's anomaly (N=4) 2 fetuses died in utero at a gestational age of 29 and 36 weeks. Parents opted for compassionate care in one fetus which died at an age of 2 days. One patient with congenital corrected transposition of the great arteries is alive at an age of 9 years after receiving pulmonary artery banding, a partial cavopulmonal connection and a Damus-Kay-Stansel operation. In this group 2 fetuses had other hypoplasia of the lungs, of which one had a chromosomal anomalies (trisomy 18).
Conclusions: Patients with a prenatal diagnosis of Ebstein's anomaly or dysplasia of the tricuspid valve represent the most serious component of the spectrum of Ebsteins malformation. The very poor outcome is representative for this selected population and cannot be compared to patients in which the anomaly is detected in a later stage of life. Parental counselling of these patients can therefor not be based upon the natural history of these older patients. Prenatal diagnosis provides opportunities for in depth counselling of the parents before the medical and emotional complexities associated with the neonatal intensive care setting are encountered. Surgical procedures of tricuspid valve repair or replacement are offered for this anomaly but this option is almost exclusively provided for patients with a diagnosis in later life, as very few patients survive the prenatal period.

P1087 Structural congenital heart disease in diabetic pregnancies

L.A. Lisowski[1], P.M. Verheijen[2], J.A. Copel[3], C.S. Kleinman[4], G.H.A. Visser[2], E.J. Meijboom[2]. [1]*Wilhelmina Children's Hospital, Pediatric Cardiology, Utrecht, Netherlands;* [2]*Wilhelmina Children's hospital, Pediatric Cardiology, Utrecht, Netherlands;* [3]*Yale University, Obstetrics and Gynaecology, New Haven, United States of America;* [4]*Yale University, Pediatric cardiology, New Haven, United States of America*

Objective: The purpose of this study was to evaluate whether the increased incidence of fetal cardiac abnormalities in diabetic mothers is significantly related to maternal diabetic control.
Methods: Medical records of women with (pre-)gestational diabetes mellitus during pregnancy between January 1988 and December 1998 were retrospectively studied in Yale New Haven Hospital, USA.
Results: In 32 fetuses(5,8%, group A) a congenital heart defect was detected at a mean gestational age of 27,9 ± 1,19 weeks. In 527 fetuses(94,2%, group B) no cardiac malformation could prenatally be detected. The severance varied from mild hypertrophic cardiomyopathy to transposition of the great arteries or hypoplastic left heart syndrome. The mean age of the mothers was 30,7 ± 0,87 (group A) versus 29,1 ± 0,77 years(group B), the mean duration of the diabetes was 11,5 ± 2,2 vs 10,9 ± 1,1 years, and the mean concentration of glycosylated hemoglobin A(HbA1c) was 9,79 ± 0,69% vs 8,14 ± 0,29% (p=0,034).
Conclusion: A significant difference in HbA1c was found in favour of the group of women where no cardiac malformation could prenatally be detected. As the techniques and knowledge of prenatal detection of cardiac lesions improves, more lesions will be detected. As long as the mechanism of high blood glucose levels on the period of organogenesis is not yet fully understood, a benefit should come from controlling the diabetes before and during pregnancy. The incidence of congenital heart defects among fetuses of diabetic mothers will then hopefully be reduced to the incidence of CHD in the general obstetric population.

P1088 Prenatal diagnosis of the fetus with a hypoplastic left heart syndrome: management and outcome

L.A. Lisowski[1], P.M. Verheijen[2], G.W.B.E. Bennink[2], P.H. Stoutenbeek[3], E.J. Meijboom[2]. [1]Wilhelmina Children's Hospital, Pediatric Cardiology, Utrecht, Netherlands; [2]Wilhelmina Children's hospital, Pediatric Cardiology, Utrecht, Netherlands; [3]Wilhelmina Children's hospital, Obstetrics and Gynaecology, Utrecht, Netherlands

Objective: To review our 13-year experience with prenatally detected hypoplastic left heart syndrome (HLHS) which management remains controversial.
Setting-A tertiary referral centre for pediatric cardiology and cardiac surgery.
Design: A retrospective study of the management and outcome in all cases of HLHS presenting in fetal life between January 1988 and July 2001.
Patients-The diagnosis of HLHS was made in 32 fetuses. One mother had two with HLHS associated pregnancies.
Results: Termination of pregnancy (TOP) was opted for in 16 cases, 4 fetuses died in utero and in 5 parents opted for compassionate care. Seven patients received a palliative reconstructive Norwood procedure, one patient is alive at 17 months. Eight fetuses had extracardiac anomalies, 3 had chromosomal anomalies and 6 had other associated intracardiac anomalies.
Conclusions: Prenatal diagnosis of the HLHS provides opportunities for in depth counselling of the parents before the medical and emotional complexities associated with the neonatal intensive care setting are encountered. Parents faced with the difficult decision of possible termination of pregnancy, compassionate care or the Norwood strategy, tend not to opt for surgery based on the dim perspective of the future quality of life in these patients. The low percentage of intention to treat among patients in European centres differs significantly from reported percentages across the Atlantic. This is most likely based on the socio-geographic and religious differences in the interpretation of the long-term quality of life.

EPIDEMIOLOGY AND PREVENTION MISCELLANEOUS

P1089 Elevated midlife serum cholesterol levels increase the risk of Alzheimer's disease later in life

M. Kivipelto[1], E-L. Helkala[2], M.P. Laakso[1], A. Mannermaa[3], J. Tuomilehto[4], H. Soininen[5], A. Nissinen[4]. [1]University of Kuopio, Dept of Neuroscience and Neurology, Kuopio, Finland; [2]University of Kuopio, Dept of Public Health, Kuopio, Finland; [3]Kuopio University Hospital, Chromosome and DNA Laboratory, Kuopio, Finland; [4]The National Public Health Institute, Helsinki, Finland; [5]Kuopio University Hospital, Dept of Neurology, Kuopio, Finland

Background: Alzheimer's disease (AD), the most common cause of dementia, is a disease of complex origin, the exact pathogenic mechanisms of which remain to be discovered. Recently, evidence for a direct association between serum cholesterol and the development of AD has been documented. Apolipoprotein E (ApoE) e4 allele, involved in cholesterol metabolism, is the most important genetic risk factor for AD. Objective: To study the relative importance and the putative relationship between midlife cholesterol and ApoE polymorphism as risk factors for late-life AD in a longitudinal, population-based study-setting. Methods: Participants were derived from random samples studied in one of the surveys carried out in 1972, 1977, 1982 or 1987. After an average follow-up of 21 years, a total of 1449 (73%) individuals aged 65-79 years participated in the re-examination in 1998. Results: Elevated midlife serum cholesterol was an independent risk factor for AD later in life. Adjusting for ApoE e4 allele and other confounding factors (age, vascular disease, education gender, smoking, and alcohol) did not change the association (OR 2.8, 95%, CI 1.2-6.7). Similarly, ApoE e4 allele was an independent risk factor for AD, even after adjusting for cholesterol and other confounders (OR 2.1, 95% CI 1.1-4.1). The combination of elevated midlife cholesterol and ApoE e4 allele increased the risk of AD in a dose-depended manner; adjusted OR for this combination was 5.9 (2.1-16.3). Conclusions: Elevated midlife cholesterol and ApoE e4 allele constitute independent risk factors for AD. The risk of AD related to elevated serum cholesterol appears to be at least of similar magnitude than the risk related to the most important genetic risk factor ApoE e4 allele. These data emphasize the need for effective primary prevention and early treatment of hypercholesterolemia as potential avenues for reducing the risk of AD.

P1090 Impact of angiotensin-converting enzyme inhibitor administration prior to acute myocardial infarction on hospital and post-hospital morbidity and mortality

S. Ilic[1], M. Deljanin Ilic[2], D. Petrovic[1], B. Ilic[1], A. Nikolic[1]. [1]Institute of Cardiology, Clinical Cardiology, Niska Banja, Yugoslavia; [2]Institute of Cardiology, Echo lab, Niska Banja, Yugoslavia

The aim of the study was to determine whether administration of ACE inhibitor therapy prior to acute myocardial infarction (MI) is related to infarct size and subsequent hospital and post-hospital cardiovascular morbidity and mortality.

Methods: Study population consisted of 240 consecutive patients (pts) admitted with a diagnosis of acute MI. Outcome data were compared between groups of patients receiving ACE inhibitor therapy at least three months prior to infarction (ACEI group) and those who were not (non ACEI group).
Results: Sixty-four (27%) were receiving prior ACE inhibitor therapy. There were not significant differences in regard to age, sex, site of infarct, aspirin therapy, frequency of hypertension and diabetes in two groups. Patients in ACEI group experienced smaller MI size, determined by peak creatine kinase elevation ($P<0.01$), and by wall motion score (13.6 ± 1.5 vs 14.3 ± 1.9; $P<0.005$) than pts in non ACEI group. Left ventricular ejection fraction was bigger in ACEI group than in non ACEI group (47.8 ± 7.2 vs $45.4 \pm 8.4\%$; $P<0.05$). In patients receiving ACE inhibitor therapy prior to acute MI, intra-hospital cardiovascular events were less frequent than in those who were not: ventricular fibrillation (8% vs 13%), heart failure (14% vs 21%), re-infarction (6% vs 9%), recurrent angina (14% vs 19%), vascular death (6% vs 10%). There were not significant differences in regard to drug therapy including ACE inhibitor between two groups during the post-discharge 3 months follow up period. After three months the incidence of post-discharge combined morbidity events (re-infarction, CHF, unstable angina, hospitalization, coronary arteriography or myocardial re-vascularization) were slightly higher in non ACEI than in ACEI group (38% vs 30%), as well as the cardiovascular death (5% vs 3%).
Conclusion: Our data showed that patients who experience an acute MI, those receiving prior ACE inhibitor therapy have smaller infarct size, better global left ventricular function and less intra-hospital and post-hospital three months period morbidity and mortality. Thus prior ACE inhibitor therapy have cardioprotective effects in patients with acute myocardial infarction.

P1091 Atrial fibrillation in a cold climate: seasonal variations in morbidity and mortality

S. Stewart[1], S.W. Willoughby[1], K. MacIntyre[2], S. Capewell[3], J.J.V. McMurray[4]. [1]The Queen Elizabeth Hospital, Cardiology Dept., Adelaide, Australia; [2]Greater Glasgow Health Board, Glasgow, United Kingdom; [3]University of Liverpool, Public Health Dept., Liverpool, United Kingdom; [4]University of Glasgow, CRI in Heart Failure, Glasgow, United Kingdom

Aims: Seasonal variations in the incidence of myocardial infarction, sudden death and, more recently, heart failure have been described. To date, however, it has not been documented in atrial fibrillation (AF). This study examined whether there is seasonal variation in hospitalisations and deaths due to AF in Scotland.
Methods: We used the linked Scottish Morbidity Record scheme, which provides individualised morbidity and mortality data for the entire Scottish population, to identify all AF-related admissions in Scotland between 1990-1996 and all deaths occurring in those patients who contributed to these admissions between 1990-1997.
Results: During the period 1990-1996, there were a total of 33,582 male and 34,463 female admissions related to AF (either as a principal or secondary diagnosis). This represented an average of 92.3 and 94.7 admissions per day. Significantly more admissions occurred in "peak" winter compared to "low" summer months ($P < 0.01$ for all comparisons). In both men and women, the peak rate of admission occurred in December (9% and 12% more than average) and the lowest admissions rates occurred in June (- 6%) for women and in August (- 3%) for men. The absolute difference in the number of male and female admissions that occurred during these months was 290 and 487, respectively. In both sexes, the greatest variation occurred in those aged > 75 years: peak winter rates being 17-26% higher in those aged 75-84 years and 35-39% higher in those aged 85+ years than average. Seasonal variation in mortality was also seen in these patients with significantly more deaths occurring in "peak" winter versus "low" summer months ($P < 0.001$ for all comparisons). In both men and women, the peak number of deaths occurred in December (22% and 23% higher than average) and the lowest number in August (17% and 14% lower). The absolute difference in the number of male and female deaths occurring during these months was 501 and 723, respectively. Similar trends were observed when these data were analysed according to whether AF was listed as a principal or secondary diagnosis and for short versus longer-term case-fatality rates.
Conclusions: There is substantial seasonal variation in AF-related admissions and deaths in Scotland (particularly in the elderly). A large proportion of this morbidity and mortality is associated with concurrent cardiovascular disease (e.g. stroke and myocardial infarction). Whilst extra vigilance in patients with AF is advisable in winter, further study is required to identify and address the reasons for the marked winter peaks observed.

P1092 Causes of a raised brain natriuretic peptide concentration in an urban population with risk factors for left ventricular dysfunction

T A. McDonagh[1], S.D. Robb[2], H.J. Dargie[2]. [1]University of Glasgow, Medical Cardiology, Glasgow, United Kingdom; [2]Western Infirmary, CRI in Heart Failure, Glasgow, United Kingdom

Many studies have concentrated on the use of brain natriuretic (BNP) peptide in diagnosing heart failure (CHF) and left ventricular dysfunction (LVD) in both hospital and community based settings. However, BNP is a marker of increased wall stress and is a non-specific marker of cardiac dysfunction. We aimed to determine the causes of a raised BNP concentration in a sample of 1599 subjects from South Glasgow. 2484 subjects were randomly sampled. All were >45 years and had risk factors for CHF or LVD ie hypertension, diabetes, angina or a previous MI. 1599 attended for a detailed echocardiogram, medical interview, an ECG, a BNP sample and plasma creatinine. Definite systolic dysfunction on echocardiography was defined as a left ventricular ejection fraction (LVEF)<=35% or a wall motion score index (WMI)<=1.4 or at least moderate LVD on subjective coding. Mild LVD was defined as a LVEF<=40% or a WMI<=1.6 or at least mild LVD subjectively. Echocardiograms were analysed for the presence of left ventricular hypertrophy (LVH) and significant valvular disease. An abnormal BNP was defined as being beyond the 95th centile for normals in an age-matched population based study (109.6pg/ml for >70 years and >67pg/ml for those <70).

In this population 333 subjects had a high BNP value. Of those with a high BNP concentration, the following list outlines the causes ranked in descending order and presented as the cumulative number of subjects with the cumulative percentage in parenthesis):the categories are mutually exclusive.

Definite LVD 77 (23.1%), mild LVD 123 (36.9%), MI 171,(51.3%), valve disease 184 (54.3%), a GFR<=60ml/min 234(69.3%), LVH 250 (75.1%), AF 251 (75.4%), GFR between 60-80mls/min 279 (83.8%) and an abnormal ECG 281 (84.4%). No cardiac strutural/functional or renal casue could be identified in the remaining 15.6% of those with an elevated BNP concentration. The remaining subjects were hypertensive or had angina without demonstrable LVH or LVD.

BNP, although higher in concentration, in subjects with CHF and LVD, is a non-specific marker of cardiorenal disease. Where it is used to detect CHF in breathless subjects or to screen for asymptomatic LVD, an elevated value should prompt a cardiological referral.

P1093 Increased mortality rates in patients with coronary artery disease presenting low fasting glucose levels: an 8-year follow-up

E. Fisman[1], S. Behar[2], A. Tenenbaum[1], V. Boyko[2], L. Mandelzweig[2], M. Motro[1]. [1]Chaim Sheba Medical Center, Cardiac Rehabilitation Institute, Ramat-Gan, Israel; [2]Sheba Medical Center, Tel-Hashomer, Neufeld Cardiac Research Institute, Ramat-Gan, Israel

Background: The close relationship between hyperglycemia and increased mortality is well established, but no consistent information is available regarding the association between low glucose levels and cause-specific mortality in patients with coronary artery disease (CAD). We aimed to investigate the relationship between hypoglycemia and all-cause, cardiovascular and cancer mortality in a large population of CAD patients along a mean 8-year follow-up period.

Methods: A total of 14670 patients with documented CAD aged 45-74 years were divided into 6 groups graded across strata of glucose levels upon screening: 1) hypoglycemic (up to 69 mg/dl); 2) low normal (70-79 mg/dl); 3) euglycemic (80-109 mg/dl); 4) patients with impaired fasting glucose (IFG) (110-125 mg/dl); 5) borderline diabetics, comprising patients considered diabetics by the new American Diabetes Association criteria but not by the former World Health Organization criteria (126-139 mg/dl); 6) diabetics (above 140 mg/dl). Mortality rates were separately assessed for each group.

Results: The population comprised 131 patients with hypoglycemia (0.9%), 731 with low normal values (5%), 9308 euglycemic (63.4%), 1577 with IFG (10.7%), 617 borderline diabetics (4.2%) and 2306 diabetics (15.7%). Patients were followed 6.2 to 9.0 years. Crude all-cause mortality was significantly higher in both diabetic (31.8%) and hypoglycemic groups (25.2%) as compared with euglycemic (14.9%; $p<0.0001$), whilst cardiovascular mortality was higher only in diabetics (17.8% vs. 7.9%; $p<0.0001$). The highest prevalence of cancer mortality was documented in the hypoglycemics (6.1% vs. 2.9 in euglycemics; $p<0.02$). Actuarial survival curves showed the lowest mortality rates in euglycemics and in the low normal group, whilst the highest was seen in both diabetics and hypoglycemic patients. Intermediate values were documented for borderline diabetics and patients with IFG. After adjustment for variables, with euglycemic patients as reference group, a significantly higher mortality rate was documented in hypoglycemics when compared with euglycemics ($p<0.0001$). Hypoglycemia was identified as an independent predictor of increased all-cause and cancer mortality with hazard ratios (HR) of 1.84 (95% CI 1.29 - 2.61) and 2.26 (95% CI 1.12-4.57), respectively, but not of increased CAD mortality, with HR 1.30 (95% CI 0.73 - 2.29).

Conclusions: The main findings of this study are the substantially increased all- cause and cancer mortality rates after a mean 8-year follow-up period among patients with CAD presenting low fasting glucose levels.

P1094 Increased circulating levels of natriuretic peptide predict future cardiac events in patients undergoing chronic haemodialysis

H. Takase[1], T. Goto[2], T. Toriyama[1], T. Sugiura[1], Y. Dohi[2]. [1]Enshu General Hospital, Department of Internal Medicine, Hamamatsu, Japan; [2]Nagoya City University Hospital, 2nd Internal Medicine Dept., Nagaya, Japan

Objective: Cardiovascular events are the major determinant of the prognosis for patients undergoing chronic hemodialysis. The present study was designed to determine whether increased plasma levels of atrial or brain natriuretic peptide (ANP or BNP) can be used to predict future cardiac events in patients undergoing chronic hemodialysis.

Methods: Fifty-three patients undergoing chronic hemodialysis without clinical evidence of cardiac disorders were enrolled in the study. Their blood was sampled for ANP and BNP measurements, and an ultrasound cardiogram and chest X-ray were performed at enrollment. We then followed them up for 11.3±0.2 months, with the endpoint being the occurrence of cardiac events. Cut-off levels of the peptides were calculated using receiver operating characteristics (ROC) curve analysis and the cumulative event-free curves were determined using the Kaplan-Meier method in order to evaluate the predictive values of the cut-off levels.

Results: Cardiac events occurred in 13 patients (CE group). Cardiac events included non-fatal myocardial infarction (1), angina pectoris (1), second grade atrio-ventricular block (1), heart failure (9) and sudden cardiac death (1). Both ANP and BNP levels were higher in patients in the CE group than in patients not presenting with cardiac events (ANP: 118±21 vs 56±5 pg/ml; $p<0.05$, BNP: 769±204 vs 193±25 pg/ml; $p<0.05$, respectively). The length of the hemodialysis period, hemoglobin concentration, cardiothoracic ratios of chest X-rays, findings obtained from ultrasound cardiograms and medication administered were the same in both groups. ROC curve analysis revealed that the cut-off levels, sensitivities and specificities were 58pg/ml, 100.0% and 63.9%, respectively, for ANP and 390 pg/ml, 61.5% and 92.5%, respectively, for BNP. Using the Kaplan-Meier method, the incidence of cardiac events was significantly higher in patients with higher levels of ANP (50.0% vs 0.0%) or BNP (72.7% vs 11.9%) than in those with lower levels of each peptide.

Conclusion: Elevated levels of ANP or BNP indicate an increased risk of the occurrence of cardiac events in patients undergoing chronic hemodialysis. The cut-off levels of these peptides are clinically acceptable and useful for prediction of the occurrence of cardiac events in patients undergonig chronic hemodialysis.

P1095 A population study of left ventricular dysfunction in long-term survivors of myocardial infarction

S.D. Robb[1], T.A. McDonagh[2], C.E. Morrison[3], J.J. Morton[4], H.J. Dargie[5]. [1]Western Infirmary, Department of Cardiology, Glasgow; [2]Royal Infirmary, Department of Cardiology, Glasgow; [3]Greater Glasgow Health Board, Public Health, Glasgow; [4]Western Infirmary, Medicine and Therapeutics, Glasgow; [5]Department of Cardiology, Western Infirmary, Glasgow, United Kingdom

More patients are now surviving their myocardial infarction (MI) but do so at the expense of developing heart failure due LV systolic dysfunction (LVD). The aim of this study was to determine the prevalence of LVD by echocardiography in long term surivors of MI within the defined population of North Glasgow, UK. All cases were identified from the MONICA Heart Attack Register for North Glasgow, having sustained a WHO validated first MI between 1985-1992. Each attendee at the study in 1995-6 completed symptom and medication questionnaries and had a full 2D echocardiogram, including a left ventricular ejection fraction (LVEF) by the Biplane Simpson's Rule Method. LVD was taken as a LVEF≤35%. Symptomatic LVD was a LVEF≤35% with breathlessness and/or loop diuretic therapy. Plasma BNP was measured using a direct IRMA method. 924 subjects attended (687 males), at a median period of 7 years post MI (range 2.5-11.5 years). The median age was 62 yrs (34-75). A LVEF could be calculated in 791 (85.6%). The median LVEF was 46.7% (11-76). LVD was identified in 147 subjects (18.6%) and was substantially more prevalent in men (21.6%) than in women (10.3%), $p<0.001$. Symptomatic LVSD was present in 105(71.4%) of those with LVD.

The geometic mean concentration of BNP in those with LVD was significantly higher than in those without (91.20±3.24) vs (29.52±2.82) pg/ml. $p<0.001$. On ROC analysis, the AUC for BNP in detecting LVD was 0.78. A BNP concentration of >=25.85pg/ml diagnosed LVD with a sensitivity of 87.6%, specificity of 42.6% and had a negative precitive value of 94%.

In contrast to previous data based on clinical trial and hospital-based series, this study reports the prevalence of LVD in a population-based study of survivors of MI. The prevalence of LVD is lower than that of the post MI treatment trials and reflects a survival effect. Interestingly the prevalence of LVD was significantly lower in women. BNP also appears to have good diagnostic potential in detecting LVD post MI in this population.

P1096 Trends in proportion of patients in killip class III and IV in myocardial infarction. Variables associated with it and with mortality (1978-1997)

I. Rohlfs[1], R. Elosua[2], R. Masiá[1], J. Sala[1], J. Marrugat[2] on behalf of the REGICOR Investigators. [1]*Hospital de Girona Dr. Josep Trueta, Cardiology - REGICOR, Girona, Spain;* [2]*IMIM, Cardiovascular epidemiology and lipids, Barcelona, Spain*

Background: The development of acute pulmonary edema (Killip class III) or cardiogenic shock (class IV) is associated with a higher mortality in the acute phase of acute myocardial infarction (AMI).
Aims: To analyse the trends in the proportion of patients that develop Killip class III and IV in the acute phase of AMI during a 20-year period (1978-1997), to determine the variables associated with its development and to determine 28-day case-fatality in this subgroup.
Methods: The study is based on a hospital registry of all patients admitted with a first AMI younger than 75 in from 1978 to 1997. Five periods (1978-81, 1982-85, 1986-89, 1990-93 and 1994-97) were defined for analysis. Sociodemographic variables, cardiovascular risk factors, clinical variables, treatments and procedures were recorded. The worst Killip class during hospitalisation and mortality at 28 days were also recorded. Logistic regression was used for statistical analysis.
Results: The registry included 2.590 patients. Mean age was 60 years and 17% were women. Killip class III and IV developed in 13.5% of the patients. There were no changes in this proportion over the five periods. Age, diabetes, previous angina and anterior location of AMI were associated with a higher risk of Killip class III and IV. Case-fatality at 28 days in this subgroup was 51.7%, with a decreasing linear trend over the years ($p<0.001$). Variables associated with a higher case-fatality were age and malignant ventricular arrhythmias. Admission during the periods 1990-93 and 1994-97 was associated with a lower case-fatality (OR=0.37 and 0.28, respectively). The protective effect of these periods disappeared after adjusting for some treatment variables (antiplatelet agents and thrombolysis).
Conclusions: The proportion of patients with AMI that develop Killip class III and IV has remained stable in the last two decades. Although 28-day case-fatality in this patients is high, a decrease has been observed in the last years. This decrease could be explained by the introduction of new treatments (antiplatelet agents and thrombolysis).

P1097 Changes in predictors for cardiovascular mortality between 10, 20, 30 and 40 years follow-up of the Seven Countries Study in Greece

J. Skoumas[1], C. Chrysohoou[1], C. Pitsavos[1], D.B Panagiotakos[1], A. Dontas[1], A. Menotti[2], C. Stefanadis[1], P.K. Toutouzas[1]. [1]*University of Athens, School of Medici, Cardiology Clinic, Athens, Greece;* [2]*Rome, Italy*

Background: The Seven Countries Study on cardiovascular diseases has completed in most of the cohorts, approximately, four decades of prospective investigation. In previous analyses the Mediterranean cohorts, and especially the Greeks, showed a markedly decrease in cardiovascular death rates, among the 16 investigated cohorts. Aim of this work is to evaluate, potential, differences in predictors of cardiovascular deaths between 10-20-30 and 40 years follow up.
Methods: From September to October 1961, an international team of specialists examined 529 men from 6 villages. The Corfu cohort was made up of almost all men (95.3%) who were 40-59 years old in the early fall of 1961. Collection of the data on mortality and causes of death was complete for all men for the subsequent 40 years, through visits at villages, ascertaining the fatal events. A survival analysis was performed with CHD mortality as the end-point, while age, blood pressure, total cholesterol, body mass index, smoking, physical activity, skinfold thickness, mid arm circumference, vital capacity and forced expiratory volume, as predictors. Cox proportional hazards models were used in order to assess changes in the investigated parameters.
Results: The death rate varied from 1.5% - 4.3% - 7% and 19.5% in the interim analyses of 10-20-30 and 40 years of follow up, respectively. The predictors for the 10 – years mortality were total cholesterol levels (HR = 1.016, $p < 0.01$) and body mass index (HR = 1.16, $p < 0.07$), for the 20 years CHD mortality were age (HR = 1.14, $p < 0.01$), total cholesterol (HR = 1.013, $p < 0.01$), smoking (HR = 4.51, $p < 0.05$) and vital capacity (HR = 0.943, $p < 0.1$), for the 30 years CHD mortality were age (HR = 1.17, $P < 0.1$), physical inactivity (HR = 3.18, $p < 0.01$), body mass index (HR = 1.064, $P < 0.05$), smoking (HR = 1.6, $p<0.05$), while the predictors for the 40 years mortality were age (Hazard ratio=1.083, $P<0.001$), total serum cholesterol (HR=1.004, $P<0.01$), smoking (HR=1.596, $P<0.05$), and body mass index (HR=1.05, $P<0.05$).
Conclusions: The cluster of the predictors of CHD mortality varies over time, in the investigated cohort. The information raised from this analysis, through a long-term assessment, may be useful in a better understanding of CHD mortality.

P1098 Prevention of CHD: implications of the Framingham study coronary risk appraisal models published in 1991 and 2000

K. Nanchahal[1], J. Duncan[2], P. Durrington[3], R. Jackson[4]. [1]*LSHTM, Public Health & Policy, London, United Kingdom;* [2]*GlaxoSmithKline, Harlow, United Kingdom;* [3]*Manchester Royal Infirmary, University Medical Unit, Manchester, United Kingdom;* [4]*University of Auckland, Faculty of Medical & Health Sciences, Auckland, New Zealand*

Background: Recommendations on prevention of CHD and management of hypertension include use of Framingham Study CHD risk appraisal models published in 1991 to identify patients eligible for drug treatment. Updated risk appraisal models published in 2000 incorporate further follow-up and include factors not used in the previously published models.
Methods and Results: We used the 1998 Health Survey for England data for participants aged 35-74 years with complete information on factors required for assessment of CHD risk, after excluding those reporting doctor-diagnosed angina, heart attack or stroke. 10- and 4-year probabilities of developing CHD were estimated using the 1991 equations and 4-year risk was calculated using the 2000 equations. Summary statistics for 4-year CHD risk per 100 persons show that both models produce similar population distributions. While there is substantial agreement between classification of subjects into risk categories based on the two models, within each category based on the 1991 models, individuals were distributed across a wide range of risk categories based on the 2000 models.
Comment: Current guidelines recommend drug therapy for hypertension or hypercholesterolaemia for patients with 10-year risk of 15% and above. As increase in risk accelerates with increasing age, we used a 5% risk of a coronary event in 4 years as being equivalent to a 10-year risk of 15%. Based on the 1991 risk appraisal models, approximately 32% men and 7% women aged 35-74 years in England are at 15% or higher risk of developing heart disease in the next 10 years. Using the 2000 models gives figures of 29% men and 6% women with a 4-year risk of 5% or more. While only 1-2% men and women ineligible for drug therapy under current criteria would be eligible using the 2000 models, 20% men and 43% women currently recommended drug therapy would not be eligible using their 4-year risk based on the updated models. Sensitivity and specificity for the 1991 risk appraisal models would be 97.6% and 90.0% for men and 79.7% and 96.0% for women respectively. A significant number of people meeting drug treatment criteria based on the 1991 models would not meet the equivalent criteria based on the 2000 models. Although thresholds for drug treatment are somewhat arbitrary and depend to a large degree on the resources available, we recommend that these findings are taken into account when current CHD prevention guidelines are updated in accordance with emerging scientific evidence for statin therapy and management of mild hypertension.

P1099 Extent of coronary artery calcifications in HIV-1 positive patients under highly active antiretroviral therapy

D. Ropers[1], A. Taubald[2], K. Pohle[1], M. Schmitt-Händle[2], W.G. Daniel[1], J.R. Kalden[2], T. Harrer[2], S. Achenbach[1]. [1]*University of Erlangen-Nürnberg, Internal Medicine II Dept., Erlangen, Germany;* [2]*University of Erlangen-Nuernberg, Department of Internal Medicine III, Erlangen, Germany*

In HIV-1 positive patients under highly active antiretroviral therapy (HAART), especially therapy with protease inhibitors (PI), accelerated arteriosclerosis and an increased incidence of myocardial infarction has been reported. To determine the extent of coronary artery calcifications in HIV-1 infected patients under HAART, we performed electron-beam tomography (EBT). The results were compared to a control group of HIV-1 negative patients.
Methods: EBT was performed in 60 HIV-1 positive patients (50 male, 10 female, mean age 41 years, average infection time 7 years) without known coronary artery disease using a standardized protocol (ECG-triggered, 40 axial slices, slice thickness, 3 mm, no overlap). The degree of coronary calcification was analyzed using the Agatston score. The HIV-1 positive patients were compared to a group of 60 HIV-negative controls (mean age 41 years) matched for age (± 5 years), gender and traditional risk factors (hypertension, cholesterol, diabetes, smoking and family history).
Results: The Agatston score was 37.7 ± 119 in the HIV-1 infected group compared to 19.9 ± 43 in the control group, but this difference did not reach statistical significance ($p = 0.5$, McNemar-Test). PI treated patients ($n = 45$) showed an Agatston score of 47.2 ± 138 compared to 34.6 ± 113 in the group of HIV-1 patients without PI treatment ($p = 0.7$).
Conclusion: In this cross-sectional study, HIV-1 positive patients showed only a tendency towards a more pronounced coronary calcification in comparison to a matched control group. PI treated patients did not differ significantly from patients without PI treatment. However, prospective longitudinal studies are needed to assess the long-term risk of HAART for coronary artery disease.

P1100 Risk factors in African compared to white patients with coronary artery disease (CAD)

R. Nethononda[1], M R. Essop[1], Y. Variava[1], J. Galpin[2]. [1]*Baragwanath hospital, Cardiology, Johannesburg, South Africa;* [2]*University of Witwatersrand, Statistics, Johannesburg, South Africa*

Background Traditional risk factors for CAD have been identified from studies of predominantly white patients in developed countries. Whether these risk factors are equally important in African populations in developing countries is unknown. The aim of this study was to identify and compare risk factors for CAD in African vs. white patients with angiographically documented CAD.
Methods Hospital records of consecutive patients admitted to our hospital over a 2 year period (1998-1999) with 50% or more stenosis of one or more epicardial coronary arteries were analysed. Coronary risk factors including smoking, diabetes, hypertension, obesity, serum total cholesterol (TC), low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol and triglyceride levels were evaluated. Data is reported as median and range, and percentages. Categorical variables were compared by Fisher's exact test or Chi-squared test. Continuous variables were analysed by the Mann-Whitney U-test. A p value < 0.05 was considered significant.
Results There were 207 patients of which 87 (42%) were Africans and 120 (58%) were whites. Age was similar between the 2 groups [59 (24-79) vs. 56 (27-79) years]. There were more females in the African compared to the white group (31% vs. 12%; $p < 0.0229$). Hypertension occurred more commonly in Africans (78% vs. 55%; $p < 0.001$). Serum TC and LDL cholesterol were significantly lower in Africans [4.9 (2.5-8.1) vs. 5.9 (3.3-12)mmolŁ; $p < 0.0006$ and 2.6 (0.9-7.3) vs. 3.8 (1.1-8.1)mmolŁ; $p < 0.0001$ respectively]. No significant differences were observed in the remaining risk factors.
Conclusion Hypertension is more prevalent in Africans with CAD than whites. A female gender appears to confer an additional risk for CAD in African compared to white patients. Baseline LDL cholesterol levels in this group of African patients with documented CAD are exceptionally low and fall into the range recommended by the National Cholesterol Education Program (NCEP) guidelines. These findings may have significant implications for risk factors management in African patients with CAD in developing countries.

P1101 Socioeconomic status and coronary heart disease risk factors: the CARDIO2000 study

D.B Panagiotakos, C. Pitsavos, C. Chrysohoou, J. Skoumas, N. Marinakis, C. Stefanadis, P.K. Toutouzas. *University of Athens, School of Medici, Cardiology Clinic, Athens, Greece*

Background: A large number of studies have shown that socio-economic status is related with cardiovascular disease mortality and morbidity among adults, in many developing societies. Aim of this work is to evaluate the relations between social class and various risk factors, in a middle-aged random sample of coronary patients and controls.
Methods: CARDIO2000 project is a population-based study for the primary prevention of CHD. Stratified random sampling from all Greek regions, consisted of 848 hospitalised patients (701 males, 58±10 -147 females, 65±9 years old) for first event of acute coronary syndromes (ACS) and 1078 paired, by sex-age, hospitalised in the same hospitals, controls, without any clinical suspicion of CHD. Social stratification (low, middle and high social class) was based on discriminant analysis of the economical, occupational and educational level of the subjects, according to Tumins' theory.
Results: 491 (58%) of the patients and 561 (52%) of the controls were classified in low class, 187 (22%) patients, 205 (19%) controls in middle class and 167 (20%) patients, 312 (29%) controls in high class ($P<0.01$). The analysis showed higher prevalence of hypertension (28.4% vs. 17.6% vs. 16.5%, $P=0.003$), smoking (36.0% vs. 34.3% vs. 33%, $P<0.01$), job stress (40.0% vs. 25.2% vs. 21%, $P<0.001$), high fat diet (54% vs. 23% vs. 22%, $P<0.01$) and high alcohol consumption (37% vs. 22% vs. 21%, $P<0.05$), between the social classes. The multivariate model showed that subjects in middle class have 45% increased coronary risk compared to subjects in high class (OR=1.45, $P=0.003$), while subjects in low class have 42% higher coronary risk (OR=1.42, $P=0.001$), after taking into account the effect of several potential confounders.
Conclusions: It seems that subjects in low-middle class need more attention from the preventive strategies, since they are more vulnerable in developing ACS compared to the others. A potential explanation is due to the adoption of unhealthy lifestyle habits and the increased prevalence of hypertension in low-moderate social class, but further investigation is needed in order to confirm or refute our findings.

P1102 Education level: association with cardiovascular risk factors and all-cause mortality

K. stankovic[1], P. champomier[1], P. lantelme[1], M. gouton[2], F. Delahaye[2], H. milon[1]. [1]*Hopital de la Croix Rousse, Cardiologie, Lyon, France;* [2]*hopital Pradel, cardiologie, Lyon, France*

The association between low educational level (EL) and poorer health has been documented in previous reports. The aim of our study was to specify the relationship, first between EL and cardiovascular risk factors, and secondly between EL and overall mortality in a population based study.
In 1982-1984, we surveyed 3690 people -3210 men (87.0%) and 480 women (13.0%)- working in 4 factories of the area of Lyon, France (response rate 90.1% of the target population). Their mean age was 41.4±9.33(DS) and 39.6±9.2(DS) years, respectively. EL was categorized in 4 groups: less than 6 years (primary school)(N=812), up to 10 years (secondary school)(N=1726), up to 15 years ("baccalauréat")(N=683), university (N=466). For each subject, we got data about smoking, alcohol consumption and other dietary habits, physical activity, and current medications. Then, weight, height, blood pressure and heart rate were measured, and a blood sample was taken for assessment of cholesterol, triglycerides, blood glucose, and renal and liver tests.
Using ANOVA statistics, we found that lower EL was significantly associated with higher frequency and/or higher level of cardiovascular risk factors, especially cigarette smoking, excessive alcohol consumption, overweight (Body Mass Index), and lack of physical activity in leisure time. It was also significantly associated with faster heart rate, higher diastolic and systolic blood pressure, hypercholesterolaemia (total and LDL-cholesterol), hyperglycemia. In women, we found an association between lower EL and the simultaneous use of oral contraception and cigarettes. The subjects with lower EL were also older but all the relations remained statistically significant after adjusting for this main confounder in an analysis of covariance. Then, using Kaplan-Meier curves, we showed that there is an inverse relationship between EL and all-cause mortality, with an average follow-up duration of 15 years. In men, the mortality was 15.1% in the primary EL group and 4.2% in the university group ($p<0,00001$).
Our results emphasize the inverse relationship between EL and cardiovascular risk factors, and mortality, which was partly explained by less favourable health habits. These results have strong implications for public health education. Prevention programs must be appropriate to the targeted audience. In addition, they must address not only specific cardiovascular risk factors, but also more general risk behaviors, keeping in mind that those are related to social conditions.

P1103 Impaired cognitive function as a risk factor of in-hospital mortality in older patients with heart failure

A. Jozwiak[1], P. Guzik[2], Z. Chmielewski[1], K. Lyczkowska[1], M. Kluczynski[1], H. Wysocki[2]. [1]*Gniezno Hospital, Department of Geriatry, Gniezno, Poland;* [2]*University School of Medical Sciences, Div. of Cardiology - Intens. Therapy, Poznan, Poland*

Heart failure (HF) and impaired cognitive function are frequent causes of hospitalization in elderly patients. Independently, both clinical syndromes are associated with increased mortality. The aim of the study was to evaluate the influence of impaired cognitive function on in-hospital mortality in old patients with HF. A modified Mini-Mental State Exam (MMMSE) was performed in 597 consecutive patients (65 - 102 years old; 355 female) with heart failure. All patients were stratified into low (6.3±1.2 points), medium (19.7±4.7 points) or high (29.1±2.1 points) tertile group according to MMMSE results. Total in-hospital mortality was 52.0% in the lowest, 34.2% in the medium and 15.1% in the highest tertile (Pearson Chi-square $p < 0.0001$ for trend). The comparison of in-hospital mortality between tertiles of MMMSE was done with the use of logistic regression adjusted to age, sex, and the presence of diabetes mellitus, renal failure and anemia. Comparison of in-hospital mortality between patients from the lowest tertile of MMSE with the highest one revealed that odds ratio was 5.93 (95% CI: 3.58 - 9.80; $p < 0.0001$) whereas it was 2.67 (95% CI: 1.60 - 4.67; $p = 0.0002$) for patients from the medium tertile. The obtained results show that the worse cognitive function is, the worse in-hospital prognosis can be observed in older patients with HF. Moreover, it also suggests that impaired cognitive function may be an independent risk factor for mortality in elderly HF patients.

P1104 Post traumatic stress disorder is the most important determinat of adherence with aspirin treatment 6 months after an acute myocaridal infarction

E. Shemesh[1], I. Dinur[2], A. Rudnick[3], E. Gilboa-Schehtman[4], A. Salah[2], O. Milovanov[2], E. Kaluski[2], G. Cotter[2]. [1]*Mount-Sinai Medical Center, Psychiatry, NY, United States of America;* [2]*Assaf-Harofeh Medical center, Cardiology, Zerifin, Israel;* [3]*Tel-Aviv University, Psychiatry, Tel-Aviv, Israel;* [4]*Bar-Ilan University, Psychiatry, Tel-Aviv, Israel*

Nonadherence to (no compliance with) medications following a myocardial infarction has been reported to be a major cause of post-myocardial infarction (MI) morbidity and mortality. We have previously introduced a novel hypothesis, linking symptoms of posttraumatic stress disorder (PTSD) to nonadherence in these patients. According to this hypothesis, patients who are traumatized by the MI may not take their medications because these serve as a painful reminder of the traumatic event. To explore this hypothesis further, we examined this association in a cohort of post-MI patients in an outpatient setting.

Patients and Methods: 100 patients were approached 6 months following an acute MI and 82 gave informed consent and enrolled. In a separate study, we evaluated 3 different methods of assessment of adherence to aspirin by platelet function and found that TxA2 production is the most reliable method. This was also reported by others. Patients where asked to answer a validated PTSD questioner (impact of event scale, 15 brief questions) and validated questioner examining broad psychopathology constructs (SCL-90-R).

Results: Above-threshold PTSD scores were associated with nonadherence (p=0.02). Other baseline variables (sex, age, employment, family status), background diseases (diabetes, hypertension, functional class) as well as psychopathological characteristics where not associated with nonadherence. Patient self-report was also did not reliably predict adherence in the present study.

Conclusion: PTSD symptoms are significantly associated with nonadherence to medications following an acute MI. These symptoms can easily be assessed in a clinical setting. If indeed medications serve as a painful reminder of the MI to patients who are traumatized by it, then trauma specific interventions hold the promise to improve adherence and hence outcome in these patients. Such treatments where previously reported by us to improve adherence in another disease process.

P1105 Stress, multiple roles and coronary disease in women. The Stockholm female coronary risk study

K. Orth-Gomer, C. Leineweber. *Karolinska Institute, Public Health Sciences, Stockholm, Sweden*

Objective: Once women get coronary disease, their prognosis is poorer and they are less likely than men to get rehabilitated, even after control for age and comorbidity. Possible reasons for this gender difference include the chronic and daily stresses of work and family roles, which may add to the burden of physiological risk factors in younger women.

Background and methods: In the Stockholm Female Coronary Risk Study,women patients who reported emotional stress from their dyadic relationship, as assessed by the Stockholm Martial Stress Scale, were more vulnerable than women who reported work stress, by the Karasek model.We further hypothesized that women who, at the same time, experienced martial and work stress may be at even greater risk of worsening coronary disease and that depressive symptoms may mediate the effects of such stress.The age and multivariated adjusted hazard ratios for the five year risk of a recurrent cardiac event in women patients, was 2.9 for marital stress (95% CI 1.3-6.5) and 1.6 for work stress (95% CI 0.8-3.3). About one third of women patients experienced marital and work stress concomtantly. Their hazard ratio for a recurrent event was 5.7 (95% CI 1.3-24.3).

Results: Women patients reporting both types of stress had an average of 5.0 (±0.6) depressive symptoms, whereas patients without any stress had 1.5 (±0.6) symptoms.

Conclusion: Patients with both marital ad work stress were at highest risk of recurrant events. Effects of multiple stress expereinces were synergetic and possibly mediated by depressive symptoms.

P1106 Hereditary haemochromatosis gene mutations, prevalence and severity of coronary artery disease

R. Surber, H.H. Sigusch, H.R. Figulla. *Friedrich Schiller University, Dept. Internal Medicine/Cardiology, Jena, Germany*

A mutation in a nonclassic MHC class I gene (HFE gene), resulting in a cysteine-to-tyrosine substitution at amino acid 282 (Cys282Tyr) has been shown to be the major cause of hereditary haemochromatosis. Heterozygotes are common in the European population (about 10%) and have slight iron overload. Individuals carrying the mutation were reported to have an increased risk of myocardial infarction and cerebrovascular death. But there are also conflicting results. We investigated the influence of the Cys282Tyr mutation on prevalence and severity of coronary artery disease (CAD) in a large angiographically controlled population.

Methods: We genotyped 1279 patients (pts) who underwent coronary angiography at our institution. Pts with a >50% stenosis were diagnosed to have CAD. The Gensini score, an established score to describe severity and functional significance of CAD, was used. Genomic DNA was extracted from blood leukocytes and standard PCR was performed to detect G-to-A transition, resulting in the Cys282Tyr mutation in the HFE gene.

Results: 116 pts (9.1%) carried the heterozygous mutation, 1 patient was homozygous. The estimated mutant allele frequency was 0.048. The genotype distribution in our population was not statistically different from expected Hardy-Weinberg-equilibrium.

In a multivariate analysis conventional risk factors but not the Cys282Tyr mutation were associated with the prevalence of CAD (table). Incidence of previous myocardial infarction was also not influenced by the mutation. In established CAD, the Cys282Tyr mutation was not associated with an extended disease.

	Odds ratio	95% CI	p*
Cys282Tyr mutation	1.46	(0.84 - 2.55)	0.17
male	3.21	(2.31 - 4.47)	<0.0001
diabetes	2.27	(1.54 - 3.33)	<0.0001
hypertension	1.02	(0.75 - 1.38)	0.90
smoking [10 py]	3.23	(2.29 - 4.56)	<0.0001
age [10 years]	2.02	(1.72 - 2.37)	<0.0001
LDL cholesterol [0.5 mmol/l]	1.10	(1.03 - 1.18)	0.002

*logistic regression analysis.

Conclusions: Our findings in over 1000 pts do not support an association of hereditary haemochromatosis gene and prevalence or severity of CAD.

P1107 G20210A prothrombin gene polymorphism and coronary ischaemic syndromes: an up-dated meta-analysis of 10620 subjects

F. Andreotti[1], K. Paciaroni[2], V. De Stefano[2], F. Crea[3], G. Leone[2], A. Maseri[3], F. Burzotta[3]. [1]*Rome, Italy;* [2]*Catholic University, Hematology, Rome, Italy;* [3]*Catholic University, Cardiovascular Medicine, Rome, Italy*

Background: Two overviews have reported the lack of a significant association between the G20210A prothrombin gene polymorphism and ischemic heart disease (IHD). However, an up-to-date, phenotype-specific analysis is currently not available.

Aim: We conducted a meta-analysis of 17 studies published in extenso (within January 2002) on the association between the G20210A prothrombin variant and IHD (globally including 4293 patients and 6327 controls). Our specific aim was to investigate the possible link between the G20210A variant and predefined phenotypic markers (age, clinical presentation, angiographic extent of coronary disease, traditional cardiovascular risk factors).

Methods: The following data were extracted from each study: sample-size, inclusion criteria, geographical location, clinical presentation, and age. Cardiovascular risk factors (hypertension, smoking, dislipidemia, diabetes), angiographic extent of disease, and heterogeneity among studies were systematically sought for. The analyses were performed according to Mantel-Haenszel.

Results: Overall, the 20210 A allele was associated with an odds ratio (OR) for unspecified IHD of 1.19 (95%CI 0.96-1.59). Similar findings were seen for acute coronary syndromes (unstable angina and myocardial infarction) or myocardial infarction (MI) without age-limits (OR=1.22, 95%CI 0.94-1.66, n=8502, and OR=1.21, 95%CI 0.93-1.66, n=8830, respectively). The OR for MI increased to 1.77 (95%CI 1.16-3.42) in the 1931 subjects <55 years of age and to 2.30 (95%CI 1.27-4.59) in the 1359 subjects <45 years. Patients with 0- or 1-vessel disease at angiography showed a greater prevalence of the A allele compared to those with multivessel disease (relative risk 2.0, 95%CI 1.2-3.1, n=2376). The published data were insufficient to allow pooled evaluations of the interactions between G20210A and traditional cardiovascular risk factors.

Conclusions: These data indicate that the G20210A prothrombin gene polymorphism represents a modest but significant risk factor for MI below the age of 55 years. Moreover, it may favour the expression of IHD among patients who have limited extent of coronary atherosclerosis at angiography.

P1108 Newly detected gene variation of the cholesteryl ester tranfer protein (CETP) strongly predicts prognosis and response to statin therapy

S. Blankenberg[1], L. Tiret[2], O. Poirier[2], C. Bickel[3], X.C. Jiang[4], J. Meyer[3], F. Cambien[2], H.J. Rupprecht[3] on behalf of The AtheroGene Investigators. *[1]Johannes Gutenberg-University Mainz, Department of Medicine II, Mainz, Germany; [2]Faculte de Medecine Pitie-Salpetriere, INSERM U525, Paris, France; [3]Johannes Gutenberg-University, Department of Medicine II, Mainz, Germany; [4]State University New York, Department of Anatomy and Cell Biology, New York, United States of America*

Introduction: Cholesteryl ester transfer protein (CETP) plays a key role in the HDL metabolism. Variations in the CETP gene determine CETP activities as well as HDL-cholesterol concentrations and might influence prognosis and response to statin therapy.
Methods: In 1303 CAD patients we tested the hypothesis that the CETP/C-629A, I405V, and TaqIB variant of the CETP gene affects CETP activity, HDL-cholesterol concentration and prognosis of CAD. TaqIB variant and CETP/C-629A genotype were in nearly complete association.
Results: Patients carrying the -629A allele had significantly lower CETP activities and higher HDL concentrations. We observed a highly significant dose-dependent association between this genetic marker and future mortality from cardiovascular causes (n=120) after a median follow-up of 4.1 years. Mortality decreased from 10.4% in homozygous C allele carriers to 4.7% in heterzygous to 4.0% in homozygous A allele carriers (P<0.0001). This association was independent of potential confounders such as A allele carriers reveal a 0.35 (95% CI 0.21 to 0.67, P<0.0001) decrease in risk in a fully adjusted model (see legend Table 1). In addition, this association was only present in patients without statin therapy. The benefit of statin therapy was restricted to patients carrying the C-allele of the C-629A genotype (P for interaction 0.02). Patients carrying the CETP/405V allele tended to have higher HDL concentrations and lower mortality rate but this association did not achieve independent significance.

CETP/C-629A	CC	CA	AA	P-univ.	P-multiv.
all pts	10.4	4.7	4.0	<0.0001	0.002
without statins	13.0	4.6	3.0	<0.0001	0.001
with statins	5.8	5.0	6.0	0.9	0.5

P values given are P for trend; P multivariate controlled for age, sex, classical risk factors, clinical and therapeutic features such as unstable angina, extent of vessel disease, history of MI, interventional strategies, betablocker and statin therapy (if appropriate) and ejection fraction.

Conclusion: We observed a significant relation between CETP/-629 A allele carriers, decreased risk of future mortality, increased HDL-concentrations, and decreased CETP activity. This common mutation appears to predict whether or not patients with CAD will experience a survival benefit from statin therapy.

P1109 Pharmacogenetics in thrombolytic therapy. Role of Factor XIII Val34Leu polymorphism

V. Roldan[1], F. Marín[2], J. Corral[3], R. Gonzalez-Conejero[3], J. Pineda[2], F. Lopez[2], V. Vicente[3], F. Sogorb[2]. *[1]Hospital San Vicente, Hematology, Alicante, Spain; [2]Hospital General de Alicante, Servicio de Cardiología, Alicante, Spain; [3]Hospital Morales Meseguer, Hematology, Murcia, Spain*

The Val34Leu polymorphism of Factor XIII (FXIII) A-subunit gene is associate with increased FXIII fibrin cross-linking activity. However, contradictory data is available about its role in thrombotic disease. Recently we have observed a higher prevalence of the Leu34 allele in premature acute myocardial infarction. Remarkably, the Leu/Leu genotype increases the risk (odds ratio:3.54; 95% CI:1.22-10.22) after multivariate analysis (p:0.019). Thrombolytic therapy is used to open quickly the acute coronary occlusion. Unfortunately one half of treated patients do not achieve optimal tissue perfusion. We hypothesise that clots might show different sensitivity to thrombolytic therapy, and this could be influenced by the FXIII Val34Leu polymorphism.
Methods: Genetic analyses were performed on 180 consecutive young patients with myocardial infarction before 45 years from our cardiology outpatients clinic. We analysed the effects of thrombolytic therapy. Thrombolytic agents were given in a standard dose. The ineligibility criteria for reperfusion therapy were recorded. Non-invasive assessment of the efficacy of coronary thrombolysis was evaluated by serial electrocardiograms and creatine kinase time-activity curves. Declination of ST segment elevation upper than 50% in 90 minutes and an early peak of creatine kinase (under 12 hours) were considered as reperfusion criteria.
Results: Genetic frequences were 108 (60.0%) Val/Val, 59 (32.8%) Val/Leu, 13 (7.2%) Leu/Leu. Seventy-two patients were treated by thrombolytic therapy. Three thrombolytic agents were used: streptokinase (n=4), APSAC (n=9), and tissue plasminogen activator (n=59 patients). Acute coronary angioplasty was performed in 11 patients (Val/Val: n=5, Val/Leu: n=5 and Leu/Leu: n=1). Efficacious thrombolysis was observed in 44/50 patients with Val/Val genotype, but only 13/22 patients carrying the Leu34 allele (Leu/Val or Leu/Leu). The efficacy of thrombolytic therapy was significantly upper in patients with Val34 allele (p: 0.005; odds ratio 5.08; confidence interval 1.32-20.22). There were no differences in the success between the different thrombolytic drugs. Interestingly, all the acute angioplasties were successful and these patients showed a good initial evolution (1st month).
Conclusions: We report the first clinical evidence suggesting that the Leu34 allele could reduce the efficacy of the thrombolytic therapy.

HYPERTENSION, OTHER RISK FACTORS AND CARDIOVASCULAR DISEASE

P1110 Doppler echocardiographic coronary flow reserve: a marker of global cardiovascular risk in uncomplicated arterial hypertension

M. Galderisi[1], S.C. Silvana Cicala[2], L.D.S. Luigi De Simone[3], P.C. Pio Caso[3], A.D.E. Arcangelo D'Errico[4], A.C. Aldo Celentano[4], G.D.M. Giovanni Di Minno[4], O.D.D. Oreste de Divitiis[4]. *[1]Federico II University, Clinical and Experimental Medicine, Naples, Italy; [2]Second University of Naples, Cardiology Dept., Caserta (Naples), Italy; [3]Ospedale Vincenzo Monaldi, Divisione di Cardiologia, Naples, Italy; [4]Federico II University, Clinical and Experimental Medicine, Naples, Italy*

In order to analyse the impact of global cardiovascular risk on coronary microcirculation, our aim was to assess the impact of coronary risk factors (RF) on coronary flow reserve (CFR) in uncomplicated arterial hypertension.
Methods: 64 newly diagnosed hypertensives (mean age = 50 years, M/F = 49/15), free of cardiac drugs and coronary artery disease (clinical history + effort ECG) underwent: anamnesis to identify standard RF; determination of body mass index (BMI), clinic BP and heart rate (HR); M-mode echo and second harmonic Doppler of distal left anterior descendent coronary artery, at baseline and after dypiridamole vasodilation (0.56 mg/Kg IV over 4') to estimate CFR (hyperemic to baseline diastolic flow velocity ratio).
Results: Blood pressure (BP) was 148/101 mm Hg and BMI 27.8 g/m^2, with overweight prevalence (BMI > 27 g/m^2) of 56%. The metabolic profile showed: glycemia = 97.5±12 mg/dl (hyperglycemia prevalence [>110 mg/dl] = 15.6%), total cholesterol = 222±45 mg/dl (hypercholesterolemia [>200 mg/dl] = 59.4%), triglycerides = 151±71 mg/dl (hypertrygliceridemia [>180 mg/dl], = 27%). Left ventricular hypertrophy (LVH = left ventricular mass index [LVMI] >50 g/m powered to 2.7) was found in 41% of hypertensives. In the overall population we observed negative association of CFR with HR (r=-0.33, p<0.005), diastolic BP (r=-0.40, p<0.001), glycemia (r=-0.28, p<0.02), total cholesterol (r=-0.41, p<0.001) and LVMI (r=-0.28, p<0.02). In a multivariate model, BMI (beta coefficient =0.42, p<0.0005), cigarette smoking (beta=-0.33, p<0.001), LVMI (beta=-0.30, p<0.005) and total cholesterol (beta=-0.26, p<0.01) were independent predictors of CFR (cumulative R square = 0.45, S.E.=0.38, p<0.00001) while the partial relation coefficients of sex, age, diastolic BP, glycemia and triglycerides were not significant. By analyzing the cumulative impact of RF (hypertension, smoke, cholesterol, glycemia), CFR was 2.20 in patients with 1 RF (only hypertension), 2.17 with 2 RF, 1.71 with 3 RF, 1.55 with 4 RF (p<0.0005). The addition of LVH to standard RF reduced further CFR only in the higher risk groups (from 1.71 to 1.60 in the group with 3 RF, from 1.55 to 1.38 in the group with 4 CRF, both p<0.01).
Conclusions: Except for overweight which is associated to a greater CFR, the concept of global risk may be applied also to the coronary microvessels. CFR is an early marker of coronary involvement in arterial hypertension, before the development of overt coronary artery disease.

P1111 Birth anthropometry and later blood pressure

V.D.L. dilegge[1], M.S. Michela Simi[2], V.T. Vittorio Taccini[3], D.F. Daniele Faraggiana[2], M.T. Marco Terrazzi[2], F.B. Francesco Busoni[2], C.G. Cataldo Graci[3]. [1]*Cardiology ANCE Pisa, Pisa, Italy;* [2]*Institute of sport medicine, Internal Medicine, Pisa, Italy;* [3]*ANCE-Pisa, Cardiology, Pisa, Italy*

The Barker's hypothesis suggested a link between low birth weight (BW) and risk of adulthood cardiovascular disease; this association may be the result of fetal adaptation to an adverse intrauterine environment. A number of studies suggest that body mass index (BMI) and blood pressure (BP) values are rising among sedentary school children; these changes may have future health implications for cardiovascular disease.
The objective of this study was to examine the effect of birth anthropometry (head circumference,BW,birth lenght)on health status development in children. The BP of 1540 school children (F 710, M 830; 11-12 years) was recorded at a screening medical examination; the parents were asked to fill in a questionnaire that included demographic data, family history, parent's weight and height, children's perinatal measurements and his or her involvement in physical activity (PA).
BW and children's BP at baseline examination are not correlated (p 0.1); BW is also unrelated to children's (p 0.1) and parent's (p 0.1) BMI; we observed a positive correlation between parental and children's BMI (paternal BMI p <0.01 r 0,2; maternal BMI p<0.001 r 0.4) and a negative correlation between PA and SBP (p<0.001 r0,3), DBP (p<0.001 r0,4), children's BMI (p<0.001 r0,4). Parent's smoking was additive predictor in children of lower physical activity (p <0.01); furthermore children's body mass index (p<0.001), BP values (p<0.001) and incidence of asthma (p<0.02) were significantly greater if parents smoked. Step-wise multiple regression analysis with BP values as dependent variable and children's, birth's and parent's antropometric measurements, familial history of disease and PA as indipendent variables showed that PA and children's BMI were the variables carrying the greatest weight on BP values; furthemore step-wise multiple regression analysis with children's BMI as dependent variable and birth's and parent's antropometric measurements, familial history of disease and PA as indipendent variables showed that PA was the variables carrying the greatest weight on children's BMI.
These data suggest that lifestyle, rather birth weight, is the early life factor most importantly related to subsequent BP and BMI in childhood.

P1112 A deletion-insertion polymorphism in the alpha-2B adrenoceptor gene modifies the response to antihypertensive drugs: a pharmacogenetic study

J.T. Salonen, V-P. Valkonen, F. Yanus, T-P. Tuomainen. *University of Kuopio, Research Institute of Public Health, Kuopio, Finland*

Background: While specific antihypertensive agents are recommended to start therapy, their blood pressure lowering effect in a given patient remains unpredictable. To provide information for personalized choice of antihypertensive agents, we carried out a pharmacogenetic population study to investigate, how a functional polymorphism in the alpha-2B-adrenoceptor (AR) gene modifies effects of common antihypertensive agents.
Methods: The subjects were the participants in the KIHD study, a population study of genetic and non-genetic risk factors of cardiovascular and related diseases. DNA samples were available of over 1500 men aged 42-60 years at baseline. Of these, 834 men participated in a 11-year follow-up study in 1998-200, at the age of 53-71 years. The antihypertensive effect of each drug category was estimated by comparison with other antihypertensive drugs.
Results: Beta-blockers reduced the mean arterial pressure by 6 mmHg in deletion carriers and none in non-carriers (p=0.009, n=834), whereas diuretics and calcium-channel blockers were antihypertensive only among the wild type (insertion homozygotes). Among 498 normotensive men, deletion homozygosity increased the 11-year incidence of hypertension 3.2-fold (95% confidence interval 1.8 to 5.8, p<0.001).
Conclusion: Our findings indicate that in men with deletion in the alpha-2B-AR gene there is an increased risk of becoming hypertensive and enhanced antihypertensive efficacy of beta-blockers, whereas the effect of diuretics and calcium-channel blockers may be attenuated. Our findings show that the I/D polymorphism of the alpha-2B-AR gene modifies the blood pressure lowering efficacy of the most commonly used antihypertensive drug types. Genetic tests, such as DNA chips, can be developed for the use in the personalized medicine for the genetic subdiagnosis of hypertension and for targeting drug treatments both in drug research and development as well as in the clinical practice. These tests could bring, besides improvement in the care of hypertensives, sizeable savings both in the drug development and in the health care.

P1113 Pulse pressure as a predictor for stroke mortality, in elderly individuals: forty years follow-up of the Corfu cohort; Seven Countries study

C. Chrysohoou, C. Pitsavos, D. Panagiotakos, J. Skoumas, A. Dontas, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, University of Athens, Attica, Greece*

Background: Epidemiological evidence indicates that hypertension predisposes to stroke. Although pulse pressure reflects aortic distensibility, the data on stroke mortality are limited in literature. This analysis aims at describing the role of increased pulse pressure on the stroke mortality, based on 40-years (1961-2001) prospective evaluation of the Corfu cohort, from the Seven Countries Study.
Methods: The population studied in this analysis consisted of rural men enrolled at 1961 (n=529, 49.7±5.7 years old) in Corfu. Among several factors systolic, diastolic blood pressure levels and their difference (pulse pressure) was evaluated with stroke mortality as the end-point. Cox proportional hazards models were applied in order to evaluate the investigated parameters. A major limitation of the study was our inability to segregate thrombotic from hemorrhagic strokes.
Results: Among 529 cardiovascular disease-free men at entry, 65 (12.3%) died because of cerebrovascular disease. The cumulative survival at the end of the follow-up was 76%. Mean age at death for stroke was 75 ± 9 years old. At baseline, Age (HR = 1.125, p < 0.001), systolic blood pressure (HR = 1.021, p < 0.001), physical activity (HR = 0.583, p < 0.05), and total serum cholesterol (HR = 0.990, p < 0.01) showed a statistically significant association with cerebrovascular disease incidence. The difference between systolic and diastolic blood pressure (pulse pressure) was significantly associated with stroke mortality (HR = 1.025, p < 0.001), after adjusting for age, physical activity, cholesterol levels, smoking habits and body mass index.
Conclusions: In these elderly men 40-years incidence of cerebrovascular disease seems to be strongly associated with pulse pressure levels, at baseline. The baseline pulse pressure is more significant predictor for stroke mortality than systolic blood pressure, as it represents the loss of aortic distensibility due to atherosclerosis.

P1114 Prevalence of primary aldosteronism among hypertensive patients

R. Fogari, P. Preti, A. Mugellini, A. Rinaldi, R.M. Pesce, G. Marasi, L. Corradi, C. Pasotti. *IRCCS Policlinico S.Matteo, Internal Medicine and Therapeuthic, Pavia, Italy*

Aim: There is increasing evidence that primary aldosteronism (PA) may be common in patients defined as "essential" hypertensive. Aim of this study was to evaluate the incidence of primary aldosteronism in a primary-care hypertensive population.
Methods: Five hundred and five consecutive unselected hypertensive patients (298 female and 207 male, 156 untreated and 399 treated, age 25-75 yr) attending to our hypertensive unit, had ambulatory measurements for plasma aldosterone and plasma renin activity (PRA); electrolyte measurements were obtained simultaneously. Subjects with renal insufficiency and those treated with glucocorticoids or spironolactone were excludes. Antiypertensive medication was stopped for 7 days in the treated patients before the blood sample collecting for aldosterone and PRA evaluation. The aldosterone to PRA ratio was used as an initial screening test to identify potential patients with PA. The patients with an elevated ratio (> 25) were admitted for the salt loading suppression test. Adrenal computed tomographic scansion was performed in biochemically confirmed cases.
Results: Seventy-one of the 505 hypertensive patients had a positive aldosterone/renin ratio; in 70 of them confirmatory studies were carried out. Using an aldosterone concentration above 7.5 ng/dl after saline infusion as the diagnostic cut-off, 35 patients had biochemically confirmed primary aldosteronism. Among these individuals, only four were hypokaliemic; an adrenal mass was detected in three patients.
Conclusion: primary aldosteronism has been traditionally regarded as a rare cause of hypertension. However the availability of the aldosterone-renin ratio as a screening test and its application to a wider population of hypertensives has resulted in a marked increase detection rate. Our data suggest that primary aldosteronism occurs in at least 6.9% of the adult hypertensive population.

P1115 Awareness of blood pressure decreased dramatically during the last decade in Poland

T. Zdrojewski[1], B. Krupa-Wojeciechowska[1], P. Bandosz[1], P. Szpakowski[1], A. Manikowski[2], E. Wolkiewicz[2], B. Wyrzykowski[1]. [1]*Medical University of Gdansk, Dept. of Hypertension & Diabetology, Gdansk, Poland;* [2]*Center for Social Research, Sopot, Poland*

The aim of our study was to evaluate changes in awareness of blood pressure (BP) during transition into market economy in Poland. Thus, in 1994 (NATPOL I, n=2080), 1997 (NATPOL II, n=1664) and 2001/2002 (NATPOL III, n=3052), we repeated the cross-sectional surveys based on questionnaire interviews on representative samples of adults in Poland, aged 18 years and over. The subjects were selected from Polish population by stratified and cluster random sampling with quotas. They were asked, if they were aware of blood pressure. The results were analysed according to age, sex, education level, income and place of living. Overall, awareness of blood pressure declined ($p<0.001$) from 71% in 1994 to 65.5% in 1997, and to 59% in 2001/2002. The data according to sex, level of education and place of living are shown in the table.

	1994	1997	2001/2002
women	77	71	64
men	65	60	54
primary or post-primary education	68	59	51
secondary or higher education	75	74	68
large cities (>200 000)	72	73	67
small cities	77	66	62
villages	65	61	52

Decline of awareness of BP was most significant in small cities and villages as well as among less educated people representing lower social status. Low awareness of blood pressure in Poland emphasizes the need for urgent preventive measures.

P1116 Homocysteine, fibrinogen and C-reactive protein levels by hypertension status, in cardiovascular disease free subjects: the ATTICA study

J. Skoumas, C. Pitsavos, C. Chrysohoou, A. Zeibekis, D. Panagiotakos, M. Toutouza, C. Stefanadis, P. Toutouzas. *Hippokration Hospital, University of Athens, Attica, Greece*

Aims: The aim of this study is to evaluate the levels of homocysteine, fibrinogen and C-reactive protein, by hypertension status, in a random sample of cardiovascular disease-free subjects.
Methods: The ATTICA study is a population -based prospective cohort designed to enrol 3073 men and women from the greater area of Athens. A random algorithm was developed and stratified, by sex- age; sampling was performed, during 2001. In this work we analysed data from 654 men (18-87 years old) and 826 women (18-89 years old). Hypertension was defined as SBP > 140 mmHg or/and DBP > 90 mmHg, or under special treatment. Among several investigated factors serum homocysteine, fast plasma fibrinogen concentration and C-reactive protein levels were evaluated, through multivariate analysis.
Results: A hundred and twenty-six (19%) of males and 132 (16%) of female subjects were defined as hypertensives. The statistical analysis showed that fibrinogen levels were significantly higher in hypertensives compared to the rest of them (346±75 vs. 317±83, $p < 0.001$). Similar results were observed in C-reactive protein levels (hypertensives: 3.07±1.5 vs. normotensive 2.18±1.9 mg/dl, $p < 0.01$), while no significant association was found between hypertension and homocysteine levels (14.3±4.2 vs. 13.2±6.1, $p = 0.246$). The results become more consistent when we evaluated continuous measurements of SBP and DBP in relation to the investigated factors. The previous findings, were, also, confirmed by the multivariate analysis that took into account the effect of age, sex, smoking status and physical activity status of the subjects.
Conclusions: Results from this population-based survey indicate that fibrinogen and C-reactive protein are strongly associated with the presence of hypertension, while homocysteine showed borderline trend. This may partially explain the mechanism by which elevated levels of these emerging risk factors may affect coronary risk. However, the prospective evaluation of the present study may confirm or refute our findings, in relation to cardiovascular disease, at population level.

P1117 Pulse pressure as an indicator of future development of isolated systolic hypertension in previously normotensive individuals

T. Makris, A. Hatzizacharias, P. Krespi, H. Michalopoulou, M. Kouli, E. Batzoglou, U. Damaa, V. Votteas. *Dept. of Cardiology, Laikon General Hospital of Athens, Athens, Greece*

Background: It is well known that there is a strong continuous, graded, consistent and etiologically significant relation between systolic blood pressure (SBP) and cardiac risk, while pulse pressure (PP) is considered as an independent risk factor for cardiovascular and renal disease. This prospective study was designed in order to examine the possible role of PP in the future development of isolated systolic hypertension (ISH) in previously normotensive subjects.
Methods: Three hundred and fifty normotensive volunteers (150M, 200F) mean age (MA) 60±8 yrs and body mass index (BMI) 23±1.8 Kg/m^2 were studied. Systolic, diastolic blood pressure (SBP, DBP) and PP levels were determined and followed-up for a 5 year time period, in the whole study population.
Results: During the follow-up period, 50 out of 350 (20M, 30F, 14.3%) individuals developed ISH (Group A), while 300 out of 350 (130M, 170F, 85.7%) remained normotensive (Group B). The characteristics of both groups in the start of this prospective study are shown in the table.It is obvious that the PP levels are significantly increased in group A.

	Group A	Group B	p
MA (years)	59±6	58±8	NS
BMI (Kg/m^2)	23±1.6	22.8±1.7	NS
SBP (mmHg)	136±3	134±4	NS
DBP (mmHg)	80±6	82±5	NS
PP (mmHg)	55±3	52±2	<.001

Conclusion: The results of our study suggest that PP may consist an individual indicator for the future development of ISH in previously normotensive subjects without any other predisposing risk factor.

EXPERIMENTAL HEART FAILURE

P1118 "In vivo" antihypertrophic effect of the sodium/proton exchange inhibitor cariporide

G. Marano[1], S. Palazzesi[1], A.U. Ferrari[2]. [1]*Ist. Sup. Sanita, Lab. Farmacologia, Rome, Italy;* [2]*Centro Fisiologia Clinica Ipertensione, Dipt Med., Prev. e Biotecnol. Sanit., Milano, Italy*

"In vitro" studies showed that the sodium/proton exchange inhibitor cariporide markedly reduces the growth-promoting effect of rhythmic mechanical stretch in cultured mouse cardiomyocytes. Our goal was was to establish whether this compound may exert antihypertrophic influences "in vivo".
Pressure overload was induced by thoracic aortic banding (Bd) in 3 month-old mice (n=16). Animals were treated with oral cariporide, 1 mg.kg-1 (Bd-Car, n=8), or vehicle (Bd-Veh, n=8). Concurrent groups of sham (Sh)-operated mice were studied (Sh-Car, n=8; Sh-Veh, n=8). Treatments were started 3 days before surgery and continued until two weeks post-surgery, after which i) blood pressure was measured via a right carotid catheter implanted under light anesthesia; ii) the mouse was euthanized, the heart removed and the left ventricle isolated and weighed, the absolute figure (LVW, mg) being normalized to body weight (BW, g); iii) LV cardiomyocyte cross-sectional area (CCSA) and the extent of LV fibrosis were assessed by computer-assisted histomorphometry.
Systolic blood pressure (SBP) was significanly higher in Bd-Veh compared to Sh-Veh mice (145±4 vs 112±3 mmHg, $p<0.01$), and was not affected by cariporide treatment (143±2 and 114±5 mmHg in Bd-Car and Sh-Car mice, respectively, p=ns compared to each Veh counterpart). As expected, Bd-Veh mice had markedly higher LVW/BW ratios than Sh-Veh mice (4.5±0.2 vs 2.9 mg/g, $p<0.01$, a 55% increase); cariporide treatment had no effects on LV weight in Sh-Car mice (3.0±0.1 mg/g, p=ns vs Sh-Veh) but dramatically attenuated its increase in Bd-Car mice (3.4±0.1, $p<0.01$ vs Bd-Veh, a 70% atternuation). Histomorphometry (data not shown) provided results largely paralleling the autoptic results, with an increase in CCSA of about 50% in Bd-Veh compared to Sh-Veh mice and with an approx 70% inhibition of such increase by cariporide treatment. In contrast, findings were different concerning fibrosis: as expected, banded animals had markedly fibrotic left ventricles, with almost twice as much collagen stained in Bd-Veh compared to Sh-Veh mice, but cariporide treatment failed under this regard to display any protective effect.
We conclude that the sodium/proton exchange inhibitor cariporide i) markedly attenuates the development of LV hypertrophy "in vivo", with significant implications for understanding the mechanisms and possibly improving the treatment of this prognostically unfavourable condition, and ii) selectively interferes with growth processes in the myocyte but not in the connective tissue component of the left ventricle.

P1119 p38 MAP kinase phosphorylation and apoptosis in pacing-induced heart failure

S. Aker, I. Konietzka, S. Belosjorow, G. Heusch, R. Schulz. *University of Essen, Pathophysiology, Essen, Germany*

In human hypertrophied and in human chronically ischemic, failing myocardium, the phosphorylation of p38 mitogen activated protein kinase (MAPK) is increased. In experimental studies of ischemia/reperfusion, increased p38 MAPK phosphorylation is associated with increased myocyte apoptosis.
We now tested whether or not p38 MAPK is also activated in pacing-induced heart failure (HF) in rabbits, which is neither associated with significant myocardial ischemia nor left ventricular (LV) hypertrophy.
In seven chronically instrumented rabbits, HF was induced by rapid LV pacing (400 bpm). After 3 weeks of pacing, the rabbits displayed clinical signs of HF. Echocardiography revealed an increase in LV end-diastolic diameter from 14±1 to 17±1 mm and a reduced LV shortening fraction from 37±2 to 12±2% (Mean±SEM, both $p<0.05$). Eight sham-operated rabbits served as controls. Total p38 MAPK did not differ between HF rabbits (239,050±25,951 AU, densitometry) and controls (229,831±21,049 AU). However, p38 MAPK phosphorylation was significantly increased in HF rabbits (76±6% of total p38MAPK) compared to controls (28±6%, $p<0.05$). The number of TUNEL-positive cardiomyocytes, as a measure of the extent of apoptosis, was also significantly increased in HF rabbits (0.025±0.006%) compared to controls (0.003±0.001%, $p<0.05$). Overall, p38 MAPK phosphorylation correlated to the extent of apoptosis ($r=0.60$).
Conclusion: In this HF model with reduced LV systolic function, p38 MAPK phosphorylation and the extent of apoptosis are increased. Further studies will have to define whether or not chronic blockade of p38 MAPK activity can interfere with apoptosis and thereby attenuate the progression of HF.

P1120 AT2-receptor activation regulates myocardial eNOS expression via the Calcineurin-NF-AT pathway

O. Ritter[1], K. Schuh[1], N. Röthlein[1], N. Burkard[1], L. Neyses[2]. [1]*University of Wuerzburg, Wuerzburg, Germany;* [2]*Manchester Heart Center, Universitiy Department of Medicine, Manchester, United Kingdom*

While the importance of AT2-receptor in the myocardium is relatively uncontested, the role of the AT2-receptor has recently been subject of considerable debate. To contribute to the elucidation of this problem we investigated the influence of AT2-stimulation/inhibition on endothelial NO synthase (eNOS, NOS-III) promoter activity and eNOS protein expression in cardiomyocytes.
Stimulation of rat cardiomyocytes with angiotensin II (AngII) increased eNOS protein expression 3.3-fold. Cyclosporin A (CsA) blocked the AngII mediated increase in eNOS protein. Inhibition of the AT1-receptor did not reduce AngII mediated eNOS protein expression whereas AT2 stimulation increased it 2.4-fold and AT2 inhibition suppressed it. In gel shift assays two putative NF-AT sites in a 1.6 kb eNOS promoter fragment showed binding of NF-AT factors. NF-AT2(-c1)-specific antibodies supershifted the AngII-induced DNA binding complex. In nuclear extracts of neonatal cardiomyocytes NF-AT1, -2 and -5 were clearly detectable. Stimulation of transfected cells with AngII resulted in a 7-fold increase in eNOS promoter activity which was blocked by CsA and by mutation of an upstream NF-AT site. Inhibition of the AT2-receptor suppressed AngII induced eNOS promoter activity. Specific stimulation of the AT2-receptor increased eNOS promoter activity 4.6-fold. eNOS inhibition and simultaneous AT2-receptor stimulation increased protein synthesis as measured by 3H-Leucin incorporation.
Therefore, we conclude: 1) AngII-stimulation of neonatal rat cardiomyocytes is accompanied by increased expression of eNOS. 2) This effect is mediated by the calcineurin pathway and induced by the AT2-receptor. 3) AT2-receptor activation in the myocardium and simultaneous NOS inhibition increase protein synthesis.

P1121 Non-excitatory cardiac contactility modulation electric signals attenuate left ventricular remodelling and improve ejection fraction in dogs with heart failure

H. Morita[1], G. Suzuki[1], W. Haddad[2], Y. Mika[2], S. Goldstein[1], S. Ben-Haim[2], H.N. Sabbah[1]. [1]*Henry Ford Health System, Detroit MI, United States of America;* [2]*Impulse Dynamics, Mount Laurel, New Jersey, United States of America*

Background: We previously showed that in dogs with heart failure (HF) LV systolic function is improved acutely with delivery of a non-excitatory cardiac contractility modulation (CCM) electric signal to the cardiac muscle during the absolute refractory period. In the present study, we examined whether long-term CCM signal delivery attenuates progressive LV chamber remodeling and sustains the improvement in LV systolic function seen with acute CCM signal delivery in dogs with HF.
Methods: Chronic HF (LV ejection fraction <35%) was produced in 12 dogs by intracoronary microembolizatons. In 6 dogs, the CCM signal delivery lead was advanced retrograde through the coronary sinus and positioned under fluoroscopic guidance into the distal anterior coronary vein. Sensing leads were also implanted in the right atrium and right ventricle and used to time the delivery of the CCM signal. In these dogs, the CCM signal was delivered for 6 hours a day with an average amplitude of 3.3 V. The remaining 6 dogs served as concurrent controls. All dogs were followed for 3 months. LV end-diastolic volume (EDV), end-systolic volume (ESV), ejection fraction (EF), and end-diastolic sphericity index (EDSI) were measured from left ventriculograms obtained just before (PRE) and after 3 months of therapy (POST). Treatment effect was based on a comparison of the change from PRE to POST between the two groups.
Results: In control dogs, EDV increased from 64±5 ml to 75±6 ml ($P=0.003$), ESV increased from 46±4 ml to 57±4 ml ($P=0.003$), and EF decreased from 28±1% to 23±1% ($P=0.001$). These changes were associated with a decrease in the EDSI from 1.37±0.04 to 1.30±0.05 ($P=0.008$) indicating ongoing increase in LV sphericity. In contrast, dogs treated with CCM showed a lesser increase in EDV from 66±4 ml to 71±5 ml ($P=0.01$), no change in ESV from 46±3 ml to 47±4 ml and an increase in EF from 31±1% to 34±2% ($P=0.04$). These beneficial changes were associated with no significant changes in EDSI. Analysis of treatment effect showed that compared to controls, treatment with CCM signals significantly attenuated the increase in EDV ($P=0.04$) and ESV ($P=0.001$) and significantly increased EF ($P=0.0001$). Similarly analysis of treatment effect showed that compared to controls, treatment with CCM signals prevented the decline in EDSI ($P=0.05$).
Conclusion: In dogs with chronic HF, long-term CCM signal delivery attenuates progressive global LV remodeling and improves LV systolic function. These results support the exploration of this mode of therapy for the long-term treatment of patients with chronic HF.

P1122 Homogenization of left ventricular SERCA gene expression after myocardial infarction in the rat

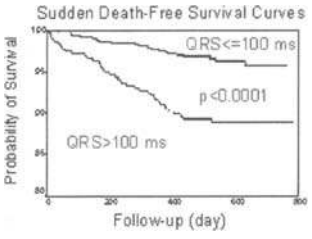
F. Prunier[1], B. Escoubet[2], R. Gaertner[3], C. Choqueux[3], M. Heimburger[3], J.B. Michel[3], J.J. Mercadier[3]. [1]*University Hospital of Angers, Cardiology Dept., Angers, France;* [2]*INSERM, U426, Paris, France;* [3]*INSERM, U460, Paris, France*

Sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA) gene expression is decreased in the pressure overload-induced model of left ventricular (LV) failure in the rat and adenovirus-mediated SERCA gene transfer has been shown to restore cardiac contractile function and delay rat death. However, the level of SERCA gene expression in the non-infarcted LV following myocardial infarction (MI) remains unclear. Accordingly, we examined SERCA2a and atrial natriuretic peptide (ANP) gene expression in the remodeled non-infarcted LV after left coronary artery ligation in rats. 54 rats (21 sham-operated, 42 MI) were killed 3 months after surgery. Rats with MI were classified as nonfailing (NF, n=25) or failing (CHF, n=12) depending on the absence or presence of pleural effusion at sacrifice, respectively. The scar was carefully dissected and its surface area measured using millimeter graph paper. LV SERCA2a and ANP mRNA levels in the non-infracted LV were determined using Northern blot analysis and specific cDNA probes. We found a significant positive linear correlation between ANP mRNA and infarct size ($R^2=0.80$; $p<0.001$) whereas SERCA2a mRNA did not correlate either with infarct size or ANP mRNA. Interestingly, SERCA2a mRNA values were highly dispersed in shams (from 0.95 to 1.85 a.u.) whereas a smaller dispersion was observed in NF and an even smaller in CHF (from 0.80 to 1.10 a.u.). We conclude that LV SERCA2a gene expression is highly variable in rats and that LV remodeling following MI markedly reduces and homogenizes its level which does not correlate with ANP gene expression, a reliable marker of myocardial hypertrophy.

P1123 Prognostic significance of conventional electrocardiogram measurement in elderly patients with symptomatic heart failure

Y. Gang[1], T. Ono[1], K. Hnatkova[1], A.J. Camm[1], B. Pitt[2], P. Poole-Wilson[3], K. Bohannon[4], M. Malik[1] on behalf of ELITE II investigators. [1]*St. George's Hospital Medical School, Cardiological Sciences, London, United Kingdom;* [2]*University of Michigan Medical Center, Ann Arbor, United States of America;* [3]*Imperial College School of Medicine, London, United Kingdom;* [4]*Merck Research Laboratories, Cardiovascular Clinical Research, West Point, United States of America*

To assess the prognostic value of conventional ECG measurements in patients (pts) with heart failure, we studied 986 heart failure pts (age 71±7 year, 703 men; NYHA II-IV, LVEF <=40%) from the ELITE II trial. A 12-lead ECG, assessment of NYHA and LVEF, and serum for biochemical analysis at baseline were investigated. Heart rate (HR), mean QRS duration (QRS), maximum QT interval (QT) and maximum heart rate corrected QT interval (QTc; Fridericia's formula) were derived from each ECG. Retrospectively adjusted dichotomy limits of 460ms for QTc (QTc460) and 100ms for QRS (QRS100) were used in analyses. Of the 986 study pts, there were 140 all-cause deaths(D), 119 died of cardiovascular events(CD) and 59 died suddenly(SD) during follow-up (540±153 days). In univariate analysis, age, HR, QRS100, LVEF, NYHA, serum potassium and creatinine were significant predictors for D, also for CD except for age and potassium. For SD, QRS100, LVEF, NYHA and creatinine were univariate predictors. Neither QT nor QTc was predictive of any mode of death. In multivariate analysis (Cox model), QRS100 (p<0.001), NYHA (p=0.001), potassium (p=0.026) and creatinine (p=0.023) predicted D independently. For CD, independent predictors were: QRS100 (p<0.001), NYHA (p=0.001) and creatinine (p=0.002). Only QRS100 (p<0.001) and creatinine (p=0.023) remained independent predictors for SD. Survival analysis showed significantly reduced survival rates in pts with QRS>100ms (p<0.0001 for D, CD and SD).



Survival curves.

In this retrospective substudy, QRS>100ms independently predicted death in elderly pts with symptomatic heart failure and in sinus rhythm. If confirmed by prospective evaluation, this simple ECG measurement, in addition to other clinical variables, may provide prognostic information in this group of pts.

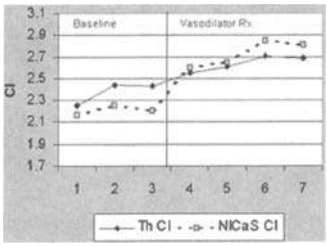
P1124 Reliability of non-invasive cardiac output measurement by whole-body electrical bioimpedence in patients treated for acute CHF

G. Cotter[1], A. Tsoglin[2], E. Kaluski[1], Y. Moshkovitz[2], A. Salah[1], O. Milovanov[1], Z. Vered[1]. [1]*Assaf-Harofeh Medical center, Cardiology, Zerifin, Israel;* [2]*NI Medical LTD, Natanya, Israel*

Background: The NICaS 2001TM system is an new device for non-invasive, continuous measurement of cardiac output (CO) based on whole-body electrical bioimpendence and analysis of impulse with a novel semi-empirical formula. We evaluated its reliability in monitoring patients with acute congestive heart failure (CHF).

Methods: Thirty-one patients submitted for invasive hemodynamic monitoring with Swan-Ganz catheters due to acute congestive heart failure (CHF) where enrolled in this study. Cardiac output was measure repeatedly, simultaneously and independently by NICaSTM 2001 (NiCAS-CO) and thermodilution (Th-CO). For each patient we obtained 3-4 measurements while under stable medical treatment. In 17 patients we also obtained 4 measurements per patient, while treatment with IV Isosorbide-dinitrate(ISDN) was initiated and uptitrated.

Results: Out of 31 patients, 10 where monitored while mechanically ventilated and 2 while treated by IABP. We have found good agreement between NiCAS-CO and ThCO: Linear regression is r=0.86 (p<0.05). In the subgroup of patients monitored while treated with IV ISDN, The NICaS 2001TM system correctly detected the CO increase induced by ISDN (Figure). However, we have found that the NICaS-CO reading was 6% lower than Th-CO if CI was < 2 L/min./M2 (p=0.025)and 9% higher if CI was > 3 L./min./M2(P=0.007). Therefore, the increase in CO detected by NICaSTM 2001 during ISDN treatment was twice that measured by Thermodilution (1.15 vs. 0.6 L./min, P<0.0001).



CO Changes by NiCaS and thermodilution.

Conclusions: NICaS 2001TM is a reliable device for monitoring CO in patients admitted due to acute CHF.

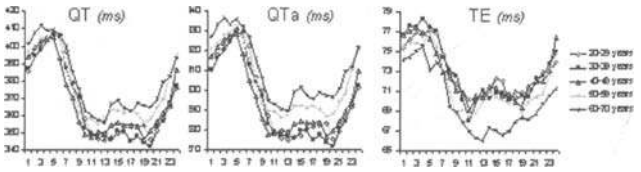
P1125 Differing effects of age on circadian profile of ventricular repolarization in 172 healthy volunteers

H. Bonnemeier, W. Braasch, U.K. Wiegand, A. Brandes, H.A. Katus, G. Richardt, J. Potratz. *Medizinische Universität zu Lübeck, Medizinische Klinik II, Lübeck, Germany*

Recent studies convincingly demonstrated a limited prognostic value of spatial inhomogeneity of ventricular repolarization (QT-dispersion). However, data on physiological variations of QT-interval in the longitudinal dimension with normal aging are surprisingly rare.

Therefore we investigated 172 healthy subjects (89 females, 83 males; 38.7±15.3 years). Beat-to-beat QT-interval duration (QT, QTapex (QTa), QTc, QTac, Tend (TE)), variability (QTSD, QTaSD, QTcSD, QTacSD) and mean RR-interval were determined from 24-hour Holter monitoring after manual exclusion of artefacts and premature beats. All volunteers were fully mobile, woke up around 7 AM and had 6 to 8 hours of sleep.

Parameters of QT-interval, as well as mean RR-interval, revealed a characteristic day-night-pattern. Diurnal profiles of QT-interval variability exhibited a significant increase in the morning hours (6-19 AM; p<0.01) and a consecutive decline to baseline levels. Aging was associated with an increase of QT-interval mainly at daytime and a significant shift of the T-wave apex towards the end of the T-wave.



Circadian profiles by decade.

The circadian profile of ventricular repolarization is strongly related to mean RR-interval, however, there are significant alterations mainly at daytime with normal aging. Furthermore, the diurnal course of QT-interval variability may be related to cardiac sympathetic activity and therewith to the reported diurnal pattern of malignant ventricular arrhythmias.

P1126 QRS prolongation on surface electrocardiogram and brain natriuretic peptide as indicators of left ventricular systolic dysfunction

S. Krüger[1], U. Janssens[1], K. Filzmaier[1], J. Graf[1], T. Stickel[1], S. Fuhs[1], D. Kunz[2], P. Hanrath[1]. [1]*University clinic, Medical Clinic I, Aachen, Germany;* [2]*Clinical chemistry, University clinic, Aachen, Germany*

Background: Prolonged QRS duration is a specific but insensitive indicator of left ventricular systolic dysfunction (LVSD). Brain natriuretic peptide (BNP) is a sensitive but only moderately specific marker of LVSD. We sought to determine, if the combination of prolonged QRS duration and BNP predicts LVSD with a higher accuracy.

Methods: We prospectively studied 128 consecutive pts (61 ± 13 years, 57 women) with suspected cardiac disease. The QRS duration on standard 12-lead resting ECG was determined. Resting BNP (pg/ml; immunoassay, Biosite Diagnostics, San Diego, USA) was obtained after 10 minutes of supine rest. BNP levels > 80 pg/ml were defined as abnormal. Left ventricular ejection fraction (LVEF) was evaluated with 2D echocardiography. A LVEF < 50% was defined as abnormal.

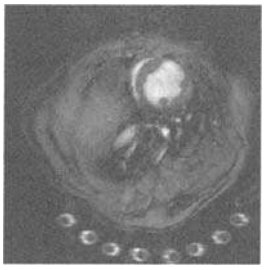
Results: LVEF in the LVSD group (n = 66) was 30 ± 8%, the control group (n = 62) had a LVEF of 60 ± 5% (p < 0.001).The QRS duration in the LVSD group was longer than in the group without LVSD (129 ± 34 vs. 96 ± 20 msec, p < 0.001). BNP was higher in the LVSD group than in the group with normal EF (467 ± 397 vs. 169 ± 242 pg/ml, p < 0.001). A QRS duration of > 0.1, > 0.11 or > 0.12 sec were highly specific (63%, 90%, 98%) but less sensitive (84%, 81%, 75%) for the prediction of LVSD. A BNP of > 80 pg/ml was highly sensitive (89%) but only modestly specific (55%) for the prediction of LVSD. The positive likelihood ratio for LVSD of abnormal BNP (2.0) and QRS prolongation > 0.1 sec (2.3) was improved by the combination of both criteria (5.1).

Conclusions: BNP is very sensitive but only moderately specific and QRS prolongation is very specific but less sensitive for the detection of LVSD. However, the combination of abnormal BNP and QRS prolongation yields to a higher positive likelihood ratio for the detection of LVSD compared with the two criteria alone.

P1127 Cardiac remodelling in mice after myocardial infarction followed by serial Cine MRI

M. Nahrendorf[1], K-H. Hiller[1], K. Hu[2], C. Waller[2], A. Haase[1], G. Ertl[2], W.R. Bauer[2]. [1]*Universität Wuerzburg, EP5, Wuerzburg, Germany;* [2]*Universität Würzburg, Med. Klinik, Würzburg, Germany*

Genetically altered mice are gaining increasing importance in vardiovascular research. To further evaluate remodeling after myocardial infarction (MI) these mice will be investigated after coronary ligation. To assess the changes after MI in mice non invasivly, cine magnetic resonance imaging (MRI) was employed. MRI was performed 1 and 8 weeks after MI in a 7 T-Biospec using an ECG-triggered FLASH-sequence: 12 short axis slices, slice thickness 1 mm, echo-time 1.2 ms, resolution 230 μm. MI-size, left and right ventricular (LV&RV) volume, ejection fraction (EF), wall thickness and -thickening and LV mass were determined in 8 MI (MI size 25 ± 5%) and 5 Sham operated CBA mice. At week 1, LV mass was still equal in both groups (Sham 94.4 ± 5.5mg, MI 109.8-/-6mg), but increased significantly in MI towards 8 weeks (Sham 105.1 ± 7.9mg, MI 144.4 ± 11.7mg, $p<0.05$). LV's were larger in infarcted mice (EDV week 8: Sham 63.5 ± 4 μl, MI 94.2 μl, $p < 0.05$). In contrast, right EDV was only slightly higher in MI (Sham 62.6 ± 5.8 μl, MI 74.4 ± 7.3 μl, p=ns). EF declined in the MI group (8 weeks: Sham 69.4 -/- 2.2%, MI 46.9 -/- 5.6%, $p < 0.05$). At 8 weeks the scar was 0.5 ± 0.1 mm, which was significantly thinner than the remote wall (MI 1.1 ± 0.03 mm, Sham 0.86 ± 0.04 mm, $p < 0.05$, respectivly). Remote wall thickening was impaired in mice with MI at 8 weeks (Sham 72.5 ± 5.1%, MI 43.2 ± 9.3%, $p < 0.05$).
In conclusion, LV hypertrophy and dilatation after MI in mice was followed noninvasivly. Application of MRI to infarcted transgenic mice will shed new light on remodeling after MI.



Short axis view, anterolateral MI.

P1128 Reorganization of the cardiac connexin distribution patterns in adriamycin induced cardiomyopathy

G. Plenz[1], V. Arps[2], H. Eschert[3], S. Christiansen[4], J. Stypmann[3], D. Hammel[4], H.H. Scheld[4]. [1]*Westfaelische Wilhelms-University, Cardiology and Angiology, Muenster, Germany;* [2]*Inst. for Arteriosclerosis Research, Cell Biology, Muenster, Germany;* [3]*University Muenster, Cardiology and Angiology, Muenster, Germany;* [4]*University Muenster, Cardiothoracic Surgery, Muenster, Germany*

Background: Gap junctions, constituting of Cx(connexin)43, Cx40 and Cx45, mediate the propagation of the electrical impulse between cardiomyocytes. In human hearts Cx43 is homogeneously distributed in all chambers, while Cx40 is more abundant in atria. Advanced heart failure is accompanied by a reorganization Cx patterns. We hypothesized that adriamycin-induced cardiomyopathy is accompanied by a reorganization of the Cxs analogous to that reported for idiopathic dilated cardiomyopathy (DCM).
Methods: In FBI dogs (N=10) cardiomyopathy was induced using intracoronary adriamycin-administration (10mg/50ml saline over 1h/week). Transmural left ventricular biopsies were taken after catheter insertion (control) and 4w after adriamycin-administration. RNA was isolated and analyzed by RT-PCR for Cx43, Cx40 and Cx45. Distribution patterns were studied by immunoconfocal microscopy.
Results: In control hearts only Cx43 was detected. Adriamycin-administration led to changes in LVEDD and FS. Moderate changes (hypertrophy=HY; LVEDD: 0.21±0.21 over control; FS: 70.65±3.7% of control) were associated with increased Cx43 levels (2.46fold) and Cx40 induction. With deterioration of cardiac function (LVEDD: 0.67±0.05 over control; FS: 46.45±3.61% of control) Cx43 decreased (8.2fold), Cx40 remained elevated and Cx45 was induced. Adriamycin treated myocardium showed the typical organization of connexins in the intercalated discs and the signal intensity directly reflected the alterations observed on the mRNA expression level.
Conclusions: Adriamycin-administration resulted in a stepwise deterioration of cardiac function. Concomitantly the Cx patterns changed. First patterns arose as reported for HY and consecutively patterns as described for DCM in humans. Our data indicate that adriamycin-administration induces DCM and therefore this dog model is suitable to study effects of surgical treatment strategies of DCM such as partial left ventriculectomy on the propagation of the electrical impulse. (Deutsche Stiftung für Herzforschung, Frankfurt)

P1129 Up-regulation of gap junction protein connexin-43 in cardiomyocytes.The tool for restoration of impaired intercellular communication?

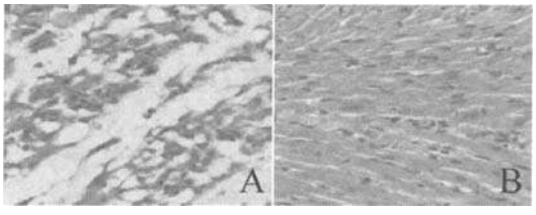
N. Tribulova[1], V. Shneyvays[2], L. Mamedova[2], S. Moshel[2], A. Shainberg[2], M. Manaoch[3], S. Kostin[4]. [1]*Inst. for Heart Research, Slovak Academy of Sciences, Bratislava, Slovakia;* [2]*Bar Ilan University, Fac. of Life Sciences, Ramat Gan, Israel;* [3]*Tel Aviv University, Dept. of Physiology, Tel Aviv, Israel;* [4]*Max-Planck-Institute, Dept. of Exp. Cardilogy, Bad Nauheim, Germany*

Mechanical function of the myocardium has been shown to be markedly dependent on thyroid status and myocardial electromechanical synchronization on intermyocyte communication mediated by gap junctions. The latter ensure electrical impuls propagation and coupling that can be modulated by various endogeneous and exogeneous compounds. The study was aimed to examine whether thyroid hormone can affect expression not only contractile but also gap junction proteins and cell-to-cell junction formation.
Methods: Cultured cardiomyocytes from newborn rats with poorly developed junctions were treated on day 3 in culture with 10 or 100 nM 3,3',5-triiodo-L-thyronine (T3) and examined 48 and 72 hrs after. Incubations with monoclonal mouse anti-Cx43 and anti-alfa-sarcomeric actin antibodies followed by either goat anti-mouse conjugated with FITC or biotinylated immunoglobulin conjugated with extra avidin-peroxidase were used for immunodetection of gap junction protein, connexin-43 and alfa-sarcomeric actin, respectively. Western blot analysis was performed, as well.
Results: Immunohistochemical labeling revealed plasma membrane location of Cx-43 in punctate gap junctions, whereby the staining was much more intensive after cells exposure to T3, indicating increased number of connections. In addition, cytoplasmic staining was observed. Quantitative immunoblotting showed that T3 induced in dose-dependent manner significant increase of Cx-43 expression after 48 and 72 hrs, compared to age-matched controls. The expression of alfa-sarcomeric actin was also significantly increased, however, 72 hrs exposure to higher dosage of T3 caused mild disintegration of alfa-sarcomeric actin, warning of over-dosage.
Conclusion: The results suggest that up-regulation of gap junction protein due to T3 treatment can enhance cell-to-cell coupling. Thus, increase and/or restoration of both intercellular communication and contractility by modulation of thyroid state can be beneficial in failing heart.

P1130 Cardioprotective effect of melatonin in experimental myocardial ischaemia induced by isoproterenol in rats

M. Acikel[1], M. Emin Buyukokuroglu[2], H. Aksoy[3], F. Erdogan[4], H. Senocak[1]. [1]*Dept. of Cardiology,* [2]*Dept. of Pharmacology,* [3]*Dept. of Biochemistry,* [4]*Dept. of Pathology, Ataturk University School of Medicine, Erzurum, Turkey*

Background: Melatonin(MEL) has been found to be effective in protecting against pathological states due to reactive oxygen species release. Isoproterenol(ISO) causes severe stress in the myocardium and produces acute myocardial necrosis. This study was performed in order to determine whether MEL might protect from ischemic injury in experimental myocardial ischemia induced by ISO in rats. Methods: 24 male Sprague Dawley rats (weight 135 to 160 g) were used for this study, and divided into 3 treatment groups: (1) Control (n=8): saline only. (2)ISO (n=8): ISO (200 mg/kg/day for 2 days, s.c.). (3) MEL+ISO(n=8). MEL (10 mg/kg/day,i.p.) was started 30 minutes before the initiation of ISO, and both MEL and ISO were continued until the end of the 2nd days. The blood samples were collected for the determination of cardiac troponin T (cTnT) and cardiac troponin T (cTnI). The hearts were removed for histological examination, and observed microscopically.
Results: Plasma cTnT and cTnI levels significantly increased in ISO-treated group in comparation with controls (1.29±0.40 vs 0.46±0.21 ng/mL, $p<0.001$; 0.56±0.23 vs 0.21±0.02ng/mL, $p<0.01$ respectively). MEL+ISO-treated group showed lower cTnT and cTnI than those of ISO-treated group(0.65±0.19 vs 1.29±0.40 ng/mL, $p<0.01$ and 0.25±0.04 vs 0.56±0.23 ng/mL, $p<0.01$ respectively). MEL+ISO-treated group showed less myocardial changes on histological examinations when compared with those ISO-treated group (Pictures: Histological examination of myocardium:(A) ISO-treated rat(H.E. X200)(B)MEL+ISO-treated rat (H.E. X200).



Conclusions: The present study suggests that melatonin could have a protective effect against ISO-induced myocardial injury in rats, and a potential clinical application in the treatment of myocardial ischemia.

P1131 Overexpression of cardiac β1-adrenoceptors leads to activation of matrix metalloproteinases in vivo

U. Seeland[1], S. Selejan[1], S. Engelhardt[2], P. Müller[1], M.J. Lohse[2], M. Böhm[1]. [1]*Universität des Saarlandes, Innere Medizin III, Homburg/ Saar, Germany;* [2]*Pharmakologie und Toxikologie, Bayerische Julius-Maximilians-Univ., Würzburg, Germany*

Objective: Overexpression of cardiac β1-adrenergic receptors in transgenic mice (β1-TG) leads to increased myocardial fibrosis and hypertrophy followed by left ventricular (LV) dilation. Extracellular matrix remodeling depends on collagen synthesis and collagen degrading matrix metalloproteinase activity (MMPs) and their inhibitors (TIMPs). The study investigates the role of chronic β1-adrenergic receptor activation on MMP/TIMP expression and activity during transition from hypertrophy to heart failure.
Methods: LV homogenates and mRNA of cardiac β1-TG were examined at the age of 12 weeks, 5 months and 1 year compared to wildtype (WT) FVB/N mice. The expression of collagenase MMP-13, gelatinases MMP-2,-9, membrane-type MMP (MT1MMP) and TIMPs (-1,-2,-4) as well as MMP-2 enzyme activity were measured with specific antibodies and zymographic activity assays. Picirosirius red staining was performed for collagen content and quantified with the Lucia G software.
Results: MMP/TIMP expression and activity were not altered at 12 weeks old β1-TG compared to WT. Chronic β1-adrenergic receptor activation leads to interstitial fibrosis (picirosirius red), hypertrophy and increased expression of the latent form of gelatinase MMP-2 (optical density [OD] MMP-2 latent:TG 1.2±0.1, WT 0.56±0.08,n=4,$p<0.05$), MT1MMP and TIMP-2 at the age of 5 months. This expression pattern could be responsible for activation of MMP-2 measured in failing hearts of β1-TG at the age of 1 year (OD MMP-2 active:TG 0.2±0.05, WT 0.04±0.01,n=4, $p<0.05$). Results of MMP-13, TIMP-1 and -4 measurements yielded no difference between WT and β1-TG at any time.
Conclusion: The increase of MMP activity without significant TIMP inhibition could be responsible for myocardial dilation with progressive heart failure. The study shows that transition from hypertrophy to heart failure is associated with activation of MMP-2 due to chronic β1-adrenoceptor activity.

P1132 Anti-apoptotic effect of the vasopeptidase inhibitor omapatrilat in rats with acute myocardial infarction

N.E. El Mokhtari, A. Meissner, A. Reinecke, D. Krueger, M. Lins, A. Tiroke, R. Simon. *University of Kiel, Clinic of Cardiology Dept., Kiel, Germany*

Background: Omapatrilat, a vasopeptidase inhibitor, simultaneously inhibits angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP). The end result is blockade of angiotensin-II formation and inhibition of the catabolism of vasodilatory hormones, such as the natriuretic peptides, bradykinin, and adrenomedullin. The aim of the study was to compare the effects of dual NEP/ACE inhibition to selective ACE inhibition on apoptotic cell death in experimental rat myocardial infarction model.
Methods: Male Wistar rats with ligation-induced myocardial infarction were assigned to placebo or treatment with omapatrilat (10 mg/kg/day) or ramipril (1 mg/kg/day) by oral gavage starting 7 days before the induction of myocardial infarction. 2 and 24 hours post-MI the rats were sacrificed and hearts were sampled. Detection of apoptosis of cardiomyocytes from left ventricle was based on terminal deoxynucleotide transferase-mediated dUTP nick end labelling (TUNEL method).
Results: The incidence of cardiac myocyte apoptosis was significantly more reduced in the omapatrilat treated rats than in the ramipril treated rats at 2 and 24 hours after LAD occlusion (3.20 ± 0.81% at 2hr and 5.68 ± 3.14% at 24hr for omapatrilat treated rats vs 5.07 ± 2.11% at 2hr and 8.27 ± 3.73% at 24hr for ramipril treated rats vs. 8.38 ± 3.52 at 2hr and 13.97 ± 5.80% at 24hr placebo treated rats, $p<0.04$)
Conclusions: The vasopeptidase inhibitor omapatrilat prevented cardiomyocyte apoptosis after MI in rats more effectively than the ace-inhibitor ramipril. These results suggest that the vasopeptidase inhibitor omapatrilat may provide a novel therapeutic approach for cardioprotection following acute myocardial infarction.

P1133 Pulmonary congestion in heart failure contributes to increased plasma ET-1 levels by up-regulation of regional tissue ECE-1 activity

T. von Lueder[1], H.K. Harald Kjekshus[1], S.U. Stig Urheim[2], T.E. Thor Edvardsen[2], E.O. Erik Øie[1], M.S.A. Muhammed Shakil Ahmed[1], O.A.S. Otto A Smiseth[1], H.A. Håvard Attramadal[1]. [1]*Rikshospitalet/The National Hospital, Institute For Surgical Research, Oslo, Norway;* [2]*The National Hospital/ Rikshospitalet, Department of Cardiology, Oslo, Norway*

Background: We have previously shown the pulmonary circulation to be the main source of the increased plasma endothelin-1 (ET-1) levels in a porcine model of rapid pacing induced congestive heart failure (CHF). The aim of the present study was to test if CHF is associated with an increased pulmonary conversion of the precursor hormone, big endothelin-1 (big ET-1) by endothelin converting enzyme type 1 (ECE-1) activity, and to study the effect of lung congestion on ECE-1 activity.
Methods and results: CHF pigs (n=6) which underwent rapid pacing (215-240 bpm) for 3 weeks were compared to controls (n=5). CHF-pigs exhibited significant left ventricular dilatation, reduced contractility, increased cardiac filling pressures and increased total wet weight of the lungs (696 ± 17 g/m^2 vs controls 455 ± 18 g/m^2, $p<0.001$). Plasma ET-1 increased 4-fold compared to controls ($p<0.001$) and correlated strongly with increased secretion of ET-1 in the pulmonary circulation. Plasma big ET-1 levels exhibited the highest increase (4.5-fold vs controls, $p<0.001$) in the pulmonary artery with slightly higher big ET-1 levels in the pulmonary artery than in the left ventricle of CHF animals, suggesting an increased supply of big ET-1 to the pulmonary circulation. To evaluate differences in ECE-1 activity between CHF and control animals and the influence of congestion on ECE-1 activity, we sampled lung tissue from well-ventilated upper-lobe segments, and from dependent lower-lobe segments. Lung tissue wet/dry weight ratios were highest in the dependent lower-lobe of CHF pigs (5.8 ± 0.1) compared to lower-lobe controls (5.2 ± 0.1, $p<0.01$), and upper-lobe CHF (5.3 ± 0.1, $p<0.02$), thus confirming significant congestion of the dependent lower lobes in CHF pigs. ECE activity was measured by incubating big ET-1 with solubilized lung membrane fractions with and without pre-incubation with the ECE-1 selective inhibitor FR901533, followed by quantification of ET-1 synthesis by ELISA. ECE-1 activity was highest in the congested lower lobes of CHF pigs (2.0 ± 0.3 pmol.min-1.mg protein-1) compared to lower lobe controls 1.1 ± 0.1 pmol.min-1.mg protein-1 ($p<0.02$), and to upper lobe CHF (1.1 ± 0.1 pmol.min-1.mg protein-1, $p<0.005$). ECE-1 activity correlated significantly with wet/dry weight ratios (ECE-1 activity = 1.6xwet/dry weight ratio-7.2, $R^2=0.56$, $p<0.001$)
Conclusion: ECE-1 activity is increased in congested lung tissue. Pulmonary congestion may thus be an important stimulus for the increased pulmonary ET-1 secretion which contributes to increase systemic plasma ET-1 levels in pacing induced CHF.

P1134 Growth hormone improves systolic function and myocardial bioenergetics in hypophysectomized rats

E. Bollano[1], E. Omerovic[2], M. Lorentzson[2], B. Soussi[2], S. Neubauer[3], F. Waagstein[2], M. Horn[2], J. Isgaard[4]. [1]*Wallenberg Laboratory, Göteborg, Sweden;* [2]*Sahlgrenska university Hospital, wallenberg laboratory, Guthenburg, Sweden;* [3]*John Radcliffe Hospital, Department of Cardiovascular Medicine, Oxford, United Kingdom;* [4]*Sahlgrenska University Hospital, Dept of Internal Medicine, Guthenburg, Sweden*

Using hypophysectomized (hx) rats in the present study, we aimed to investigate the physiological role and mechanisms of growth hormone (GH) effects on cardiac function, geometry and myocardial bioenergetics.
Methods: Hx rats receiving hormonal supplementation with thyroxine and hydrocortisone (for three week) were used Thereafter, animals were divided into two groups: Hx group continuing the above hormonal regime, and Hx+GH group receiving s.c. injections with rhGH (1mg/kg/d),for two weeks. Intact age-matched rats were used as normal controls. Transthoracic echocardiography and in vivo 31P magnetic resonance spectroscopy were performed at the end of study. Creatine kinase (CK) activity, isoenzyme distribution were measured in heart tissue. The expression of sarcoplasmatic calcium transport ATPase (SERCA2) was evaluated.
Results: GH treatment significantly increased body weight and heart weight. Left ventricular (LV) systolic function and diastolic function were impaired in Hx group at rest and during stress compared to normal rats. Systolic wall stress (WS) was significantly higher in Hx group as compared to controls. GH treatment partially normalized systolic and diastolic LV function and significantly decreased WS. Phosphocreatine/ATP was lower in Hx-group compared with normal rats (1.68 ± 0.02 vs 2.62±.03 $p<.0001$) and was normalized with GH treatment (2.44 ±.04, $p<.0001$). Total CK activity was lower in Hx rats compared with intact rats and was not affected by GH treatment. Expression of SERCA2 was significantly lower in Hx group and partly normalized in
Conclusion: Systolic and diastolic function was significantly decreased in hx rats and normalized by GH treatment. Effects on myocardial bioenergetics and intracellular Ca^{2+} handing may be important mechanisms in the GH regulation of cardiac function and structure.

EXPERIMENTAL STUDIES IN HEART FAILURE

P1135 Therapy with the Acorn Cardiac Support Device normalizes gene expression of alpha-myosin heavy chain in dogs with heart failure

S. Rastogi, S. Mishra, R.C. Gupta, H. Morita, H.N. Sabbah. *Henry Ford Health System, Detroit MI, United States of America*

Background: Myosin heavy chain (MHC) is a key component of the cardiac contractile machinery. Recent studies have shown that a switch from alpha-to beta-MHC isoforms takes place in myocardium of patients with chronic heart failure (HF). This switch may be partly responsible for the progressive deterioration of LV function characteristic of the heart failure state. In the present study, we examined whether chronic therapy with the Acorn Cardiac Support Device (CSD) restores gene expression of alpha-MHC in dogs with intracoronary microembolization-induced HF. Chronic therapy with the CSD has been shown to prevent progressive LV dilation and to improve LV ejection fraction in dogs with chronic HF.
Methods: The CSD, a preformed polyester device, was surgically implanted in 6 dogs with HF. Six other dogs with heart failure served as concurrent controls. All dogs were followed for 3 months. At the end of 3 months of follow-up, LV tissue was obtained from all 12 dogs and from 6 normal dogs and used to extract total RNA. Alpha- and beta-MHC isoforms were measured using reverse transcriptase polymerase chain reaction and each normalized to total MHC.
Results: mRNA for alpha-MHC was significantly reduced in untreated HF dogs compared to normals (2.9 ± 0.3 vs. 9.2 ± 1.3%, $P<0.05$); whereas mRNA for beta-MHC was significantly increased in untreated HF dogs compared to normals (97.1 ± 0.4 vs. 90.8 ± 1.6%, $P<0.05$). Chronic therapy with the CSD restored mRNA gene expression of alpha-MHC to normal levels (10.2 ± 0.6%) and decreased mRNA of beta-MHC to near normal levels (89.8 ± 0.7, %).
Conclusions: In dogs with microembolization-induced HF, LV mRNA gene expression of alpha-MHC is decreased and mRNA gene expression of beta-MHC is increased compared to normal dogs. Chronic treatment of HF dogs with the CSD normalizes mRNA gene expression for both alpha- and beta-MHC. Since alpha-MHC is a more efficient form of MHC, this normalization is likely to restore LV systolic function, albeit in part and is consistent with the observation of increased in LV ejection fraction after long-term therapy with the CSD.

P1136 Combination therapy of an endothelin receptor antagonist and an angiotensin-converting enzyme inhibitor preserves renal function in experimental congestive heart failure

M. Ohnishi, A. Wada, T. Tsutamoto, M. Fujii, T. Matsumoto, T. Yamamoto, T. Takayama, M. Kinoshita. *Shiga University of Medical Science, First Department of Internal Medicine, Otsu, Japan*

Impaired renal function, in particular, glomerular filtration rate (GFR) has recently been reported to be a stronger predictor of mortality than impaired cardiac function in advanced congestive heart failure (CHF). Endothelin (ET)-1 and angiotensin (AT)-II cause body fluid retention in CHF, however, it has not been well evaluated whether the inhibition of ET-1 and AT-II improves renal function. We administered an ET receptor antagonist (ETRA), TA-0201 alone (0.3 mg/kg/day, n=6), an angiotensin converting enzyme inhibitor (ACEI), enalapril alone (3 mg/kg/day), a combination (n=6) of TA-0201 (0.3 mg/kg/day) plus enalapril (0.3 mg/kg/day), or placebo (Control, n=6) to dogs with CHF induced by rapid right ventricular pacing (270 bpm, 3 weeks). The results are shown in the table below. Chronic treatment of ETRA or ACEI improved cardiorenal function and neurohumoral activation. Moreover, combination therapy increased GFR and prevented renal damage expressed as a further reduction of kidney weight and the expression of collagen type 1 mRNA in the kidney.

	Control	ETRA	ACEI	ETRA+ACEI
CO (L/min)	1.7±0.2	2.6±0.2 *	2.0±0.3 *	2.4±0.4 *
NE (pg/mL)	817±72	563±76 *	584±96 *	563±89 *
ANP (pg/mL)	492±50	237±18 *	390±55 *	298±29 *
UFR (mL/min)	0.24±0.05	0.37±0.04 *	0.44±0.07 *	0.52±0.12 *#
GFR (mL/min)	22.1±3.5	34.3±4.1 *	33.2±5.8 *	46.1±1.4 *#$
kidney/BW (g/kg)	4.33±0.41	3.75±0.56	3.15±0.15 *	2.32±0.11 *#$
Collagen 1/GAPDH mRNA	1.01±0.06	0.72±0.02 *	0.67±0.03 *	0.50±0.03 *#$

ETRA indicates endothelin receptor antagonist, ACEI; angiotensin coverting enzyme inhibitor, CO; cardiac output, NE; norepinephrine, ANP; atrial natriuretic peptide, UFR; urine flow rate, GFR; glomerular filtration rate, BW; body weight, Collagen 1; collagen type 1 mRNA. * $P<0.05$ vs Control, # $P<0.05$ vs ETRA, $ $P<0.05$ vs ACEI

These findings suggest that chronic inhibition of both the ET and renin-angiotensin systems may provide additional advantages by preserving renal function in the treatment of CHF.

P1137 Increase of TNF alpha-concentration in serum and liver but not in myocardium during pacing-induced heart failure in rabbits

S. Aker, T. Neumann, S. Belosjorow, I. Konietzka, G. Heusch, R. Schulz. *University of Essen, Pathophysiology, Essen, Germany*

In heart failure (HF) patients with left ventricular (LV) systolic dysfunction, the serum TNF alpha-concentration (sTNF alpha) is increased. An increase in myocardial TNF alpha-concentration (mTNF alpha) during intracoronary TNF alpha-infusion is associated with the development of contractile dysfunction in dogs.
To study whether the increase in sTNF alpha is a cause or consequence of HF, HF was induced by rapid LV pacing (400 bpm) in ten chronically instrumented rabbits. After 3 weeks of pacing, rabbits displayed clinical signs of HF. Echocardiography revealed an increase in LV end-diastolic diameter from 15±2 to 18±2 mm and a reduction in LV shortening fraction from 35±5 to 11±4% (Mean±SEM; both $p<0.05$). Nine sham-operated rabbits served as controls. sTNF alpha, mTNF alpha and liver TNF alpha-concentrations (lTNF alpha) were measured using the WEHI-cell assay.
sTNF alpha was increased in HF rabbits compared to controls (267±27 vs. 171±24 U/ml, $p<0.05$). lTNF alpha was also increased in HF rabbits compared to controls (2215±295 vs. 1495±125 U/g, $p<0.05$). In contrast, mTNF alpha did not differ between HF rabbits and controls (700±55 vs. 625±70 U/g, ns). In the liver (HE-staining), the number of leukocytes was higher in HF rabbits than in controls (112±40 vs. 48±14 cells/mm^2, $p<0.05$). Close, linear correlations between the number of leukocytes and lTNF alpha ($r=0.78$) as well as between lTNF alpha and sTNF alpha ($r=0.68$) were demonstrated.
In this HF model with reduced LV systolic function, mTNF alpha remains unchanged. The increase in sTNF alpha appears to be a consequence rather than a cause of HF, and it is possibly a result of gastrointestinal congestion and subclinical inflammation.

P1138 Paradoxical effect of parathyroid hormone-related peptide on the hearts of spontaneously hypertensive rats

K. Schlüter, H. Degenhardt, K. Schorr. *University, Physiology, Giessen, Germany*

Background: Parathyroid hormone-related peptide (PTHrP) is a peptide hormone with positive chronotropic, inotropic and dilating properties on hearts from normotensive rats. It is locally released during energy depleting conditions, like ischemia. It is not known whether PTHrP influences ventricular function in SHR in the same way than in normotensive rats. PTHrP can exert opposite effects on vascular smooth muscle cells from SHR or normotensive rats. The aim of the present study was therefore, to characterize the influence of PTHrP on ventricular function of SHR under basal and post-ischemic conditions. Methods: Isolated hearts from age matched normotensive Wistar rats and SHR were perfused in the Langendorff mode under flow constant conditions (10 ml/min). Left ventricular function was determined as developed pressure (LVDP). Hearts were perfused with synthetic PTHrP(1-36), a biologically agonist for PTHrP receptors, and D-Trp12-PTH(7-34), a PTHrP-receptor antagonist (each 100 nM). Peptides were given shortly before the onset of ischemia (30 min no-flow) to be present at the beginning of reperfusion. PTHrP concentration was determined in the perfusate. Results: No significant difference between the PTHrP release from the hearts of normotensive rats and SHR was determined at any time point. During the pre-ischemic periode, PTHrP(1-36) did not influenced LVDP in normtensive rats (123±9 mm Hg vs. 121±4 mm Hg ($n=18$), $p=0.638$) but it reduced LVDP in hearts from SHR (from 96±4 mm Hg to 83±2 mm Hg ($n=12$, $p=0.0012$)). The antagonist reduced LVDP in 5 from 6 hearts from normotensive rats (mean LVDP: 123±9 mm Hg vs. 120±3 mm Hg, $p=0.0457$) but only in 2 from 6 hearts from SHR (mean LVDP: 96±4 mm Hg to 94±9 mm Hg, $p=0.5889$). Post-Ischemic recovery was not modified by PTHrP(1-36) in hearts from either strain. In contrast, the antagonist significantly reduced post-ischemic recovery in hearts from normotensive rats from 61±9% to 17±3% ($p=0.01$), 78±5% to 36±7% ($p=0.02$), and 87±5% to 47±4% ($p=0.03$) of pre-ischemic values at 5, 15, and 30 min of reperfusion, respectively. It significantly improved post-ischemic recovery in hearts from SHR from 50±7% to 97±18% ($p=0.06$), 89±6% to 108±13% ($p=0.25$), and 95±6% to 117±8% ($p=0.01$) at 5, 15, and 30 min of reperfusion, respectively. Conclusion: The effects of PTHrP on cardiac function seem to be reversed in the SHR model of genetic hypertension. This study shows for the first time, that a single molecule may have opposite effects on cardiac function under physiological and pathophysiological conditions.

P1139 Transgenic expression of kallikrein prevents from diabetic cardiomyopathy by inhibition of ICAM-1 induction and infiltration

C. Tschope[1], F. Escher[1], F. Spillmann[1], T. Walther[1], M. Bader[2], H.P. Schultheiss[1], M. Noutsias[1]. [1]*University Hospital Benjamin Franklin, Cardiology Dept., Berlin, Germany;* [2]*Max-Delbrück Center, Molecular Biology, Berlin, Germany*

We investigated the role of cell adhesion molecules (CAMs) and the kallikrein-kinin system (KLK) in experimental diabetic cardiomyopathy in rats.
Immunohistochemically stained endothelial CD54/ICAM-1 and the counter-receptor+ CD18+ and CD11a/LFA-1+ infiltrates were quantified by digital image analysis in 5μm thick cardiac cryosections in male Sprague-Dawley (SD) rats, SDSTZ rats with streptozotocin(STZ)-induced diabetic cardiomyopathy (6 weeks after STZ injection 70 mg/kg i.p.), KLK rats transgenically expressing human kallikrein and KLK rats with STZ-diabetic cardiopathy (KLK-STZ) (n=7/group). Haemodynamic parameters (LV pressure/LVP and dP/dtmax) were measured by a Millar tip catheter.
LVP (53,6 (range: 45-64) vs. 81,2 (72-90) mmHg) and the dP/dtmax (2575 (1999-3117) vs. 4656 (4200-6010) mmHg/s) were significantly reduced in SD-STZ animals compared to normoglycemic SD and KLK controls and of KLK-STZ animals. Endothelial CD54/ICAM-1 expression and infiltrate density were significantly increased in STZ-rats compared to normoglycemic controls and KLK-STZ rats (table). Infiltrates and CAMs-expression correlated significantly with LVP and dP/dtmax ($p<0.05$).

	SD-rats	KLK-rats	KLKSTZ-rats	SDSTZ-rats
CD54	0.03 (0.02-8)	0.05 (0.03-6)	0.03 (0.02-7)	0.17 (0.09-26)
CD18	23.6 (17-25)	26.8 (20-30)	27.4 (19-33)	59.6 (43-72)
CD11a	8.3 (5-11)	8.6 (4-10)	10.1 (6-14)	22.6 (20-26)

Our data indicate that inhibition of CAMs-induction and of the consequent counter-receptor+ immunocompetent infiltration constitutes a relevant mechanism by which transgenic activation of the KKS prevents from LV contractile dysfunction in experimental diabetic cardiomyopathy.

P1140 Reverse left ventricular remodelling with the Acorn Cardiac Support Device in dogs with advanced heart failure: a randomized, placebo controlled study

H.N. Sabbah[1], N.H. Fanous[2], H. Morita[1], G. Suzuki[1], B.E. Haithcock[2], G. Paone[2], B. Brewer[2]. [1]*Henry Ford Health System, Detroit MI, United States of America;* [2]*Henry Ford Health System, Surgery Dept., Detroit, MI, United States of America*

Background: Chronic progressive left ventricular (LV) chamber remodeling in patients with heart failure contributes to progressive LV dysfunction. We previously showed that in dogs with moderate heart failure, the Acorn Cardiac Support Device (CSD), a preformed polyester device that is surgically fitted over the cardiac ventricles, prevents progressive LV remodeling. In the present study, we examined the effects of the CSD on reversal of progressive LV remodeling in dogs with advanced HF (LV ejection fraction, EF <27%).
Methods: Advanced heart failure was produced in 13 dogs by multiple sequential intracoronary microembolizations. Dogs were randomized to monotherapy with the CSD (n=6) or to a sham surgical procedure (Control, n=7). All dogs were maintained for 6 months following surgery. LV end-systolic volume (ESV) and end-diastolic volume and LV EF were measured from left ventriculograms performed at the time of randomization (PRE) and at the end of 6 months of follow-up (POST). Evaluation of treatment effect was based on a comparison between the two study arms with respect to the change between PRE and POST treatment values.
Results: Of the 7 dogs randomized into the control arm, 2 died prior to completion of the 6 months follow-up period; one from congestive heart failure and one from sudden cardiac death. All of the dogs randomized into the CSD-treatment arm survived the entire duration of the study. In the 5 control dogs that survived, LV ESV increased from 55 ± 4 ml to 69 ± 6 ml (P=0.007), LV EDV also increased from 74 ± 6 ml to 85 ± 6 ml (P=0.0004) and LV EF decreased from 25 ± 1% to 19 ± 1% (P=0.014). In contrast, in CSD-treated dogs, LV ESV decreased from 58 ± 5 ml to 51 ± 3 ml (0.005), LV EDV decreased from 78 ± 6 ml to 69 ± 5 ml (P=0.003) and LV EF tended to increase from 25 ± 1% to 27 ± 1% (P=0.18). Analysis of treatment effect showed that compared to controls, treatment with the CSD significantly reduced ESV (P=0.0001)and EDV (P=0.0001) and prevented the progressive decline of EF (P=0.001).
Conclusions: In dogs with advanced heart failure, long-term therapy with the Acorn CSD elicits reverse LV remodeling in association with prevention of progressive LV systolic dysfunction. These results support our findings in dogs with moderate heart failure.

ASSESSING VIABLE MYOCARDIUM: CURRENT PERSPECTIVES

P1141 Comparison of low dose DSE and echocardiography during GIK infusion for the detection of myocardial viability after anterior myocardial infarction

E. Yetkin[1], S. Kubilay[2], R. Atak[2], M. Ileri[2], I. Tandogan[3], H. Turhan[2], F. Kosar[3], S. Cehreli[1]. [1]*Inonu University Faculty of Medicine, Department of Cardiology, Malatya, Turkey;* [2]*Turkiye Yuksek Yhtisas Hospital, Dept. of Cardiology, Ankara, Turkey;* [3]*Inonu University Faculty of Medicine, Cardiology, Malatya, Turkey*

Background: Low dose dobutamine stress echocardiography (LDDSE) is one of the method most used to assess myocardial viability. Glucose-insulin-potassium(GIK) has been shown to increase contraction of the ischeamic zone.
Objectives: We aimed to compare LDDSE and echocardiography during GIK infusion for detecting myocardial viability.
Methods: Thirthy two patients who had first anterior myocardial infarction (MI) and without previous MI were included in the study. Echocardiographic evaluation was carried out on the 7th ±2 days after MI. Intravenous infusion of dobutamine(3mg/kg body weight/min) was started and continued for 5 minutes and than increased to 5mg/kg/min and 10mg/kg/min for another 5 minutes. Glucose-insulin-potassium protocol consisted of fixed dose of insulin(100mU/kg/hour iv) and a variable glucose/potassium infusion rate. GIK echocardiography was made at baseline and after 60 minutes of GIK. The detected viable myocardium was defined as 1 or 2 scores decreasing in at least two adjacent abnormal segments during LDDSE and GIK echocardiography.
Results: Viability was detected in 20%(57 segments) of the asynergic segments at baseline with GIK echocardiography and 22%(62 segments) of those segments with LDDSE($p>0.05$). Left ventricular wall motion score index at baseline was 1.87 and it decreased significantly during both LDDSE and GIK echocardiography ($p<0.001$, vs 1.75 and 1.76 respectively). The agreement between LDDSE and GIK echocardiography for detection of myocardial viability was 96%.
Conclusion: We have shown that GIK augments the myocardial contractility after anterior MI in viable segments. The high agreement between LDDSE and GIK echocardiography suggests that GIK can be used to detect myocardial viability after acute MI

P1142 Ischaemic preconditioning protects myocardium against reperfusion injury by attenuating Ca^{2+}-induced cell fragility

J. Inserte, D. Garcia-Dorado, A. Rodriguez-Sinovas, F. Padilla, P. Pina, N. Escalonia, L. Agullo, M. Ruiz-Meana. *Hospital Universitary Vall d'Hebron, cardiology, Barcelona, Spain*

The wealth of knowledge on the triggers and signal transduction systems involved in the genesis of the protective effect of ischemic preconditioning (IP) against cell death secondary to ischemia-reperfusion is in striking contrast with the lack of information regarding the effectors mechanisms responsible of the protection. Here we investigated whether these effectors act during ischemia or during reperfusion. The effect of IP (two cycles of 5 min of ischemia/5 min reperfusion) were analyzed in isolated, isovolumetric contracting rat hearts (n=16) submitted to transient (60 min) ischemia. IP had no beneficial effect during ischemia; on the contrary, it accélerated ATP depletion (from 7.7±0.8 μmols to 5.1±0.6 μmols measured 10 min after onset of ischemia, p=0.041), the onset of ischemic rigor (increase in LV diastolic pressure (LVDP), from 11.9±0.4 min to 5.8±0.5min, $p<0.001$), and electrical uncoupling (tissue electrical resistivity, from 10.2±0.4 ohms x cm to 8.7±0.5 ohms x cm, p=NS). In contrast, IP protected against reperfusion-induced hypercontracture (increase in LVDP, 140.2±6.3 mmHg in control hearts vs. 106.2±2.9 in IP hearts, p=0.001), LDH release (52.0 U/gdw in control hearts vs. 13.8 U/gdw in IP hearts, $p<0.001$), and improved functional recovery (10.0±4.2% in control hearts vs. 47.4±7.2% in IP hearts, $p<0.001$. The effect of IP was then studied in 18 hearts submitted to Ca^{2+} overload by removing Na^+ from the perfusion buffer (osmolarity maintained with mannitol), and then to cell swelling by reintroduction of Na^+ during normoxic conditions. This protocol resulted in no LDH release during Na^+ deprivation, and in severe myocardial edema, LDH release and impairment of contractile function (pulse pressure 33% respect to basal) upon reintroduction of Na^+. This effects were markedly attenuated by inhibition of NCX1 with KB-R7943 during Na^+ deprivation, or by increasing osmolarity with mannitol during reintroduction of Na^+. Application of IP before deprivation of Na^+ did no attenuate edema associated to reintroduction of Na^+, but markedly reduced LDH release (44.0±3.3 U/gdw vs. 23.9±4.1 U/gdw, p=0.010) and contractile failure (pulse pressure 57% respect to basal, $p<0.001$). These results suggest that IP protect against cell death during reperfusion by attenuating cell fragility secondary to Ca

P1143 Heat stress and ischaemic preconditioning produce similar patterns as regards p38 MAPK and JNKs activation in the isolated rat heart

C. Pantos[1], V. Malliopoulou[1], S. Tzeis[1], I. Paizis[1], I. Mourouzis[1], D.D. Cokkinos[1], D. Varonos[1], D.V. Cokkinos[2]. [1]*University of Athens, Pharmacology, Athens, Greece;* [2]*Onassis Cardiac Surgery Center, 1st Cardiology Department, Athens, Greece*

Introduction: Heat stress (HS) has been shown to protect the heart against ischaemia; however apart from heat shock protein increase, its mechanism has not been thoroughly investigated. In order to identify possible mechanisms of HS induced cardioprotection we studied the activation pattern of p38 MAPK and JNKs, intracellular protective molecules and compared it to that of ischaemic preconditioning (IP).
Methods: 1. Wistar rats were subjected to whole body HS at 42°C for 15min (HEAT) or sham anesthesia (SHAM). 24hours later their hearts were perfused in the Langerdorff mode and subjected either to 20min of stabilization (HEAT-BASE, n=4 and SHAM-BASE, n=4) or 20min of stabilization followed by 20min zero-flow global ischaemia (I) and 45min of reperfusion (R) (HEAT-I/R, n=9 and SHAM-I/R, n=8). The postischaemic recovery of function was assessed by the recovery of of left ventricular developed pressure (LVDP) expressed as % of the initial value (LVDP%). 2. After 20min of stabilization, isolated hearts were subjected to 4 cycles of PC (3min I, 5min R and 3 cycles of 5min I and 5min R) followed by 20min of I and 45min of R (PC-I/R, n=6) and compared to control hearts (CONT-I/R, n=6). 3. Phosphorylated and total p38 MAPK and p54 and p46 JNKs were measured by Western blot analysis at the end of I/R. These proteins as well as HSP70 were measured at HEAT-BASE and SHAM-BASE.
Results: 1. LVDP% was higher in HEAT-I/R compared to SHAM-I/R [60.3(6.3) vs 42.9(4.1), $p<0.05$]. In addition LVDP% was higher in PC-I/R than in CONT-I/R [59.17(4.67) vs 37.22(4.5), p,0.05]. 2. In SHAM-BASE HSP70 was not detectable while it was induced in HEAT-BASE hearts. Phospho-p38, p38, phospho-JNKs and JNKs were not different between SHAM-BASE and HEAT-BASE. 3. Phospho-p38 was not different between SHAM-I/R and HEAT-I/R and was non-significantly less in PC-I/R than in CONT-I/R, p=0.09. 4. Phospho-p54 JNK was 1.45fold higher in SHAM-I/R than in HEAT-I/R, $p<0.05$ and phospho-p46 JNK was 1.6fold higher in SHAM-I/R than in HEAT-I/R, $p<0.05$. Moreover phosphorylated p54 JNK was 1.85fold higher in CONT-I/R than in PC-I/R, $p<0.05$ and phosphorylated p46 JNK was 2.0fold higher in CONT-I/R than in PC-I/R, $p<0.05$.
Conclusion: HS induced cardioprotection is associated with attenuated activation of JNKs, but not p38 MAPK, in response to ischaemia and reperfusion. This pattern is identical to that produced by IP.

P1144 Prognostic importance of myocardial viability in revascularized patients with coronary artery disease and left ventricular dysfunction

J. Meluzin[1], J. Èerný[2], L. Groch[1], M. Frélich[2], F. Stìtka[2], R. Panovský[1]. [1]*St. Anna Hospital, 1st Internal Dept., Brno, Czech Republic;* [2]*Centre of Cardiovascular Surgery, Brno, Czech Republic*

The aim of this study was to assess the prognostic value of the amount of dysfunctional but viable myocardium in revascularized patients with chronic coronary artery disease (CAD) and left ventricular (LV) dysfunction.
Methods: Four hundred and thirty-one consecutive patients with chronic CAD and LV ejection fraction of 40% or less underwent low-dose dobutamine echocardiography for viability assessment. To quantify the amount of dysfunctional but viable myocardium, wall motion was scored using a 16-segment model. Two hundred and twenty patients were revascularized and followed up for a mean period of 33 ± 23 months (range, 0 to 86) for cardiac-related death and hospitalization for heart failure.
Results: Receiver operating characteristic curve analysis identified 6 dysfunctional but viable segments as the optimal cutoff value for discriminating patients with and without risk of cardiac events. Thirty-eight patients exhibited a large amount of dysfunctional but viable myocardium (6 segments or more, group A), 103 patients had 2-5 dysfunctional but viable segments (group B), and 79 patients were found to have dysfunctional myocardium irreversibly damaged (group C). Similar baseline LV ejection fractions of 36 ± 4%, 34 ± 5%, 35 ± 5% in groups A, B, and C increased to 46 ± 6% ($p < 0.01$ vs baseline and vs groups B and C), to 39 ± 5% ($p < 0.01$ vs baseline and group C), and to 36 ± 7% ($p < 0.01$ vs baseline), respectively, after revascularization. The greatest functional improvement after revascularization in group A patients was accompanied by a lower frequency of cardiac events during follow-up (1 vs 27 in group B, $p < 0.01$, and vs 18 in group C, $p < 0.01$) and by a better cardiac event-free survival according to Kaplan-Meier survival analysis ($p < 0.01$ vs groups B and C, respectively).
Conclusion: In revascularized patients with CAD and moderate-to-severe LV dysfunction, the presence of 6 or more dysfunctional but viable myocardial segments identifies patients with the best prognosis.

P1145 Preconditioning alters mitochondrial transition pore opening in the rabbit heart

L. Argaud, O. Gateau-Roesch, L. Gomez, J. Loufouat, M. Ovize. *hôpital Cardiologique, Unité 81, Lyon, France*

Mitochondria permeability transition (MPT) seems to be a pivotal event in both necrosis and apoptotis. Recent studies suggest that preconditioning, that has antinecrotic and antiapoptotic effects, may protect the myocardium through modulation of mitochondrial metabolism. The aim of the present study was to determine whether preconditioning might influence permeability transition pore opening. NZW rabbits underwent either no intervention (sham, n=7) or 10 min. of ischemia and 5 min. of reperfusion. Before ischemia/reperfusion, rabbits underwent either no intervention (control, n=8) or 5 min.ischemia/5 min. reperfusion (PC, n=6). The area at risk of these hearts were rapidly harvested at the end of this protocol. Mitochondria were isolated using differential centrifugation and suspended in an isolation buffer. Integrity of the mitochondria was checked using electronic microscopy. Mitochondrial Ca^{2+} uptake and release was measured as a change in the free Ca^{2+} concentration within the suspension using a calibrated Ca^{2+} - selective minielectrode. Pore opening was defined as the massive released of Ca^{2+} by mitochondria in the suspension following Ca^{2+} overload. Specifically, we measured the total Ca^{2+} load necessary to open the pore and time to pore opening. Data are expressed as % of sham. *$p<0.05$ vs control, *$p<0.05$ vs sham (table).

	sham	control	preconditioned
total Ca^{2+} load (%)	100	67±9 †	79±10 †*
time to pore opening (%)	100	69±8 †	77±12 †*

In the control group, both total Ca^{2+} load and time to pore opening were significantly reduced versus sham. Interestingly, preconditioned mitochondria needed a higher Ca^{2+} load to open the permeability transition pore and displayed a delayed pore opening when compared to controls. These data suggest that preconditioning may modulate mitochondrial transition pore opening in the rabbit heart.

P1146 Chronic hypoxic preconditioning modulates nitric oxide synthase expression and improves post-ischaemic recovery in isolated working rat hearts

P. Di Napoli[1], A.A. Taccardi[2], A. Grilli[3], M.A. De Lutiis[3], M. Felaco[3], A. Barsotti[4], R. De Caterina[2]. [1]*Casa di Cura Villa Pini D'Abruzzo, Dept. Cardiology, Chieti, Italy;* [2]*Lab. Experimental Cardiology, Dept. Clinical Science and Bioimaging, Chieti, Italy;* [3]*Dep. of Biomorphology, Chieti, Italy;* [4]*Dep. of Internal Medicine, Genoa, Italy*

Background: several studies reported that chronic hypoxia may induce a preconditioning against ischemia in the heart. The mechanism of chronic hypoxic preconditioning is unknown; it appears to be different from that of classic ischemic preconditioning. The chronic hypoxic preconditioning involves the transcription of mRNA and subsequent synthesis of certain protective proteins, including antioxidant proteins. We tested the hypothesis that the cardioprotection exerts by chronic exposure to hypoxia is associated with an increase in antioxidant enzyme activity induced by the initial oxidative stress. Methods: Wistar rat hearts were used for experimental procedure, and divided into two groups: A) Normoxic; B) Hypoxic (maintained in a chamber filled with 10% oxygen for 2 weeks). Haemodynamic parameters (coronary and aortic flows, heart rate, aortic pressure, minute work and coronary resistances), heart weight changes, creatinekinase (CK) release in coronary effluent and microvascular permeability (FITC-albumin extravasation) were evaluated. In addition, endothelial and inducible nitric oxide synthase (eNOS and iNOS) gene expressions were estimated by rt-PCR, and eNOS and iNOS protein levels were detected by Western blot analysis. SOD activity was evaluated by spectrophotometric method. Results: in normoxic hearts a significant functional damage, necrosis enzyme release and ultrastructural damage were detected. Hypoxic hearts showed significantly reduced I/R damage (decreased enzyme release and reduction of post-ischemic myocardial edema and ultrastructural alterations) compared to A group. The e-NOS mRNA and protein levels were significantly higher in groups B, while i-NOS mRNA and protein levels were less expressed respect control group. SOD activity was higher in hypoxic hearts (basal: A: 37 U/mg ± 3, B: 40 U/mg ± 4; after I/R A: 39 U/mg ± 5, B: 50 U/mg ± 6, $P<0.02$ vs basal and A). Conclusions: our data suggest that the chronic exposure to hypoxia preserves e-NOS gene expression, reduces i-NOS postischemic overexpression and increases SOD activity; these effects, able to reduce cellular oxidative stress, may be responsible for the observed cardioprotection against ischemia-reperfusion injury.

P1147 Dobutamine-induced contractile reserve in stunned, hibernating, and scarred myocardium in patients with ischaemic cardiomyopathy

A.F.L. Schinkel, J.J. Bax, E.C. Vourvouri, M.A. Bountioukos, M. Kertai, F.B. Sozzi, J.R.T.C. Roelandt, D. Poldermans. *Erasmus Medical Center Rotterdam, Cardiology Dept., Rotterdam, Netherlands*

Aim: Due to chronic exhaustion of cardiomyocytes and damage of the contractile apparatus, contractile reserve may be observed less frequent in hibernating than in stunned myocardium. The aim of this study was to assess the presence of contractile reserve in response to dobutamine infusion in a large group of patients with stunned and hibernating myocardium.
Methods: A total of 198 consecutive patients with ischemic cardiomyopathy (LVEF<40%), underwent F18-fluorodeoxyglucose SPECT imaging to assess myocardial perfusion and glucose metabolism. Contractile reserve was evaluated by dobutamine stress echocardiography. Dysfunctional segments (identified by resting echocardiography) were subsequently evaluated for viability. Dysfunctional segments with a normal perfusion were considered stunned myocardium. Dysfunctional segments with a perfusion defect and a relatively increased FDG uptake were considered hibernating. Dysfunctional segments with concordantly reduced Tc-99m-tetrofosmin and FDG uptake were considered scar. Subsequently, these segments were divided into nontransmural scars (tracer activities of >50%) and transmural scars (tracer activities <50%)
Results: Dobutamine-induced contractile reserve was more frequently found in stunned than in hibernating myocardium (61% versus 51%, respectively, $p<0.01$). Only 14% of the scarred segments improved in wall motion during dobutamine infusion, this was considerably less often than the contractile reserve seen in stunned or hibernating myocardium ($p<0.001$). Moreover, nontransmural scar more often exhibited contractile reserve than transmural scar tissue
Conclusion: The progressive reduction of contractile reserve in stunned, hibernating, and scar tissue, supports the hypothesis that stunning, hibernation, and scar are not circumscript pathophysiological entities but represent gradual ultrastructural damage on the myocyte level.

P1148 Oral nicorandil recaptures the waned protection of preconditioning in vivo

E.K. Iliodromitis, E. Bofilis, A. Zoga, I. Steliou, R. Vrettou, P. Cokkinos, D.T.H. Kremastinos. *Onassis Cardiac Surgery Center, B' Cardiology, Athens, Greece*

Protection from preconditioning (PC) wanes and is eventually lost when multiple bouts of short ischemia (isc) or a prolonged reperfusion (rep) interval preceeds the following sustained isc. The activation of mitochondrial KATP channels plays a pivotal role in the intracellular signaling of PC. We tested whether the specific KATP channel opener nicorandil (nic) preserves the given protection from PC in conditions where this benefit decays and is lost.
Methods: Eight groups of male rabbits (n=6-7/group) were divided in 2 equal series of experiments: one series without (-) and one with (+) oral nic treatment. Nic was given for five consecutive days in a dose of 5 mg/kg/d, and the last dose was given a few hours before the isc. All the animals were anesthetized and then subjected to 30 min regional myocardial isc and 2 hours rep with one of the following interventions before the sustained isc: control groups C to no intervention; 3PC groups to 3 cycles of 5 min isc/10 min rep; 8PC groups to 8 cycles of 5 min isc/10 min rep and 3PC90 groups to the same interventions as the 3PC groups but with a prolonged (90 min) intervening rep interval before the sustained isc. The infarcted (I) and the risk areas (R) were defined with TTC staining and Zn-Cd fluorescent particles and their ratio was expressed in percent (%I/R).
Results: The infarct size in %I/R is shown in the table.

	Group C	Group 3PC	Group 8PC	Group 3PC90
Nic(-) series	41.5±4.7	10.3±3.4	47.7±8.8	37.3±6.0
Nic(+) series	43.9±7.1	12.2±3.9	13.0±2.6*	14.2±2.4*

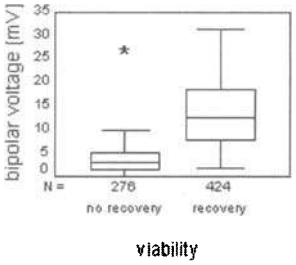
* $P<0.01$ vs respective groups of Nic(-) series.

Conclusion: Nic recaptures the waned protection of PC, both after repetitive bouts of short isc or after a prolonged rep interval, preserving the initially obtained benefit. Nic, by itself is not sufficient to initiate PC in vivo.

P1149 Direct epicardial mapping predicts the recovery of chronically ischaemic dysfunctional myocardium

C. Vahlhaus[1], H.J. Bruns[1], J. Stypmann[1], F. Janssen[1], D. Hammel[2], H.H. Scheld[2], G. Breithardt[1], T. Wichter[1]. *[1]University of Muenster, Dep. of Cardiology, Muenster, Germany; [2]University of Muenster, Dep. of Cardiovascular Surgery, Muenster, Germany*

Background: The preoperative assessment of myocardial viability is crucial in the planning of revascularization procedures in patients with coronary artery disease (CAD). Therefore, this study investigated the value of direct bipolar epicardial mapping immediately before CABG in the differentiation of viable from non-viable myocardium.
Methods and Results: In 34 patients with CAD a maximum of 102 bipolar epicardial electrograms per patient (n=3,468 electrogramms) were recorded intraoperatively simultaneously with a ventricular jacket array. In accordande to the position of each electrode segmental myocardial function (echocardiography) was assessed before and 3 months after CABG using a wall motion score. Only electrodes with good myocardial contact (n=1,813, 52±14 per patient) were considered. Based on the echocardiographic findings at baseline and following CABG segments preoperatively dysfunctional segments (n=700) were classified as viable (improvement of at least 20%, n=424) or non-viable (no improvement, n=276). Bipolar voltage was significantly lower in non-viable when compared to viable myocardium (Fig. 1: *: $P<0.001$, ANOVA) ROC-curve-analysis for bipolar voltage to discriminate between viable and non-viable myocardium revealed a sensitivity of 83% with a specificity of 83% and an area under the ROC-curve of 0.92 at a cut-off value of 5.9 mV.



Conclusion: Viable myocardium can correctly be differentiated from non-viable myocardium by direct epicardial mapping. Based on these findings in future, viability myocardium may be detectable by body surface mapping techniques using inverse solutions.

P1150 Dynamic and low-dose dobutamine stress echocardiography in the assessment of late doxorubicin-induced cardiotoxicity

L. Elbl[1], H. Hrstkova[2], V. Chaloupka[3], J. Novotny[4]. *[1]Faculty Hospital, Cardiology, Brno, Czech Republic; [2]Faculty Hospital, Dept. of Pediatrics, Brno, Czech Republic; [3]University Hospital, Cardiopulmonary Testing, Brno, Czech Republic; [4]Masaryk University, Dept. of Physical Education, Brno, Czech Republic*

Background: Late cardiac toxicity of doxorubicin has been a serious side effect of the anticancer treatment. The development of anthracycline cardiomyopathy late after successful completion of chemotherapy can substantially worsen the perspective of these patients.
Aim of study: The aim of present study was to assess the value of low-dose dobutamine stress test and dynamic stress echocardiography in the detection of early changes of LV function in asymptomatic survivors treated for childhood cancer.
Methods: Dobutamine was administered four minutes in two periods: 5 - 10 ug/kg/min and echocardiographic examination was performed before and at the top. We have calculated parameters of LV systolic function: EF, FS, mVcfc, endsystolic wall stress (ESS); global function: MPI (Tei index); diastolic function: E/A ratio, DT and IRT. Ejection fraction was measured before and immediately after symptom-limited dynamic stress echocardiography.
Patients: All patients completed successfully chemotherapy and were in long-term remission of the disease with a good quality of life comparable to the controls. The time of follow-up was 7+3 yrs. 69 patients (15+5 yrs) underwent the dynamic stress and 36 patients (12+5 yrs) also pharmacological stress test. The mean cumulative dose of administered doxorubicin was 226+106 mg/m^2. The control group consisted of 20 volunteers (12 male, 8 female, 12+4 yrs).
Results: We have not found any changes in exercise tolerance and hemodynamic response to the dynamic stress between patients and controls. The exercise increment of EF was also similar (15+5%/14+4%, n.s.). Dobutamine has not influenced heart rate and diastolic blood pressure in any subgroup but slightly increased systolic blood pressure. The patients differed significantly in mVcfc ($p<0.05$), MPI ($p<0.02$), ESS ($p<0.04$) and IRT ($p<0.05$) at rest in the comparison to the controls. The administration of dobutamine has confirmed these differences in MPI ($p<0.001$), ESS ($p<0.05$) < and IRT ($p<0.05$). 63% of the patients revealed a pathological response of one or more variables to the dobutamine, which was not observed in the controls
Conclusions: Despite normal findings during dynamic stress echocardiography, low-dose dobutamine stress test proved to be a very sensitive method for the detection of early subclinical changes in LV function in children and adolescents after the treatment with doxorubicin. The clinical value of these changes has to be assessed during the long-term follow-up.
The study was supported by grant of Ministry of Healthy of Czech Republic 5920-3.

P1151 Improve detection of myocardial viability by rest GIK-^{99m}Tc-sestamibi comparison with Tl-201 reinjection,in post myocardial infarction patients

A. Orea[1], L. Lilia Castillo[2], J. Jual Rull[3], F. Francisco Gomez[3], V. Verónica Rebollar[4], J. Jesus Sepulveda[5], J. Joel Dorantes[4], R. Rene Narvaez[4]. [1]Inst. Nal. de Ciencias Med y N. "SZ", Cardiologia y Medicina Nuclear, Mexico, Mexico; [2]Inst. Nal. Ciencias Med. y Nut. SZ, Heart Failure Clinic, Mexico City, Mexico; [3]Inst. Nal. Ciencias Med. y Nut. SZ, Endocrinology, Mexico, Mexico; [4]Inst. Nal. de la Nutricion "S.Zubiran", Cardiology Dept., Mexico City, Mexico; [5]Inst. Nal. Ciencias Med y Nut. SZ, Medicina Nuclear, Mexico City, Mexico

The ability of Tl-201 imaging to detect potential reversibility of severe regional perfusion defects after rest injection and thallium reinjection techniques have been compared with the use of NTG- MIBI protocols achieving similar results for detecting exercise perfusion defects reversibility. GIK solutions could improves electrical and mechanical performance, preserving intracellular adenosine triphosphate concentrations and myocardium viability after acute infarction. Methods and results: forty four patients (32 men, 12 women mean age 57.33±12.84 years) with previous myocardial infarction (mean evolution 4.7±3.4 months) underwent pharmacological stress (dipiridamole), redistribution and reinjection Tl-201 imagine as well rest Tc-99m Sestamibi, after the intravenous administration of GIK (200 gr. Glucose + 30 UI regular insuline+ 40 mEq potassium cloride/500ml in continuous infusion during 3 hr.), Group A (n=14) or oral administration of 70 gr. of glucose + 40 mEq of potassium cloride taking in advantage the endogenous insulin secretion, to non-diabetic patients (Group B, = GB, N=15) and group C (GC, diabetic patients N=15).All of the 44 patients received 10 mg of sublingual isorbide previous to 25 mCi of Tc- 99m Sestamibi in different 2 days protocol. A total a 880 myocardial segments were assessed and number and severity of perfusion defects in segments involved, supplying by anterior descending (LAD), right coronary (RC) and Circumflex (Cx) arteries according to follow: score normal=0, hipoperfusion, mild= 1, moderated =2, severe =3 and the average were compared between Thallium 201 re-injection and GIK- MIBI. Involved territories number: 4.12 ± 2.60 vs 6.78 ± 2.02, p =0.005 for AD; 5.4 ± 1.46 vs6.34 ± 1.01, p =0.05 for RC and 1.60 ± 1.10 vs 2.07 ± 1.04, p= 0.05 Cx. For GIK-MIBI vs Tl-201 reinjection respectively, and defect severity: 8.4 ± 6.17 vs13.68± 5.43, p= 0.01 for LAD; 11.92 ± 5.18 vs 15.13± 4.65, p= 0.005 for RC and 2.71± 2.16 vs 4.73 ± 3.48, p= 0.003 Cx. For GIK-MIBI vs Tl-201 reinjection respectively. Conclusion: Our data suggest that GIK-MIBI protocol is a safe and easy procedure that improve the detection of perfusion reversible defects compared with Tl-reinjection getting better information about myocardial viability, with lower cost and acquisition time.

P1152 Dobutamine-response of Doppler myocardial performance index: a marker of viable myocardium and coronary artery disease

R. Rambaldi[1], N. Colombo[1], D. Castini[1], L. Massironi[1], A. Mantero[1], C. Fiorentini[2]. [1]"S Paolo" Hospital, Division of Cardiology, Milano, Italy; [2]University of Milan, Department of Biomedical Sciences, Milan, Italy

Aim: Dobutamine stress echocardiography (DSE) remains a subjective technique. Systolic and diastolic Doppler time interval assessment (Doppler myocardial performance index or MPI) during DSE may represent an objective adjunct to potentially recognize both viable and ischemic myocardium.
Methods: Fifty-five consecutive patients, mean (±SD) age 64 ± 4 years, with ischemic left ventricular dysfunction (mean ejection fraction 38 ± 6%), underwent DSE for assessment of myocardial viability and ischemia. Pulsed-wave Doppler of mitral flow and left ventricular outflow tract (ejection time) was recorded at each stage of DSE at a sweep rate of 100 mm/s. Isovolumic interval was obtained by subtracting ejection time from inter-mitral interval. MPI was calculated off-line as isovolumic interval divided by ejection time. Patients with significant arrhythmias, mitral or aortic valve disease, diastolic restrictive pattern and excessive loading reactions to DSE were excluded. Tl-rest-redistribution SPECT for myocardial viability was performed. At coronary angiography was defined significant a stenosis >70% of lumen diameter of epicardial coronaries (>50% of left main coronary artery).
Results: Resting MPI correlated to both extension and severity of resting myocardial dyssynergy (r <0.74). During DSE a cut-off <0.07 shortening of MPI at low dose (10μg/kg/min of dobutamine) predicted myocardial viability as detected by Tl-rest-redistribution: agreement 68%, kappa 0.15. At peak dose of DSE lengthening of MPI (cut-off >0.14) predicted coronary artery disease (CAD): agreement 78%, kappa 0.35. During all steps of DSE a biphasic pattern of MPI correlated to a biphasic wall motion pattern, thus allowing recognition of myocardial ischemia (r = 0.85).
Conclusions: In patients with ischemic left ventricular dysfunction, MPI calculated during DSE appears an objective and easy-to-measure marker of viable myocardium. An accurate prediction of MPI appears also for CAD and myocardial ischemia. MPI appears a promising objective adjunct during the main stages of DSE.

TREATMENT OF HYPERTENSION

P1153 Antioxidant status in essential arterial hypertension during therapy with Amlodipine

F. Franzoni, F. galetta, A. Magagna, A. Bellagotti, G. Santoro. university of pisa, internal medicine, Pisa, Italy

Background: Recent studies demonstrated that calcium-antagonist amlodipine inhibits lipid peroxidation, suggesting an intrinsic antioxidant activity of this drug, which may explain its higher efficacy in the medical practice. Aim of the present study was to evaluate with a new analytical assay the total plasmatic antioxidant activity in patients with essential hypertension treated with amlodipine.
Methods: The total plasmatic antioxidant activity as the ability to antagonise the oxidation of a-keto-g-methiolbutyric acid by both peroxyl and hydroxyl radicals (obtained through thermal decomposition of an azo-bis precursor and a modified Fenton reaction) was measured in 15 patients (9M, 6F, range 44-60 years) with essential hypertension in wash-out and after 6 weeks of treatment with 10 mg/die of amlodipine and compared with that of 15 age-sex-matched controls. The results are expressed as TOSC (Total Oxyradical Scavenging Capacity) units.
Results: At follow-up visit after 6 weeks, patients showed systolic blood pressure (148.4±9.2 vs 130.2±8.6 mmHg, p<0.001) and diastolic blood pressure (98.8±6.3 vs 82.4±5.4 mmHg, p<0.001) significantly reduced, while heart rate did not significantly differed from baseline (70.4±6.8 vs 72.6±8.9 bpm, ns). The total plasmatic antioxidant activity at baseline was significantly lower in patients with hypertension than control subjects (TOSC 25.2±7.7 vs 32.6±4.5, p<0.01); at follow-up visit, after treatment with amlodipine, patients showed a significant improvement of scavenging capacity (TOSC 33.8±5.2 vs 25.2±7.7, p<0.001), while controls did not modify their antioxidant efficiency (TOSC 32.6±4.5 vs 31.9±4.2, ns).
Conclusion: The results of this study confirms an intrinsic antioxidant activity of amlodipine. We may hypothesise that, for the combined anti-hydroxyl and anti-peroxyl activity, amlodipine seems to be useful in hypertension because it decreases oxidative stress, and normalize of pressure values.

P1154 Differential effect of antihypertensive drugs on pulse pressure

E. Karpanou[1], G. Vyssoulis[2], D. Daskalova[1], D.V. Cokkinos[1], P. Toutouzas[2]. [1]Onassis Cardiac Surgery Center, Cardiology, Athens, Greece; [2]University of Athens, Athens, Greece

Aim: Pulse pressure (PP) is emerging as a major predictor of cardiac risk. The results of antihypertensive (AH) treatment have mostly included systolic and diastolic blood pressure changes (SBP, DBP) but not PP. This paper explores PP changes in a large cohort of hypertensive patients.
Methods: We examined 10185 consecutive patients, 5395 men and 4790 women 56±13 years old, with uncomplicated essential hypertension, after a 15-day wash-out period and after 6 months of antihypertensive monotherapy. All patients included in the final cohort had normalized their blood pressure. % SBP, DBP and PP changes were calculated and compared.
Results: PP was decreased least with diuretics and most with angiotensin II receptor antagonists (AIIRA), followed by Ca-antagonists and ACEI (p< 0.0001 as compared to diuretics, α-blockers, β-blockers). These differences were accounted by a greater decrease of SBP with those 3 drug families (p<0.0001) (table).

Changes in %ΔPP, %SBP,%DBP

Rx	n	%Difference PP	%SBP	%DBP
Diuretics	560	-13±22	-18±8	-22±8
a-blockers	454	-23±22	-21±9	-20±8
b-blokers	2190	-26±25	-23±9	-22±7
Ca antagonists	3223	-34±27	-27±11	-23±8
ACEI	2260	-30±24	-25±9	-22±7
AIIRA	1498	-45±27	-31±10	-24±7

Conclusion: Among AH drugs used for monotherapy, AIIRA, ACEI and Ca-antagonists decrease PP most. Since PP has adverse prognostic implications, these differences may be of practical value.

P1155 Beta blocker therapy has favorable effects on serum homocyteine levels

I.L.Y.A.S. Atar, M. Korkmaz, S. Demircan, H. Muderrisoglu, A. Sonat, E. Tayfun, A. Yildirir, B. Ozin. *Baskent Universitesi Hastanesi, Cardiology, ankara, Turkey*

Background: It has been shown that serum levels of homocysteine is elevated in hypertensive patients. In one report of hypertensives, studying the relationship with high homocysteine levels and atherothrombosis, it was observed that serum homocystein levels were lower in patients on beta blockers. Also in neuron astrocyte cultures, beta adrenergic stimulation caused homocyteinic acid secretion, and this was blocked by concominant use of atenolol. These data led us to investigate if beta-blockers has an homocysteine lowering effect. We also tested if the diuretic spironolactone with anti-aldesterone properties also has this effect or not.
Methods: To investigate this hypothesis we enrolled newly diagnosed 65 hypertensive patients who had not used any medication. Patients were requried to have no medical problems apart from essential hypertension and have normal serum vitamin B12 and folat levels. Patients were randomized to either spironolactone 50 mg/day or metoprolol 100 mg/day. No other medications were allowed during the 5 month follow-up. If their blood pressures were not normalized (< 140/90 mmHg) doses of both drugs were doubled. Serum biochemistry and homocystein levels were investigated at baseline, 1 month and 5 months after the commencement of therapy.
Results: There were 41 patients (17 men and 24 women; mean age, 49.4±9.7 years) in metoprolol group and 24 (5 men and 19 women; mean age, 48.8±6.5 years) in spironolactone group. Drug doses had to be increased in 14 (34%) individuals in the metoprolol group, and in 10 (42%) patients in the spironolactone group ($p>0.05$). In patients receiving metoprolol serum homocystein levels decreased in the 1st month and this was more pronounced in the 5th month (from 13.5 ± 4.4 to 12.4 ± 4.0 to 11.9 ± 2.5 μmol/L, $p = 0.011$). In spironolactone group there was not a significant change from the baseline both on the 1st and 5th months (from 13.6 ± 8.3 to 13.1 ± 5.4 to 13.2 ± 5.0 μmol/L, $p> 0.05$).
Conclusions: The data suggest that the selective BB metoprolol decreases plasma homocysteine levels in hypertensive patients, whereas spironolactone does not have this effect. This preliminary observation however needs to be tested in larger trials.®

P1156 Intravenous enalaprilat in hypertensive emergencies complicated with left ventricular failure

O. Dyadyk, A. Bagriy, I. Tsiba, K. Zhukov, M. Khomenko, Y. Galaeva, L. Kholopov. *DSMU, FPO department, Donetsk, Ukraine*

Little and controversial information is available concerning the use of intravenous (i.v.) enalaprilat in hypertensive emergencies.
The purpose of the study was to detect the safety and efficacy of enalaprilat in treatment of hypertensive emergencies with left ventricular (LV) failure.
46 patients with hypertensive crisis who had clinical signs of LV failure and pulmonary edema (35F:11M, mean age 53 yrs) were recruited. Among them 65.2% had chronic coronary artery disease, 13.0% had dilated cardiomyopathy. Initial mean systolic blood pressure (BP) levels were 234 mmHg, diastolic BP levels were 146 mmHg. Studied patients were randomly divided into group A (n=23, who received nitroglycerine i.v. + furosemide i.v.) and group B (n=23, who received enalaprilat i.v. + furosemide i.v.). In some cases due to partial inefficacy of basic antihypertensive treatment morphine and/or trimetaphan i.v. were also used. BP target in all the groups was typically 10-15% decrease of initial BP level; then we usually started oral medications.
Results: In A group during 6 hours after admission target BP was achieved in 82.6% of patients, although in 21.7% patients there was more substantial then desirable decrease of BP (BP failling). In B group during this period target BP was achieved in 86.9%, and only 4.3% of patients demonstrated nondesirable decrease of BP. There were no substantial differences between groups in the mentioned above parameters as well as in post-crisis follow-up.
Conclusion: Enalaprilat i.v. represents safe and effective medication in treatment of hypertensive emergencies complicated with LV failure.

P1157 Calcium channel activity as a predictor of the therapeutic effictiency of amlodipine in the treatment of essential hypertension

A. Dzumagulova, A.G. Polupanov, A.A. Aldashev. *National Centre of Cardiology & Intern, Arterial Hypertension, Bishkek, Kyrgyzstan*

The therapeutic effectiveness of amlodipine was studied in 25 patients with essential hypertension (EH) taking into account calcium channel activity in platelets. Methods of 24-hour blood pressure (BP) monitoring, two-dimension echocardiography were used, and basal and induced Ca^{2+} levels in platelets were determined using a fluorescent probe Fura – 2. As an inducer of the entry of calcium into platelets we used adenosine diphosphate (ADP) in a concentration of 10 mkM. Treatment with amlodipine (Norvask of the firm "Pfizer", USA) lasted 6 months, the daily dose was 5-10 mg. Depending on the effectiveness of the treatment all the EH patients were divided into 2 groups. The first group consisted of 18 patients in whom during long-term treatment with amlodipine average daily levels of mean BP decreased by 10 mm Hg and more. The second group included 7 patients in whom reduction of average daily levels of mean BP by the end of treatment was less than 10 mm Hg.
When calcium channel activity in the analyzed groups of patients was studied before treatment we found significant differences in the induction of Ca^{2+} entry into the cell in response to ADP. Thus, in group 1 EH patients the maximal increase of intracellular Ca^{2+} during stimulation by ADP was consistently greater than in group 2 patients (404,1±10,1 nM versus 238,5±16,6 nM, respectively), indicating calcium channel hyperactivity in these patients. Six-month therapy with amlodipine in group 1 EH patients led to a considerably lesser increase in the concentration of ADP-induced Ca^{2+} in platelets, indicating effective blockade of Ca^{2+} entry into the cells through ATP/ADP-dependent calcium channels by amlodipine. At the same time, in group 2 EH patients course treatment with this agent was not accompanied by a consistently lesser increase in the concentration of intracellular Ca^{2+} in platelets in response to stimulation by ADP. Basal concentration of intracellular Ca^{2+} remained unchanged in both groups after treatment with amlodipine.
Thus, administration of calcium antagonists in patients with calcium channel hyperactivity ensures effective blockade of Ca^{2+} entry into the cells, and this is accompanied by a stable hypotensive effect.

P1158 A population-based study of compliance and persistency with selected agents used in hypertension management

F. Frech, Jenifer Wogen, Charles A. Kreilick, Richard C. Livornese. *Novartis Pharmaceuticals Corporation, East Hanover, United States of America*

Purpose: To conduct a head to head comparison of persistency and compliance associated with representative agents used in the pharmacologic management of hypertension including lisinopril (Zestril), valsartan (Diovan), amlodipine (Norvasc) in a usual care setting.
Methods: This retrospective database study utilized patients continuously benefit-eligible from the Merck-Medco pharmacy claims database from 8/1997 through 7/2000 (N=14.6M). Patients who received an initial (no prescription filled within class during prior 12 months) prescription for lisinopril, valsartan, or amlodipine between 8/1998 through 7/1999 (N=142,945) were included and followed for 12 months. Compliance was assessed using the medication possession ratio (MPR), or the percentage of time a patient had drug available over a 1-year time period. Patients were considered to remain "on therapy" until a therapy gap of >60 days occurred. To control for differences in overall baseline chronic disease burden, a Chronic Disease Score (CDS), which uses drug markers to identify chronic con-ditions, was used to classify the cohort as mild, moderate, or severe.
Results: Mean age of the study cohort was 63.1 years and 53% were female. Over half (51%) of the cohort used amlodipine as initial therapy, 21% valsartan, and 28% lisinopril. More valsartan patients remained persistent on therapy at 12-months post-therapy initiation (63%) compared to amlodipine (53%) and lisinopril (50%) ($p<.0001$, both comparisons). Mean duration of therapy was 266 days for valsartan patients versus 246 days for amlodipine and 240 days for lisinopril ($p<.0001$, both comparisons). Compliance was also greatest for valsartan patients, reflecting a mean MPR of 76% vs. 67% for amlodipine, 65% for lisinopril ($p<.0001$, both comparisons). While a slightly greater proportion of valsartan patients had a lower CDS (31% classified as severe, vs. 35% for both lisinopril and amlodipine), compliance and duration of therapy remained greater for valsartan patients across all CDS strata. Valsartan patients classified as severe via CDS had a mean duration of therapy of 266 days, compared to 245 for amlodipine and 237 for lisinopril ($p<.0001$, both comparisons). These patients also had a mean MPR of 75% as compared to 67% and 64% for amlodipine and lisinopril patients, respectively ($p<.0001$, both comparisons).
Conclusions: These preliminary results suggest that patients receiving valsartan in a typical managed care setting for the treatment of hypertension may be more adherent to therapy. These differences appear to be independent of baseline CDS.

P1159 Discontinuation, switching and adding among antihypertensive drug classes

D. Gause, F.H. Frech, K.K. Yokoyama. *Novartis Pharmaceuticals Corporation, Health Economics & Outcomes Research, East Hanover, United States of America*

Medical and pharmacy claims from a database containing 2.5 million covered members were used to estimate discontinuation, switching, and adding rates for calcium channel blockers (CCB), angiotensin converting enzyme inhibitors (ACEI), angiotensin II receptor blockers (ARB), and beta-blockers (BB).
Continuously enrolled members (1/1/97 to 8/30/99) with at least one ICD-9 diagnosis code for hypertension, no claims for antihpertensive drug in 1997, and at least one claim for a CCB, ACEI, ARB and BB initially filled after 1997 were followed until end of study period (8/30/99). For all drug groups, discontinuation rates were estimated using non-parametric survival analysis. Switching patterns were assessed for patients who discontinued therapy and addition patterns were assessed for patients who did not discontinued therapy.
Patients identified in each drug classes were as follows: CCB 7,315; ACEI 6,882; ARB 2,018 and BB 5,829. Mean age of patients was similar between the drug classes (range 57-61). Most patients were females (range 52-55%) except for beta-blocker patients where 48% were females. The percentages of patients discontinuing therapy in each drug class were 51% (CCB), 50% (BB), 49% (ACEI), and 46% (ARB). Non-parametric survival estimates of time to discontinuation indicated slightly higher persistency at one year for ARB (44%) compared to ACEI and BB (42%) and CCB (40%). Almost 7% of patients who discontinued CCB switched to other antihypertensives (10.7% ACEI; 12.7% ARB and 7.7% BB).
Among patients who did not discontinue initial therapy, 25.2% of BB; 22% of CCB patients; 20.3% of ACEI patients; and 17.7% of ARB patients added another antihypertensive medication. Diuretics were the most commonly added medication for all drug groups (CCB 9.5%, ACEI 8.3%, ARB 7.3%, and BB 10.5%). In addition, ACEI therapy was added to 5.7% of CCB patients. For ACEI, ARB, and BB patients, 5-6% added CCB therapy.
In review of the drug classes, this analysis suggests that patients initiating ARB therapy have the highest persistency. Additionally, ARB has the lowest and BB has the highest rates of antihypertensive drug added to the regimen.

P1160 Angiotensin-converting enzyme inhibitor, but not beta blocker diminish the influence of gene polymorphisms of the renin-angiotensin system on blood pressure

R. Winkler[1], R. Gök[1], B. Klein[1], J. Friedrich[1], W. März[2], B.R. Winkelmann[3], J. Senges[1], G. Taubert[1]. *[1]Herzzentrum Ludwigshafen, Medizinische Klinik B, Ludwigshafen, Germany; [2]Universität Freiburg, Cardiology, Freiburg, Germany; [3]Universität Heidelberg, Medizinische Klinik, Kardiologie, Heidelberg, Germany*

Background: Several gene polymorphisms (PM) of the renin-angiotensin-aldosteron system (RAAS) and of the endothelial NO-release are associated with the incidence of arterial hypertension (HT).
Objective: Influence of PM of the RAAS [angiotensinogen (ANG Thr174Meth, ANG Meth235Thr, ACE insertion/deletion (ID)] and the endothelial NO-system [eNos glu298asp (eNos298) and eNos T-786C PM (eNOS786)] on blood pressure (BP)
Methods: Analysis of stable consecutive pts with hypertension who underwent a coronary angiography due to clinical reasons. BP was measured invasively during heart catheter procedure at steady state.
Results: 1738 pts met inclusion criteria: HT (age 65±9, male 72%, CAD 77%, previous myocardial infarction 51%, smoking 35%, diabetes 41%, hypercholesterolemia 71%, treatment: beta blocker 73%, ace inhibitor 65%). All PM were in Hardy Weinberg equlibrium. In ANG 235 and eNOS786 PM there was no association with BP.

BP in pts without beta blocker and ACE inhibitor (n=102)

PM	ACE ID	ANG 174	eNOS298
	II/ID/DD	TT/TM/MM	GG/AG/AA
BP mean, mmHG	97/102/104*	100/106/115*	103/103/92*
BP systolic, mmHG	144/151/152	147/154/170*	151/151/129*
BP diastolic, mmHG	72/74/74	72/77/88*	74/74/69*

data are median; *p<0.05 for trend (Kruskal Wallis test)

In patients treated with beta blockers, Ang174, ACE ID, Ang235 PM showed again a stepwise increase of BP with the number of mutated alleles (p<0.05 for trend). In patients treated with ACE inhibitors alone or in combination with beta blockers, an association between the determined PM were not observed.
Conclusion: (1) Consenting with literature data, polymorphisms of RAAS and endothelial NO-system are associated with blood pressure levels in stable hypertensive patients.
(2) Chronic beta blockade alone does not alter the association of the PM of the RAAS on BP, while ACE inhibitors are able to suppress the effects of the PM on BP.

P1161 Very low-dose perindopril 2mg/indapamide 0.625mg reduces left ventricular hypertrophy in hypertensive patients

N. De Luca[1], M.E Safar[2], R. Asmar[3], J.M. Mallion[4], M.F. O'Rourke[5], R. Romero[6], K.H. Rahn[7], B. Trimarco[1] on behalf of investigators and national co-ordinators. *[1]Università "Federico II", CENTRO IPERTENSIONE, Napoli, Italy; [2]Hôpital Broussais, Medecine Interne I - Dpt d'HTA, Paris, France; [3]ICV, Paris, France; [4]CHRU, service de cardiologie, Grenoble, France; [5]Saint Vincent's hospital, Darlinghurst, Australia; [6]Hospital Germans Trias y Pujol, Badalona, Spain; [7]Medizinische Universitäts, Munster, Germany*

Objective: The aim of this study is to compare the LVH regression over 12 month in hypertensive patients receiving Perindopril 2mg/Indapamide 0.625mg versus atenolol 50mg.
Methods: Ancillary, international (13 countries), double blind, randomized, controlled study with 2 parallel groups: Perindopril 2 mg/Indapamide 0.625mg combination (Per/Ind) or atenolol 50mg (ate). Out of the 471 randomised patients, 124 patients (59.7% men; age: 53.2±11.8 years; BMI: 26.9±2.9 kg/m^2) with essential systolic and diastolic or isolated systolic hypertension (160=<SBP<210mmHg and/or 95=<DBP<110mmHg) and with left ventricular hypertrophy confirmed by control echocardiography (defined by left ventricular mass index LVMI >100 g/m^2 for women, >120g/m^2 for men) are analysed. Doses could be adapted according to the BP level (1 or 2 tablets once daily).
Results: The echocardiography results (mean±sd) are summarized in the following table (PPS analyses).

Mean change (end - M0) of echo parameters

	Per/Ind (n=70)	ate (n=54)	P inter group
LVMI (g/m^2)	-11.3±15.4*	-5.3±15.1*	0.031
LVIDd (mm)	-0.9±2.1*	-0.2±1.9ns	0.017
IVSTd (mm)	-0.4±0.8*	-0.2±0.8ns	ns
PWTd (mm)	-0.6±0.8*	-0.2±0.7*	ns

p Fisher test adjusted on age sex and baseline; *p intra group <0.05; LVMI: left ventricular mass index caculated from LVM/BSA; LVIDd: diatolic left ventricular internal diameter; IVSTd: diastolic interventricular septal thickness; PWTd: diatolic posterior wall thickness

In this substudy the decrease (mean±sd mmHg) in brachial SBP, PP and DBP are respectively for Per/Ind: -22.7±14.0; -9.7±11.1; -13.0±6.9 and for ate: -17.6±18.4; -5.4±16.4; -12.2±9.8, (p=0.037; p=0.026; p=0.501). Similar results are observed in the echocardiography full analysis set (Per/Ind n=110, ate n=104): the decrease (mean±sd) in LVMI, LVIDd, IVSTd, PWTd are respectively for Per/Ind:-6.6±15.6;-0.6±2.0; -0.2±0.8;-0.3±0.8 and for ate:-2.1±14.5;-0.0±2.7;-0.1±0.8;-0.1±0.6,(p=0.032;p=0.016;p=0.869;p=0.245).
Conclusion: Very-low dose Perindopril/Indapamide combination shows a greater and significant decrease in LVH parameters than atenolol after one year of treatment.

P1162 Beneficial effects of nebivolol on the NO-pathway in essential hypertensive patients

C. Napoli[1], A. Liguori[2], F. de Nigris[3], A. Casini[4], M. Condorelli[1], L.J. Ignarro[5]. *[1]Naples, Italy; [2]Hospital of Pellegrini, Division of Cardiology, Naples, Italy; [3]UCSD, Dept of Medicine, La Jolla, United States of America; [4]Menarini Group, Central Medical Direction, Florence, Italy; [5]UCLA, Molecula Pharmacology, Los Angeles, United States of America*

A number of experimental studies indicate that nebivolol interferes with the nitric oxide (NO) pathway. Essential hypertension (EH) is well known to be associated with endothelial dysfunction, a marker of future vascular atherosclerosis. The present study addresses the comparative effects of vasodilating beta-blocking agent nebivolol and atenolol on basal NO production during long-term treatment in essential hypertensive patients. 53 patients with EH were randomized to nebivolol 5 mg/day (n=25) and atenolol 100 mg/day (n=28) and treated for 24 weeks. The mean patients age was 55±8 yrs. Patients had no concomitant diseases and medication. Plasma and urinary nitrate concentrations were assessed in all EH patients at baseline (38±7 nmol/ml and 0.29±5 micromol/ml, respectively). Blood pressure reduction was achieved in both treatment arms and the drug antihypertensive action did not differ significantly. In nebivolol group plasma nitrate levels were significantly increased to 52±5 nmol/ml (p< 0.05 vs hypertensive patients at baseline), while in atenolol group this increment was nonsignificant (42±6, nmol/ml; p=0.837 vs hypertensive patients at baseline). Similarly, urinary nitrate concentrations were significantly increased to 0.59±0.12 micromol/ml (p< 0.01 vs hypertensive patients at baseline), while in atenolol group this increment was nonsignificant (0.32±0.13, micromol/ml; p=0.911 vs hypertensive patients at baseline). Our data indicate that in hypertensive patients nebivolol, but not atenolol, can produce a significant effect on basal NO production. These long-term beneficial effects on the NO-pathway can retard vascular dysfunction and atherogenesis in hypertensive patients.

P1163 Eplerenone is safe and effective as add-on therapy in hypertensive patients uncontrolled with calcium channel blockers or beta blockers

W. Van Mieghem[1], V. von Behren[2], I. Balazovjech[3], B. Roniker[4], C. Lademacher[4], W. He[4], S. Krause[4] on behalf of The Study Investigators.
[1]St. Jan Ziekenhuis, Dienst Cardio, Genk, Belgium; [2]Intermed, Wiesbaden, Germany; [3]Faculty Hospital II, Internal Clinic, Bratislava, Slovakia; [4]Pharmacia Corporation, CV/Metabolic Diseases, Skokie, United States of America

In hypertensive patients who respond inadequately to monotherapy, JNC-VI recommends add-on therapy with a second drug of different MOA. This study examined whether the selective aldosterone blocker eplerenone (EPL) was safe and efficacious as add-on therapy in difficult-to-treat hypertensives uncontrolled on calcium channel blockers (CCBs) or beta-blockers (BBs).
In this 8-week, double-blind, multicenter study, 272 hypertensives whose blood pressure was not controlled with a CCB or a BB were randomized to receive 50 mg EPL once daily (uptitrating to 100 mg if required) or placebo (PBO). Study assessments included mean change from baseline in SBP/DBP, responder rates (DBP <90 mmHg or >=10 mmHg reduction from baseline DBP), AEs, and clinical laboratory values.
Within each cohort, there were no significant differences in heart rate, clinical laboratory values, and incidence of overall or specific treatment-emergent AEs between EPL and PBO. One patient in the BB plus EPL group withdrew due to a non-serious case of elevated K^+.

Efficacy at Week 8

	EPL	PBO	P-value
CCB cohort (1)	N=67	N=66	
Baseline SBP/DBP (mmHg)	154.2/98.9	157.6/99.4	
Change in SBP/DBP (mmHg	-17.2/-11.7	-10.5/-9.8	<0.001/0.101
Responder rate	71.6%	62.1%	0.204
Up-titration rate	43.3%	65.2%	
BB cohort (2)	N=69	N=66	
Baseline SBP/DBP (mmHg)	158.2/99.0	157.2/98.8	
Change in SBP/DBP (mmHg)	-19.1/-12.3	-11.0/-8.8	<0.001/0.008
Responder rate	75.4%	50%	0.002
Up-titration rate	39.1%	68.2%	

(1) Most common CCB: amlodipine (37.1% EPL, 41.8% PBO) and felodipine (20.0% EPL, 16.4% PBO).(2) Most common BB: bisoprolol (36.2% EPL, 34.8% PBO) and atenolol (29.0% EPL, 27.3% PBO).

In conclusion, addition of eplerenone further reduced blood pressure and increased responder rates in this difficult-to-treat population uncontrolled on CCBs or BBs. Aldosterone receptor blockade with eplerenone provides incremental blood pressure lowering on top of CCB or BB and is rational add-on therapy in uncontrolled hypertensive patients.

P1164 Case-control investigation into the risk factors of the undesirable effects of antihypertensive treatments in general medicine

F.A. Allaert[1], C. Causse[2]. [1]university hospital, Dpt medical evaluation, Dijon, France; [2]Laboratoires Pierre Fabre, Dept. Cardiovasculaire, Castres, France

Objectives: to look into the existence of specific clinical profiles in patients presenting with undesirable effects during antihypertensive treatments.
Methods and Material: Epidemiological case-control investigation. The cases were patients with treated hypertension presenting with any kind of undesirable effect. The controls were the first two patients with treated hypertension consulting a doctor during the same period and not presenting with any undesirable effect.
Results: 3031 patients aged 63 ± 11 years took part in the investigation, among whom 37.9% (n=1149) presented with a secondary effect which justified a modification in their antihypertensive treatment. The controls and cases were comparable in terms of age, sex, length of time they had suffered from hypertension, tension parameters, the existence of a cardiovascular history. They differed in terms of the conditions of discovery (5.9% vs 8.4% for occupational medicine: $p<0.05$), the frequency of occurrence of undesirable effects from antihypertensive medication (8.2% vs 19.0%: $p<0.001$) or from other medication (14.5% vs 19.8%: $p<0.001$), the existence of a known allergic condition (4.5% vs 8.6%: $p<0.001$), a history of acute allergic reactions (8.9% vs 12.0%: $p<0.01$), the existence of a condition which could induce allergy (7.5% vs 10.4%: $p<0.01$); the extent of treatment compliance (80.8% vs 76.2%: $p<0.05$) and the number of medication (more than 5: 9.5 vs 15.4%: $p<0.001$). All of these factors, significant in univariate analysis, were introduced into a multivariate model of logistic regression. Its results showed a common profile among patients presenting with undesirable effects during antihypertensive treatment characterized by the existence of a history of undesirable effects from antihypertension medication ($p<0.001$) or others ($p<0.01$), of chronic allergies ($p<0.01$), a large number of medication ($p<0.01$), and the lack of compliance of the patient with his/her treatment ($p<0.01$).
Conclusion: An undesirable effect occurs within a framework of three possible dimensions, a chemical dimension, linked with the number of possible interactions between medication, an allergic dimension, and a psychological dimension, influenced by the conditions of discovery of the hypertension and the compliance of the patient with his or her treatment. A predictive score is now being studied on the basis of these results.

P1165 Efficacy and safety of sildenafil citrate in men with erectile dysfunction who are taking multiple antihypertensives

S. Taylor[1], D.B. Glasser[2], N. Sherman[2]. [1]Chorley Clinical Research Centre, Chorley, United Kingdom; [2]Pfizer Inc, New York, United States of America

Erectile dysfunction (ED) is common in men taking antihypertensive agents (anti-HTNs). We evaluated the efficacy and safety of sildenafil citrate in men with ED taking >=2 anti-HTNs. 568 men with ED taking >=2 anti-HTNs were randomized to sildenafil (50 mg, flexible) or placebo for a 6-week, double-blind (DB) phase followed by a 6-week, open-label (OL) extension. Primary efficacy variables were questions 3 (Q3; achieve erection) and 4 (Q4; maintain erection) of the International Index of Erectile Function. Patients completing DB were eligible for OL. Adverse events (AEs) and causality were recorded. 562 men (mean age 59.3 years) received study drug. The mean duration of ED was 4.5 years; the mean duration of HTN was 11.7 years. For analytic purposes, patients were divided into men taking 2 anti-HTNs (n=324) and those taking 3+ anti-HTNs (n=235). Results were similar in men taking 2 or 3+ anti-HTNs. At week 6, scores on Q3 and Q4 improved significantly from baseline in sildenafil- versus placebo-treated patients. 62% of intercourse attempts were successful in the sildenafil group vs 26% in the placebo group. After OL, >80% of patients who received DB sildenafil or placebo reported improved erections and intercourse. Intercourse success rates in the 2 groups were identical (71%). At week 6, 40% of sildenafil- and 26% of placebo-treated patients experienced AEs; 3 (1.9%) sildenafil- and 2 (1.4%) placebo-treated patients discontinued due to treatment-related AEs. Two other patients (0.7%) from each group had serious adverse events (SAEs); none were treatment-related. AEs associated with changes in blood pressure were (sildenafil vs placebo): hypotension (0.7% vs 0%), postural hypotension (0.4% vs 0.4%), and dizziness (2% vs 2%). During OL, 3 DB placebo patients (1.9%) discontinued due to treatment-related AEs. There were no SAEs related to changes in blood pressure. These results suggest that sildenafil is an effective and well-tolerated treatment for ED in men taking 2 or more anti-HTNs.

P1166 Selective aldosterone blockade with eplerenone regresses ventricular mass in patients with left ventricular hypertrophy

R. Willenbrock[1], B. Pitt[2], H. Darius[3], F. Zannad[4], V.B. Alonso[5], W. He[6], D. Burns[6], B. Roniker[6] on behalf of The Study Investigators.
[1]Franz-Volhard-Klinik, Clinical & Experimental Heart Failure, Berlin, Germany; [2]Univ. of Michigan Health System, Internal Medicine, Ann Arbor, United States of America; [3]Klinikum der Joh Gutenberg Universität, Medizinische Klinik und Poliklinik, Mainz, Germany; [4]Université Henri Poincaré, Départ. des maladies CardioVasculaires, Nancy, France; [5]Hospital Ramón y Cajal, Servicio Cardiología. Ecocardiología, Madrid, Spain; [6]Pharmacia Corporation, CV/Metabolic Diseases, Skokie, United States of America

High levels of aldosterone correlate with left ventricular hypertrophy (LVH) and mediate an inflammatory response in animals that may result in myocardial fibrosis. This study examined whether aldosterone antagonism with eplerenone (EPL), the selective aldosterone blocker, reduced LV mass compared to enalapril (ENAL) and EPL/ENAL combination therapy.
In this 9-month, double-blind, forced-titration study, patients with LVH and hypertension (DBP ≥90 mmHg and <114 mmHg; SBP >140 mmHg and ≤200 mmHg) were randomized to receive once-daily EPL 200 mg, enalapril (ENAL) 40 mg, or EPL 200 mg/ENAL 10 mg (doses reached by forced titration over 4 weeks). The primary endpoint was change in LV mass (LVM) as assessed by MRI. To limit hypertension as a confounding variable, HCTZ 12.5, HCTZ 25 mg, or amlodipine (AML) 10 mg were added at Week 8 if BP remained uncontrolled. SBP/DBP, urinary albumin:creatinine ratio (UACR), and safety were also assessed at Month 9 (see table, p. 212).
Add-on HCTZ or AML was required by 30%, 59%, and 20% of patients receiving EPL, ENAL and EPL/ENAL, respectively. A significantly greater proportion of ENAL patients experienced coughing than EPL patients (14.1% vs 3.1%, P=0.033).
Selective aldosterone blockade with eplerenone was as effective as enalapril in regressing LVH. The combination of eplerenone and enalapril conferred cardiovascular benefits additive with an ACE inhibitor.

Abstract P1166 – Table: Change in LVM, BP, and UACR

	EPL (N=50)	ENAL (N=54)	EPL+ENAL (N=49)
LVM			
Mean baseline LVM [g (SD)]	189.9 (53.9)	188.5 (51.7)	192.8 (61.4)
Adjusted mean change [g (SE)]	-14.5 (3.36)	-19.7 (3.20)	-27.2 (3.39)
P-values vs ENAL	0.258		
P-values vs EPL/ENAL	0.007	0.107	
SBP/DBP			
Mean baseline SBP/DBP [mmHg]	163.2/97.4	163.7/98.9	162.9/98.5
Adjusted mean change [mmHg (SE)]	-23.8/-11.9(1.78/1.02)	-24.7/-13.4(1.69/0.97)	-28.7/-14.4(1.79/1.03)
P-values vs ENAL	0.718/0.269		
P-values vs EPL/ENAL	0.048/0.076	0.098/0.480	
Change in UACR from baseline (%)*	-24.9%	-37.4%	-52.6%
P-values vs EPL/ENAL	0.001	0.038	

*All treatments significantly reduced UACR from baseline

P1167 Effects of adding an aldosterone receptor antagonist to an angiotensin converting enzyme inhibitor in patients with hypertension

R. Rossi, F. Bursi, S. Bonatti, G. Fantini, M.G. Modena. *Policlinico, Internal Medicin. Institute of cardiol, Modena, Italy*

Background: Hypertensive patients (pts) have been shown to have abnormal endothelium-dependent vasodilatation (EDVD). Considering that either angiotensin II or aldosterone has been implicated in determining endothelial dysfunction in experimental hypertension, we hypothesised a positive interaction between aldosterone receptor antagonist (ARA) and angiotensin converting enzyme inhibitor (ACE-I) in improving endothelial function.
Methods: We examined 52 pts [57.6% females (n=30); age 62 ± 8] with mild-moderate hypertension. Pts with diabetes mellitus, hyperlipidemia, smoking habits were excluded. Among the enrolled pts, 25 (48%) (group 1) were randomly assigned to the treatment with an ACE-I (lisinipril 20 mg/die), and 27 (52%) (group 2) to a combined treatment with lisinopril (20 mg/die) plus low-dose of an ARA (potassium kanrenoate, 50 mg/die). EDVD was assessed at baseline and after 6 months of treatment. It was evaluated by measuring the diameter of the brachial artery (ultrasound method) before and during reactive hyperaemia (induced after deflation of a blood pressure cuff inflated to suprasystolic pressure for 5 minutes) and was calculated from the diameters as: (reactive hyperemia - baseline)/baseline X 100%.
Results: After 6 months of treatment, we noticed a significant decrease in mean blood pressure and a significant increase in EDVD in the two groups respect to baseline. EDVD was significantly less in the lisinopril treated group (group 1) than in the lisinopril plus potassium kanrenoate treated group (group 2) (Table)

	baseline	6 months
Mean blood pressure, mmHg		
ACE-I treated group	115.3 ± 9.9	100.2 ± 9.6 *
ACE-I plus ARA treated group	115.2 ± 9.5	98.9 ± 9.3 *
intergroup comparison	p < ns	p < ns
Endothelial dependent vasodilation, %		
ACE-I treated group	6.4 ± 3.6	9.2 ± 4.1 *
ACE-i plus ARA treated group	6.5 ± 4.3	14.5 ± 5.1 **
intergroup comparison	p < ns	p < 0.01

* p < 0.01 versus group 1; ** p < 0.001 versus group 1

Conclusions: low-dose of an ARA added to an ACE-I leading to marked effects on endothelial function that were less apparent by treatment with ACE-I alone.

P1168 Effect of antihypertensive therapy on arterial distensibility in older patients

G.-A. Dan[1], A. Gonta[1], C. Stanescu[2], M. Bengus[1], E. Dinca[1], B. Igna[1].
[1] *"N.G.Lupu" Medicine Institute, Rhythmology, Bucharest, Romania;*
[2] *Colentina University Hospital, Cardiology Dept., Bucharest, Romania*

Arterial compliance decline substantially with age. In older patients (pt) the effect of antihypertensive therapy on the arterial stiffness should be taken into account. In this regard antihypertensive drugs have unequal efficacy.
The aim of this study was to assess the ability of three different antihypertensive regimens to improve arterial distensibility. There were included 85 pt, with similar basal characteristics, mean age 72±12 yrs, with mild to severe hypertension. Secondary hypertension, complicated hypertension with severe organ damage and concurrent severe illness requiring sustained medication were exclusion criteria. The pt. were randomly assigned to one of the three therapy groups: felodipine (5mg qd, group F), perindopril (4mg qd, group P) and losartan (25mg bid, group L). The dosage was increased to10mg qd in group F, 8mg qd in group P and 50mg bid in group L and/or a diuretic was added in order to achieve a target blood pressure (BP) < 140/90 mmHg. The evaluation of drug efficacy was performed monthly during the first 3 month and at the end of the follow-up period of 11±3 months (FU). BP was measured according WHO guidelines and an average of three measurements was analyzed. Aortic distensibilty (AD, 10^{-3} mmHg^{-1}) was determined at baseline and at FU. The AD was defined as the difference between end-systolic and end-diastolic aortic area divided by the product of brachial pulse pressure (PP) and end-diastolic aortic area. Aortic area was determined by echocardiography at 4 cm above aortic valves.
After the FU period the systolic BP decreased significantly in all groups (-6±14mmHg in group F, -23±17mmHg in group P, -24±16 in group L, p<0.01), without significant differences between groups. Diastolic BP also decreased significantly (-21±13mmHg in group F, -13± 9mmHg in group P and -14±10mmHg in group L) but more in group F (p<0.05). PP decreased significantly only in group P and L (p<0.01 vs. basal, p<0.05 vs. F, p:NS P vs. L). AD increased significantly in group P and L (1.1± 0.1 in group P, 1.5± 0.3 in group L, p<0.01 vs. basal, p<0.05 L vs. P) but not in group F.
Conclusion: felodipine, perindopril and losartan are equally effective antihypertensive drugs in elderly pt. However, the efficacy on the arterial wall seems to be better for perindopril and losartan. This effect could be mediated through a decrease in PP and possibly through a direct arterial wall effect for losartan.

P1169 Effects of pravastatin on blood pressure and vascular reactivity in hypercholesterolemic patients with borderline hypertension

C. Borghi, M. Veronesi, A. Dormi, E. Cosentino, E. Ambrosioni. *St. Orsola Hospital, Internal Medicine, Bologna, Italy*

Objective: Increasing data have shown that 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) possess vascular protective actions beyond their primary cholesterol-lowering effects. The present study was designed to investigate the effects of two different doses of pravastatin and a low salt diet on resting and stimulated blood pressure (BP), peripheral vascular hemodynamic and lipid profile in hypercholesterolemic patients with borderline hypertension (HC-BHT).
Design and Methods. Nineteen untreated young (age 33.5±5.5 year) HC-BHT subjects with average office BP=145/88 mmHg were studied at baseline (B), 4 weeks after a low salt diet (LS, NaCl 50-75 mEq/day) and 8 weeks after a single-blind, randomized treatment with pravastatin 20 or 40 mg/day (P). Each patient underwent the following determination: office and 24-hour ambulatory systolic and diastolic BP, forearm blood flow (FBF) and vascular resistance (FVR) by venous occlusion plethysmography, mental arithmetic (MA) and hand grip (HG) test, and serum cholesterol (T-Chol, HDL and LDL) levels.
Results: Pravastatin reduced both systolic and diastolic BP in comparison to B and LS both during day-time and night-time (average 24-hour BP: B=137/88, LS=136/88, P=131/82 mmHg; p<0.001 P vs. B, LS). The average 24-hour BP reduction was enhanced in patients treated with the higher dose of P (40 mg/day 136/87 vs. 127/78 mmHg, p<0.01; 20 mg/day 137/88 vs. 133/84 mmHg, p<0.05). Pravastatin also blunted the pressor response to MA and HG, increased FBF (B=3.4, LS=4.1, P=5.4 ml/min/100 ml; p<0.01 P vs. LS) and reduced FVR (B=29, LS=23, P=19 units; p<0.01 P vs. LS) in comparison to LS diet and again the changes were enhanced in patients treated with the higher dose. Serum cholesterol levels were reduced by P even whether the changes were only weakly and not significantly related to BP modifications observed both at rest (Delta DBP Casual/Delta T-Chol, R2=0.02, p=0.647) and in response to MA (Delta DBP MA/Delta T-Chol, R2=0.26, p=0.285) and HG (Delta DBP HG/Delta T-Chol R2=0.09, p=0.304).
Conclusions: These data suggest that statins can significantly improve BP control in patients with BHT both at rest and in response to various stressful stimulations. Moreover, BP decline was associated with an enhancement of the peripheral vasodilator capacity that could contribute to improve BP control. In particular, the effects of pravastatin seem to be dose-related and only weakly related to serum cholesterol changes suggesting a direct effect of the drug on peripheral vascular tone in patients with BHT.

P1170 Benefit of a treatment strategy based on a very low dose combination of perindopril and Indapamide in albuminuric hypertensive type 2 diabetics

S. Halimi[1], C.E. Mogensen[2], G. Viberti[3], E. Ritz[4], L. Ruilope[5], G. Jermendy[6], J. Widimsky[7] on behalf of Investigators and National Coordinators. [1]*Centre Hospitalier Universitaire, Endocrinologie-Diabétologie, Grenoble Cedex 09, France;* [2]*Aarhus Kommunehospital, Medical Department M, Aarhus, Denmark;* [3]*Guy's Hospital, Endocrinology, London, United Kingdom;* [4]*Ludolf-Krehl-Klinik, Endokrinologie u. Stoffwechsel, Heidelberg, Germany;* [5]*Hospital 12 de Octubre, Servicio de Nefrologia, Madrid, Spain;* [6]*Magloti ut.89-91, Bajcsy Zsilinsky Korhaz III Belosztaly, Budapest, Hungary;* [7]*Videnska 800, IKEM, Praha, Czech Republic*

The objective is to compare the beneficial effect of treatment based on the very low dose combination Perindopril 2mg/Indapamide 0.625mg (Per/Ind) vs Enalapril (Ena) on albuminuria excretion rate (AER) regression in hypertensive type 2 diabetics.

The design was a 12-month, randomised, double-blind, parallel group study. AER was evaluated on overnight urine collections in central laboratory. Albuminuric (20<=AER<500µg/min) hypertensive (140mmHg<=SBP<180mmHg and DBP<110mmHg) type 2 diabetics (well-controlled: HbA1c<9%) were randomised to Per/Ind or to Ena od. A dose titration by doubling the dosage in 3 steps, from Per 2/Ind 0.625mg to Per 8/Ind 2.5mg or Ena 10mg to 40mg was permitted after W12. Statistical analysis was carried out on the log transformed values using a Student's- t test after adjustment on the baseline and country, alpha=2.5%. 481 patients were randomised: 59.1±8.7 years, 61% male.

Results from 457 patients (ITT) have shown a significant higher reduction of AER in Per/Ind group -42% [-50%;-33%] compared with Ena group -27% [-37%;-16%](p=0.002).

Both treatments reduced BP. A statistical significant higher decrease in SBP(-3.01mmHg) and DBP (-1.54mmHg) was observed in the Per/Ind group. Therefore, the higher reduction in AER remained significant after adjustment on final mean BP (MBP) (p=0.007). For each quartiles of final MBP, the residual AER were always lower with the Per/Ind than with Ena: see Table 1.

Table 1: Final AER according to final MBP

Quartiles of MBP (mmHg)	<98.9	[98.9;103.8[	[103.8;110.9[	>=110.9
Per/Ind (N=227)*	n=68	n=57	n=54	n=48
AER(µg/min)** 95%CI	40.3 [30.6;53.0]	45.4 [34.0;60.6]	42.6 [29.6;61.4]	51.5 [35.7;74.2]
Ena (N=222)*	n=57	n=45	n=56	n=64
AER(µg/min)** 95%CI	60.9 [42.3;87.8]	51.9 [34.2;78.5]	57.9 [40.4;82.9]	86.1 [63.2;117.3]

*missing values:6 for Per/Ind, 2 for Ena; **AER: Geometric mean

The frequency of adverse events was similar in the two groups. Incidence of emergent dyskaliemia <3.4mmol/l was 2.5% for Per/Ind vs 1.7% for Ena and >5.5mmol/l was respectively 3.3% vs 5.5%.

A treatment strategy based on a first line very low dose combination Per 2mg/Ind 0.625mg induces a greater decrease in albuminuria than Ena. The beneficial effect of the combination may not be explained by BP control alone and a possible synergistic effect between ACEI Perindopril and diuretic Indapamide may increase target organ protection through pharmacospecific effects.

P1171 Effects of losartan and enalapril at hypotensive and non-hypotensive doses on cardiac and renal interstitial matrix in hypertensive rats

D. Guelfi, D. Rizzoni, E. Porteri, I. Sleiman, C. De Ciuceis, G. Boari, E. Agabiti Rosei. *Dept.of Medical and Surgical Sciences, Chair of Internal Medicine, Brescia, Italy*

Hypertension is associated to abnormal accumulation of extracellular matrix in the heart and in the kidney. Angiotensin II and bradykinin may be involved, respectively, in the control of extracellular collagen synthesis and degradation. Thus, ACE inhibitors and angiotensin II type 1 receptor blockers (ARB) may have some effect on cardiac and glomerular extracellular matrix.

Objective: To evaluate the effects of an ACE inhibitor, enalapril (ENA) and of an ARB, losartan (LOS), administered either at hypotensive or non-hypotensive dosage, on the cardiac and renal interstitial matrix of spontaneously hypertensive rats (SHR).

Methods: One hundred rats were included in the study: 16 SHR were treated with low-dose (ld, 1mg/Kg/day) ENA, 16 with low-dose (ld, 0.5 mg/Kg/day) LOS, 16 with high-dose (hd, 25 mg/Kg/day) ENA, 16 with high-dose (hd, 15 mg/Kg/day) LOS, while 18 WKY and 18 SHR were kept untreated (unt). Treatment was given from the 4th to the 12th week of age. Systolic blood pressure (SBP) was measured non-invasively every week. The left ventricular weight to body weight (RLVM) and the left + right kidney weight to body weight (RKW) were measured, and the cardiac and glomerular collagen content was evaluated using Sirius red staining and image analysis.

Results: BP was significantly reduced in SHR ENA hd and in SHR LOS hd, while no reduction was observed in SHR ENA ld and SHR LOS ld. A significant reduction in RLVM was observed in SHR ENA hd and SHR LOS hd. The cardiac collagen was significantly reduced in SHR ENA hd and SHR LOS hd as well as in SHR LOS ld. No significant differences in RKW was observed between groups. However, the collagen content in the glomerular perivascular space was significantly reduced in all treated groups.

	SBP (mm Hg)	RLVM (g/Kg)	Cardiac collagen (%)	RKW (g/Kg)	Renal collagen (units)
WKY unt	157±16 ***	2.42±0.33 ***	3.3±0.6 ***	6.75±0.60	1792±800 ***
SHR unt	216±25	2.64±0.11	8.20±0.32	6.76±0.38	5724±225
SHR ENA ld	218±18	2.54±0.14	8.25±2.0	6.54±0.35	2524±464 ***
SHR LOS ld	216±18	2.61±0.15	5.11±0.26 ***	6.73±0.42	1922±777 ***
SHR ENA hd	157±16 ***#	2.15±0.14 ***	6.54±0.29 ***	6.70±0.33	1565±304 ***
SHR LOS hd	184±18 ***	2.23±0.13 ***	4.02±0.48 ***	6.84±0.38	1248±67 ***

***p<0.001 vs. SHR unt; #=p<0.001 vs. LOS hd

Conclusions: LOS and ENA may have different effects on the interstitial matrix in different organs.

P1172 Health care resource utilization among patients starting ACEI and ARB therapy

F.H. Frech, M. Karbachinskiy, K.K. Yokoyama. *Novartis Pharmaceuticals Corporation, Health Economics & Outcomes Research, East Hanover, United States of America*

Medical and pharmacy claims from a database containing more than 2.5 million covered lives were examined to evaluate the costs of outpatient laboratory and physician visits, hospitalizations, and ER visits among patients initiating angiotensin converting enzyme inhibitors (ACEI), angiotensin II receptor blockers (ARB), ACEI-diuretic combination, and ARB-diuretic combination.

Continuously enrolled members (1/1/97 to 8/30/99) with at least one ICD-9 diagnosis code for hypertension, no claims for antihpertensive drug in 1997, and at least one claim for an ACEI, ACEI-diuretic, ARB, ARB-diuretic therapy filled between Jan 1, 1998 and August 30, 1998 were followed for 12 months after initial prescription fill. Patient demographics, cardiovascular comorbid conditions and costs of health care utilization (outpatient laboratory and physician visits, hospitalizations, and ER visits) were assessed.

There were 3,725 ACEI patients, 426 ACEI-diuretic patients, 1,112 ARB patients, and 302 ARB-diuretic patients identified. The average age of patients in all groups was similar (57-59). The majority of patients starting ACEI and ARB were males (51% and 56%, respectively). Patients starting ACEI-diuretic and ARB-diuretic were mainly females (56% and 53%, respectively). Except for diabetes, baseline cardiovascular comorbid conditions were similar for all drug classes. Diabetes (17.4%) was more prevalent with ACEI patients than were ARB patients (10.8%) and similarly, for ACEI-diuretic (12.2%) and ARB-diuretic (5.6%) patients. The average annual total costs of health care utilization per patient were $2,551 for ACEI versus $2,329 for ARB and $1,665 for ACEI-diuretic versus $1,411 for ARB-diuretic. Lower cardiovascular and non-cardiovascular hospitalizations contributed to the lower total health care costs associated with ARB therapy. When averaged over all groups, hospitalization accounted for 71.8%; outpatient physician visits accounted for 21.3%; ER visits accounted for 2.4%; and outpatient laboratory accounted for 4.5% of the total costs.

This analysis suggests that patients initiating ARB therapy had lower total health care resource utilization costs one year following initiation of therapy.

MYOCARDIAL ISCHAEMIA – EXPERIMENTAL STUDIES

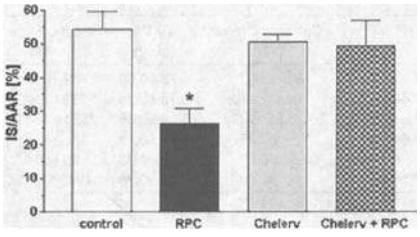
P1173 Remote preconditioning protects the heart by activating myocardial PKCepsilon-isoform

S. Wolfrum[1], K. Schneider[2], M. Heidbreder[2], J. Nienstedt[2], P. Dominiak[2], A. Dendorfer[2]. [1]*University of Luebeck, Medical Clinic II, Lübeck, Germany;* [2]*University of Luebeck, Institute for Pharmacology, Luebeck, Germany*

Myocardial protection can be achieved by brief ischemia-reperfusion of remote organs, a phenomenon described as remote preconditioning (RPC). Since the intracellular mechanisms of RPC are not known, we tested the hypothesis that RPC might activate myo-cardial PKCepsilon - an essential mediator of classical ischemic preconditioning. Furthermore, we tried to delineate the mechanisms by which RPC is transduced to the heart with respect to the possible contribution of kinins and neuronal reflexes.

Methods: Anesthetized rats were ran-domized to undergo either 30min of waiting (controls) or RPC (brief mesenteric artery occlusion followed by reperfusion) in the absence or presence of chelerythrine (5mg/kg), a specific PKC inhibitor. Myocardial infarct size was measured by TTC staining after 60 min of coronary artery occlusion followed by 150 min of reperfusion. In separate sets of experiments RPC was performed with or without pretreatment with HOE140, a selective B2-antagonist or hexamethonium was used to explore the influence of ganglion blockade on RPC. Translocation of PKCepsilon from cytosol to the particulate fraction was measured by quantitative im-munoblotting.

Results: RPC significantly reduced infarct size which was completely blocked by PKC inhibition. RPC shifted the ratio between cytosolic and particulate PKCe, an indica-tor for PKC-activation, from 0.95±0.06 in controls to 0.41±0.09 ($p<0.05$), and this effect was abolished by HOE140. Activation of PKCepsilon could not be achieved after pretreatment with HEX (0.69±0.06 in HEX vs. 0.78±0.06 in HEX+RPC).



RPC and PKC.

Conclusions: RPC activates myocardial PKCepsilon through a neuronal and bradykinin-dependent pathway. We assume that activation of PKCepsilon is an important step in cardioprotection induced by remote preconditioning.

P1174 Acute reduction of myocardial infarct size by a HMG-CoA reductase inhibitor is mediated by endothelial nitric oxide synthase

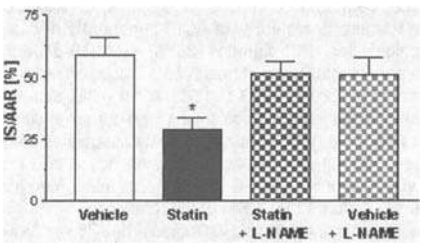
S. Wolfrum[1], M. Grimm[2], M. Heidbreder[3], A. Dendorfer[3], H.A. Katus[1], J.K. Liao[2], G. Richardt[1]. [1]*University of Luebeck, Medical Clinic II, Lübeck, Germany;* [2]*Brigham & Women's Hospital, Department of Medicine, Boston, MA, United States of America;* [3]*University of Luebeck, Institute for Pharmacology, Luebeck, Germany*

Background: In addition to their lipid lowering properties, statins improve endothelial function by increasing the activity of endothelial nitric oxide synthase (eNOS). By this mechanism, we hypothesized that statins may protect the myocardium from ischemic injury.

Methods: Anaesthetised rats underwent 30 min of coronary artery occlusion (CAO) followed by 180 min of reperfusion. Heart rate and arterial blood pressure were continuously monitored throughout the experiments. Plasma cholesterol concentrations were determined at the end of the experiments. Infarct size was measured by TTC staining and expressed as percentage of area at risk. Myocardial eNOS activity was measured by arginine to citrulline conversion assay. The rats were pretreated for one week either with cerivastatin (0.3 mg/kg/d) or placebo. In one set of experiments L-NAME (15 mg/kg), an inhibitor of eNOS, was applicated 15 min prior to CAO.

Results: Cerivastatin increased myocardial eNOS activity by 58% (12 ± 1 to 19 ± 2 pmol/mg/min, $P<0.05$) and decreased infarct size by 49% (59 ± 7% to 29 ± 5%) without affecting hemodynamics or plasma cholesterol levels. Cardioprotection and upregulation of eNOS activity were absent in rats co-treated with L-NAME.

Conclusion: Statins reduce the extent of myocardial necrosis after acute ischemia/reperfusion injury by increasing myocardial eNOS activity. Therefore, statins may protect the heart not only by reducing the incidence of ischemic events, but also by limiting cell damage during acute myocardial infarction.



Infarct size reduction by statins.

P1175 The development of an experimental closed chest animal model which simulates the clinical spectrum of chronic regional ischaemic myocardium

C. Dommke[1], O. Turschner[1], P. Claus[1], F. Weidemann[2], E.V. Verbeken[3], B. Bijnens[1], I.K. De Scheerder[1], G.R. Sutherland[1]. [1]*University Hospital Gasthuisberg, Cardiology Dept., Leuven, Belgium;* [2]*University Hospital Wuerzburg, Cardiology, Wuerzburg, Germany;* [3]*University Hospital Gasthuisberg, Pathology Dept., Leuven, Belgium*

There remains a need to establish a closed-chest, closed pericardium, non-collateralised animal model to mimic the varying clinical substrates associated with chronic regional ischemia.

Methods: A chronic porcine model was developed in which either a non-transmural (NTMI) or transmural (TMI) infarct or ischemia could be created by producing progressive intimal proliferation by implanting a copper-coated steal stent. Different stent coating protocols were tested. In Group 1 stents were electroplated for 120 seconds at 100mA current. Group 2 (less coated)-60 seconds at 100 mA. Group 3 (more coated)-60 seconds @100 mA plus 30 seconds at 150mA. In 32 pigs (Group 1-7 pigs, Group 2-18 pigs, Group 3-7 pigs), stents were implanted in the proximal Cx artery. All received aspirin and clopidogrel to prevent acute stent thrombosis. Weekly ultrasound studies were performed to monitor LV function. After 4-6 weeks, ultrasound Strain/Strain Rate, angiographic, Positron Emission Tomographic (PET), histopathologic and vessel morphometric data were compared (table).

Echo, histologic and angiographic data

	Normal Group (n=8)	NTMI Group (n=14)	TMI Group (n=4)
Wall-thickness (mm)	5.1 ± 0.1*	4.6 ± 0.4	3.5 ± 0.5
LV Diameter (mm)	37 ± 0.8*	42 ± 1.5	50 ± 2.1
Stenosis LCx (%)	0 ± 0 * #	93 ± 3	99 ± 1
Scar extension (%)	0 ± 0 * #	62 ± 8 *	100 ± 0

LV=left ventricle, LCx=left circumflex artery,*$p<0.05$ vs Transmural Infarction Group, #<0.05 vs Nontransmural Infarction Group

Results: Group 1: 4 pigs died during week one due to MI and 3 pigs progressed to severe stenosis (SS, >95%). Since this protocol was too aggressive it was stopped. Group 2: 4 pigs died from TMI during week one, 11 developed SS and 3 non-severe stenosis (NSS). In Group 3: 1 died from early MI, 2 developed SS and 4 survived TMI. The 4 pigs with TMI (occluded stents after 4 weeks) showed poor collateralisation on angio at 8 weeks. Quantitative coronary angiographic analysis was correlated to stent morphometry. Hibernating or infarcted myocardium was correctly identified in the "at risk area" by ultrasound findings and confirmed by PET and histology.

Conclusion: By varying the amount of copper deposited on the stent, it was possible to bias the resultant ischemic substrate to either NS (Group 2: 14%), SS (Group 2: 61%) or NTMI (Group 3: 57%) with a low mortality of 20% (Group 2+3).

P1176 The influence of PK-C inhibition, alfa adrenoreceptors antagonist and endocardial endothelium damage on heart contractility in hypoxic conditions

I. Kocic[1], R. Dworakowski[2], D. Dworakowska[3], A. Rynkiewicz[2], J. Petrusewicz[1]. [1]*Medical University, Dept. of Pharmacology, Gdansk, Poland;* [2]*Medical University of Gdansk, I Dept. of Cardiology, Gdansk, Poland;* [3]*Medical University of Gdansk, Dept. of Internal Medicine, Gdansk, Poland*

Aim: the aim of present work was to examine the effects of 4-N-benzoyl staurospirine (CGP 41251 - inhibitor of alfa, beta protein kinase C isomers) on the rat isolated heart contractility under normoxic and hipoxic conditions. Additionally the effects of CGP 41251, alfa1a-adrenoreceptor antagonist (WB-4101), alfa1b adrenoreceptor antagonist (CEC - chloroethylclonidine) and selective damage of endothelium on the protection against hypoxia induced by ischemic preconditioning were examined. Materials and methods: the experiments were performed on rat isolated left ventricular papillary muscle mounted in organ bath. Force of contraction (Fc), velocity of relaxation (+dF/dt) and velocity of relaxation (-dF/dt) were measured. Isolated heart tissue was perfused with modified Krebs-Henseleit solution gassed with 95%O2; the temperature of perfusate was 37±0,5C. The papillary muscle was paced using two silver electrodes with frequency of 0,5Hz. Hypoxia was achieved by perfusion of tissue with substrate free solution gassed with 95%N2 for 60 min. Preconditioning was achieved by perfusion of tissue with substrate free solution, gassed with 95%N2 and pacing 1Hz for 10 min followed by 10 minutes of reperfusion. Results: At concentrations less than 1μM CGP 41251 did not cause any changes in contractility of rat heart. At concentration 3μM was observed significant positive inotropic effect (Fc 0,5±0,14mN in control vs 0,71±0,1mN, $p<0,05$). Pretreatment of papillary muscle by CGP 41251 at 3μM reduced decreasing of contractility by stimulated hypoxia and reperfusion (Fc 32% of control after hypoxia/reperfusion in control vs 59%, $p<0,05$). Preconditioning was not affected by addition of CGP 41251 neither 1 nor 3Mμ on Fc but velocity of relaxation (-dF/dt) was higher in group treated with CGP 41251 (1,4±0,04 vs 2,5±0,4 mN/s, $p<0,01$). Pretreatment with CEC at 3μM (Fc 84% of control vs 32% in CEC group, $p<0,01$) and selective damage of endocardial endothelium induced by fast immersion of papillary muscle in 0,5% Triton X-100 (Fc 84% of control vs 38% in Triton group, $p<0,01$), but not pretreatment with WB-4101 abolished the protective effects of preconditioning. Conclusions: The results imply that PK-C inhibition improves contractility of heart under normoxic and hypoxic conditions and does not alter hypoxic preconditioning in rat papillary muscle. Selective damage of endocardial endothelium prevented the protection of preconditioning against hypoxia/reperfusion injury. Alfa 1b adrenoreceptors and endocardial endothelium are both involved in triggering of preconditioning in rat isolated heart muscle.

P1177 The role of oxidative stress in alteration of Na-K ATPase isoform expession in rat heart during ischaemia-reperfusion

P. Ostadal[1], A.B. Elmoselhi[2], I. Zdobnicka[2], D. Chapman[2], M. Chappellaz[2], N.S. Dhalla[2]. [1]*University Hospital Motol, Dpt. of Internal Medicine, Prague, Czech Republic;* [2]*St. B. Research Centre, Inst. of Cardiovasc. Sciences, Winnipeg, Canada*

The aim of this study was to assess (a) whether depression of cardiac performance and Na-K ATPase activity during ischemia and reperfusion is associated with alteration in Na-K ATPase isoform expression and (b) whether oxidative stress participates in this alteration. Cardiac performance, enzyme activity, isoform protein content as well as gene expression were studied in isolated rat hearts subjected to global ischemia alone (30 min) and global ischemia followed by reperfusion (60 min) in the presence or absence of superoxide dismutase plus catalase (SOD+CAT), a potent scavenger of oxyradicals. The effect of ischemia and reperfusion was compared to infusion with H2O2 or xanthine plus xanthine oxidase (XXO). Attenuation of cardiac performance and Na-K ATPase activity during ischemia and reperfusion was similar to that induced by H2O2 or XXO. Ischemia and reperfusion caused significant reduction of all alpha and beta isoform protein content, however, while alpha 2, alpha 3, beta 1, beta 2, and beta 3 were preserved by SOD+CAT, alpha 1 was reduced only slightly by ischemia and reperfusion and this decrease was not prevented by antioxidant treatment. H2O2 and XXO also depressed all isoforms but alpha 1. Similarly, mRNA level of alpha 1 was less affected than the other isoforms and was not protected by SOD+CAT. These results indicate that ischemia and reperfusion cause alteration in Na-K ATPase isoform expression and that oxidative stress plays a role in this alteration. Antioxidant treatment improves expression of all isoforms except alpha 1, which appears to be more resistant to oxidative stress.

P1178 Reduction of myocardial infarct size by a novel indole derivative with antioxidant and free radical scavenging properties

I. Andreadou[1], A. Tasouli[2], E.K. Iliodromitis[2], I. Steliou[2], A. Tsanitili-Kakoulidou[1], T. Siatra[1], D.T.H. Kremastinos[2]. [1]*School of Pharmacy, University, Division of Pharmaceutical Chemistry, Athens, Greece;* [2]*Onassis Cardiac Surgery Center, B' Cardiology, Athens, Greece*

Reactive oxygen species are involved in ischemia (isc)-reperfusion (rep) injury. The aim of this study was to investigate: a) the antioxidant properties of 3-[(1H)-indolylmethyl-4-amino 4,5-dihydro-H,1,2,4 triazolo thione] (C6458) in vitro, b) the protective ability of this compound against the oxidative damage of the heart after isc-rep in vivo and c) the potential efficacy of C6458 on the reduction of the infarct size (IS) in vivo. Methods: The ability of C6458 to scavenge free radicals was tested by the interaction with the 1,1-diphenyl-2-picrylhydrazyl (DPPH) stable free radical and by the competition with DMSO for OH. The protective ability of C6458 against oxidative damage after isc-rep was examined in male rabbits that were subjected to 30 min regional isc and 120 min of rep. C6458 was continuously infused for 30 min starting at the 10th min of isc and ending at the 10th min of rep at 2 doses (100 μM and 200 μM). The antioxidant activity was detected by the measurement of malondialdehyde (MDA) formation and the IS was assessed. Results: C6458 showed significant antioxidant properties in all the above assays in vitro; it also exerted significant antioxidant activity in vivo and protected against oxidative damage during isc -rep in both doses. The levels of MDA produced by C6458 at the dose of 200 μM were significantly lower from the 1st min of rep compared to the controls, while at 100 μM this reduction was observed at the 20th min of rep. 200 μM/Kg of C6458 reduced significantly the IS from 45.4±5.4% to 27.3±3.3% ($P<0.05$ vs Control). Conclusion: The novel antioxidant agent C6458 is protective against the oxidative damage of the myocardium after isc-rep and reduces IS. This beneficial effect may be related to its antioxidant and free radical scavenging activity.

P1179 Endothelin-A receptor antagonist LU 135 252 has no electrophysiological and antiarrhythmic effects during myocardial ischaemia-reperfusion in dogs

H. Vago[1], P. Soos[1], E. Zima[2], K. Keltai[1], L. Geller[1], V. Kekesi[1], A. Juhasz-Nagy[1], B. Merkely[1]. [1]*Semmelweis University, Dept. of Cardiovascular Surgery, Budapest, Hungary;* [2]*Semmelweis University, Dept. of Cardiovascular Surgery, Budapest, Hungary*

Antiarrhythmic role of endothelin-A receptor antagonists during myocardial ischemia and reperfusion remains controversial. Moreover electrophysiological mechanism has not yet been identified. The aim of the study was to investigate the role of endogenous endothelin-1 (ET-1) in the development of ventricular tachyarrhythmias during myocardial ischemia and reperfusion using endothelin-A receptor antagonist LU 135 252 (LU) in a canine model. LU (1mg/kg, n=10) or saline (control, n=10) bolus was injected intracoronary into the left anterior descending coronary artery (LAD) before the onset of ligation of this vessel for 30 minutes followed by a 90-minute reperfusion period. Left and right ventricular monophasic action potentials (MAP) were registrated. Serum ET-1 and big-endothelin levels were determined from coronary sinus. Results: There was no difference in hemodynamical parameters and in the left ventricular ischemic mass between the two groups. Total incidence of ventricular fibrillation (VF) during ischemia and reperfusion was 40% in control and 50% in LU group (NS). There was no significant difference in the incidence of sustained tachycardias (VT) and nonsustained VT-s and in the number of ventricular premature beats between the two groups. During ischemia, MAP duration at 90% repolarization (MAPD90) decreased significantly, while during reperfusion a significant prolongation of MAPD90 was observed in LAD region similar in both groups. During reperfusion ET-1 and big-endothelin levels increased significantly similar in both groups. ET-1 level increased significantly higher during ischemia in dogs with VF compared to dogs surviving ischemia and reperfusion (survival vs. VF: control: 15.1±1.3 vs. 15.2±1.3 fmol/ml; ischemia 30': 17.6±1.2 vs. 22±1.6 fmol/ml, $p<0.05$). Conclusion: Although endothelin level was increased during reperfusion, LU did not affect the repolarization changes and did not have antiarrhythmic effect during either ischemia or reperfusion, probably due to the multifactorial origin of arrhythmias.

P1180 Cardioprotective effect induced by brief exposure to nitric oxide before myocardial ischaemia-reperfusion in vivo

A. Gourine, A. Bulhak, A. Gonon, J. Pernow, P-O. Sjöquist. *Karolinska Hospital, Department of Cardiology, Stockholm, Sweden*

Background: Administration of nitric oxide (NO) donors during ischaemia and reperfusion protect from myocardial injury. It is, however, unknown whether administration of an NO donor during a brief period prior to ischaemia protects the myocardium and the endothelium against ischaemia-reperfusion injury in vivo.
Methods: Anaesthetised pigs were subjected to 45 min ligation of the left anterior descending coronary artery (LAD) followed by 4 h of reperfusion. In dose-finding experiments, vehicle or three different doses of the NO donor S-nitroso-N-acetyl-D,L-penicillamin (SNAP, 0.1; 0.5; 2.5 μmol) were infused into the LAD during 3 min starting 13 min before ischemia. Infarct size, endothelium-dependent responses to substance P and myocardial myeloperoxidase activity were evaluated.
Results: Only the 0.5 μmol dose of SNAP reduced infarct size (from 85±3% of the area at risk in the vehicle group to 63±3% in the SNAP treated group ($p<0.01$). There were no significant differences in haemodynamics between the vehicle and SNAP groups during ischaemia-reperfusion. Endothelium-dependent dilatation of coronary microvasculature induced by substance P was larger in the SNAP group than in the vehicle group. Myeloperoxidase activity was lower in the ischaemic/reperfused myocardial area of pigs given SNAP (4.97±0.61 U/g) than in vehicle treated pigs (8.45±0.25 U/g; $p<0.05$).
Conclusions: Intracoronary administration of the NO donor SNAP for a brief period before ischaemia reduces infarct size, attenuates neutrophil accumulation and improves endothelial function. These results suggest that NO exerts a classic preconditioning-like protection against ischaemia-reperfusion injury in vivo in a narrow concentration range.

P1181 Stress activated protein kinases and ischaemic preconditioning in vivo

E.K. Iliodromitis[1], C. Gaitanaki[2], A. Lazou[3], A. Zoga[1], I. Steliou[1], I. Beis[2], D.T.H. Kremastinos[1]. [1]*Onassis Cardiac Surgery Center, B' Cardiology, Athens, Greece;* [2]*University of Athens, School of Biology, Athens, Greece;* [3]*University of Thessaloniki, School of Biology, Thessaloniki, Greece*

There are controversies concerning about the role of the stress activated protein kinases, p38-MAP and p46/p54 JNKs, in preconditioning (PC). The aim of this study was to evaluate their effect on infarct size (IS) in different modes of PC. Anesthetized rabbits were divided in two equal series consisted of 8 groups each. In the 1st series all the animals were subjected to 30 min ischemia (isc) of the heart and 2 hours reperfusion (rep) with one of the following interventions before isc: Control to no intervention, 1PC to one cycle of 5 min isc/10 min rep, 3PC to three cycles 5 min isc/10min rep and the Aortic Clamp group (AoC) to a 5 min mechanical obstruction of the aorta with hypertensive response and 10 min rep which simulated PC. Four more groups, called Gd-Control, Gd-1PC, Gd-3PC and Gd-AoC were respectively subjected to the previous manipulations but they additionally received the stretch blocker gadolinium (Gd); the IS was evaluated. In the 2nd series of experiments, 8 groups of animals were subjected to the same protocol as in the 1st up to the 20th min of isc when the hearts were harvested for p38-MAPK and JNKs assessment. Results: The IS was 42.0±4.4% in Control and 14.2±3.4%, 12.9±3.0%, 15.9±3.3% respectively in 1PC, 3PC and AoC ($P<0.01$ vs Control). Gd did not change IS in Gd-Control (46.2±6.7%), Gd-1PC (16.9±4.2%) and Gd-3PC (15.2±3.7%) but only in Gd-AoC (46.9±4.5%, $p<0.01$ vs AoC); p38-MAPK, p46 and p54 were respectively activated 3.5 to 4.5-fold, 7 to 11-fold and 6 to 7-fold above the control values, independently of the way of PC. The addition of Gd returned the activation of these proteins to baseline values. Conclusion: PC with isc or aortic-clamping are equally effective in reducing the IS and in activation of stress proteins. Although Gd significantly decreases their activation it does not abrogate the beneficial effect of ischemic PC on IS. Thus, p38-MAP and p46/p54 JNKs are involved but with no critical role in the protective mechanism of PC.

P1182 Calcium channel blockade reduces glibenclamide-induced deleterious effects on arrhythmia appearance and diastolic function in conscious sheep

H. del Valle, J.A. Negroni, E.C. Lascano. *Universidad Favaloro, Fisiología, Farmacología y Bioquímica, Buenos Aires, Argentina*

Introduction: Second generation sulfonylurea compounds have been shown to exert deleterious cardiovascular effects in laboratory and clinical practice. Although the exact mechanism is not fully known, it has been postulated that the KATP channel blockade is the most plausible explanation since KATP channels protect against ischemia-reperfusion damage by reducing Ca^{2+} overload. At present it is not known whether sulfonylureas affect arrhythmia appearance and diastolic mechanical function during ischemia and reperfusion and whether their effects might be due to a Ca^{2+} overload mechanism.
Material and Methods: 23 Hampshire Down sheep underwent a 12 min ischemia followed by 1 h reperfusion after being randomly ascribed to one of the following groups: a) control (C, n=8), b) glibenclamide 0,4mg/Kg 30 min before ischemia (n=8) and c) glibenclamide plus diltiazem (n=7), same as b) with diltiazem (40 micro g/Kg) infused 10 min before ischemia. Arrhythmia appearance and severity were evaluated according to the Lambeth convention and Bernauer's severity index (BSI) while diastolic function was assessed by calculating % radial compliance variations (RC) during ischemia and reperfusion with respect to the basal value considered as 100%.
Results: glibenclamide worsened RC during ischemia (52±4.3 vs C= 76±3.4, $p<0.05$) and reperfusion (75±5.1 vs C= 100.2±2.6, $p<0.05$) and resulted in an increase of BSI (9±0.8 vs C: 4±0.3, $p<0.01$). Interestingly, the addition of diltiazem was capable of eliminating both pro-arrhythmic (BSI: 3,5±0.4, $p<0.01$) and pro-stunning effect of glibenclamide during ischemia (RC: 77±4.3, $p<0.05$) and reperfusion (RC: 98±2.7$p<0.05$).
Conclusions: calcium channel blockade eliminates glibenclamide-induced arrhythmias and diastolic dysfunction. This seems to corroborate that KATP channel blockade determines Ca^{2+} overload injury accounting for the deleterious cardiovascular actions of sulfonylureic compounds.

P1183 Induction of IEX-1, an NFkappaB-dependent gene that controls hypertrophy, by hypoxia and myocardial infarction

G.W. De Keulenaer, E.O. Weinberg, R.T. Lee. *Partners Research Facility, Cardiology, Cambridge, United States of America*

We previously identified the immediate early growth and survival related gene IEX-1 as a biomechanically regulated gene in vitro and in vivo (De Keulenaer et al., Circ Res 2002). In cardiomyocytes, IEX-1 is an NFkappaB target gene and negatively regulates hypertrophy, suggesting that IEX-1 participates in ventricular remodeling. In the present study, we tested the hypothesis that IEX-1 is involved in ischemic cardiomyopathy in vitro and in vivo. Using an in vitro model of neonatal cardiomyocytes exposed to hypoxia (1% O2), Northern analysis demonstrated that IEX-1 expression rapidly increased within 2 hours of hypoxia reaching a maximum at 8 hours, whereas VEGF expression only increased after 24 hours of hypoxia. Induction of IEX-1 was consistent with a 2 fold increase of NFkappB activity by hypoxia (1% O2, 1 hour), as quantified by NFkappB-dependent luciferase activity. To further extend these in vitro observations, male FVB mice underwent coronary ligation, and myocardial IEX-1 expression was analyzed by in situ hybridization and immunohistochemistry. Interestingly, IEX-1 transcripts were detected in the infarct border zone, but not in the infarct region or in intact myocardium. Furthermore, when samples were analyzed by immunohistochemistry, a similar distribution of IEX-1 protein in the infarct border zone was observed, with a specific localization in cardiomyocytes. In conclusion, in the present study we demonstrated induced expression of the NFkappaB-target gene IEX-1 in hypoxic cardiomyocytes in vitro and in the infarct border zone in vivo. We postulate that IEX-1 may participate in early remodeling after myocardial ischemia.

P1184 Improved endothelial and myocardial function by an ETA/B receptor antagonist during ischaemia and reperfusion via a NO-dependent mechanism

A. Gonon, D. Erbas, J. Pernow. *Karolinska Hospital, Stockholm, Sweden*

Endothelin (ET) receptor antagonists protect from ischaemia-reperfusion injury. We hypothesized that the the cardioprotective effect of the dual ETA/ETB receptor antagonist bosentan during ischaemia and reperfusion is related to nitric oxide (NO) bioavailability.
Method: Buffer-perfused rat hearts were subjected to 30 min ischaemia and 30 min reperfusion. At the onset of ischaemia the hearts received 3 ml of vehicle, bosentan (10μM), the NO synthase inhibitor L-NNMA (100μM), the combination of bosentan and L-NMMA or the combination of bosentan, L-NMMA and the NO substrate L-arginine (1mM). The NO levels in the coronary effluent were analyzed.
Results: The recovery of myocardial function was poor in the vehicle group. Administration of bosentan resulted in significantly improved myocardial contractile function during reperfusion. The recovery of rate-pressure product (left ventricular x heart rate) was 65±9% in the bosentan group compared to 25±6% in the vehicle group ($P<0.001$). The improved myocardial function induced by bosentan was inhibited by co-administration with L-NMMA (39±8% recovery in rate-pressure product; $P<0.05$ vs. bosentan). Addition of L-arginine restored the cardioprotective effect of bosentan. The recovery of NO release during reperfusion was better preserved in the bosentan group than in the vehicle group (63±10% vs. 39±6%; $P<0.01$). The endothelium-dependent vasodilator adenosine diphosphate increased coronary flow by 18±9% at the end of reperfusion in the bosentan group, whereas it reduced coronary flow by 7±5% in the vehicle group ($P<0.001$).
Conclusion: The dual ETA/ETB receptor antagonist bosentan preserves endothelial and cardiac contractile function during ischaemia and reperfusion via a mechanism dependent on maintained NO production.

P1185 Absence of PK-C loses cardioprotection induced by preconditioning in mice

B. Metzler[1], J. Mair[1], Y. Hu[2], M. Leitges[3], O. Pachinger[1], Q. Xu[2]. [1]*University Hospital Innsbruck, Dept of Cardiology, Innsbruck, Austria;* [2]*St George's Hospital Medical School, Dept of Cardiological Sciences, London, United Kingdom;* [3]*Max-Planck-Institute, Experimental Endocrinology, Hannover, Germany*

Background: Ischemic preconditioning confers cardiac protection during subsequent ischemia-reperfusion, in which protein kinase C (PKC) is believed to play an essential role. Most of our knowledge concerning the role of PKCs in preconditioning comes from studies using a variety of PKC inhibitors, and some controversy exists especially concerning the involvement of PKC isoforms.
Methods: In the present study we investigated the role of PKCdelta (PKCd) in preconditioning using PKCd-knockout mice generated in our laboratories. Both PKCd-/- and PKCd+/+ mice underwent three cycles of 5-minute left descending artery occlusion/5-minute reperfusion followed by a 30-minute occlusion and 2-hour reperfusion.
Results: In wildtype mice serum concentrations of creatine kinase-MB were higher than those in PKCd-deficient mice induced by 30-min ischemia and 2-hour reperfusion. Preconditioning of wildtype mice significantly reduced serum levels of creatine kinase-MB ($p<0.05$). Unexpectedly, about 3-fold enhanced release of cardiac damage markers in PKCd-deficient mice was observed (CK-MB, 1376±286 vs. 5021±355; $p<0.001$). Histological analysis of cardiac tissues revealed that preconditioning treatment resulted in less cardiac damage in PKCd+/+ mice, but traumatic injury in PKCd-/- mice. The damage score was significantly decreased in wildtype mice after preconditioning, while markedly cardiac damage in PKCd-/- mice was found. Furthermore, preconditioning treatment resulted in significantly increased O2- production in hearts of PKCd+/+ mice, and no changes in PKCd-/- animals, indicating the involvement of PKCd-dependent free radical induction.
Conclusions: Our findings demonstrated that PKCd is essential for the cardiac protective effects of preconditioning, implicating the importance of PKCd as a target for therapy.

P1186 Heart rate reduction and negative inotropism exert contrasting cardioprotective effects during exercise-induced ischaemia and stunning in dogs

X. monnet, P. Colin, B. Ghaleb, A. Bizé, J.F. Giudicelli, A. Berdeaux. *Département de Pharmacologie, INSERM E 00 01, Le Kremlin-Bicêtre, France*

The effects of heart rate (HR) reduction induced either by the selective If channel inhibitor ivabradine or the beta-blocker atenolol were assessed on exercise (Ex)-induced myocardial ischemia and stunning in 7 dogs chronically instrumented to measure left ventricular (LV) wall thickening (Wth) and coronary blood flow (CBF). Coronary artery stenosis was set up to suppress the increase in CBF during a 10 min treadmill Ex. When administered before Ex, HR was similarly reduced by ivabradine and atenolol at rest (-18%) and during Ex (-28%) vs saline. During Ex under saline, LVWth dramatically decreased from 29±4% to 2±1% in the ischemic zone. This depression was strongly limited with ivabradine (LVWth=10±3%, $p<0.05$ vs saline) and further reduced by atenolol (LVWth=17±4%, $p<0.05$ vs saline and ivabradine). After completion of Ex, ivabradine significantly reduced the severity of myocardial stunning whereas atenolol failed to improve LVWth vs saline. Interestingly, when administered after the end of Ex, the intensity and severity of myocardial stunning was still strongly reduced by HR reduction with ivabradine and this effect disappeared when HR reduction was abolished by atrial pacing. In contrast, administration of atenolol after the end of Ex was unable to improve myocardial dysfunction and importantly, LVWth was further severely depressed vs saline. In conclusion, this study confirms the beneficial role of HR reduction during myocardial ischemia. Importantly, it also demonstrates the interest of a selective bradycardic agent devoid of negative inotropic activity rather than a beta-blocker in the management of myocardial stunning.

P1187 Histochemical and ultrastructural characterisation of arrhythmogenic cellular substrate in ischaemic pig heart

N. Tribulova[1], L. Okruhlicova[1], S. Goetzfried[2], S. Sass[2], S. Thomas[2], T. Podzuweit[2], M. Manoach[3]. [1]*Institute for Heart Research, Slovak Academy of Sciences, Bratislava, Slovakia;* [2]*Max-Planck-Institute, Department of Experimental Cardiology, Bad Nauheim, Germany;* [3]*Tel Aviv University, Department of Physiology, Tel Aviv, Israel*

Pig heart by its size, coronary anatomy, presence of M cells and intramural Purkinje fibers as well as susceptibility to ischemia/reperfusion-induced lethal arrhythmias is close to human heart, thus useful for the study of arrhythmogenesis. Since survival of endocardial Purkinje fibers after myocardial infarction was shown to be highly arrhythmogenic in dog heart, the aim of this study was to reveal by in situ enzyme histochemistry and examination of ultrastructure the anatomic substrate that could underlie electrical instability of the ischemic pig heart.
Methods: Experiments were performed on anaesthetized landrace pigs (32-40 kg b.w.). The heart was subjected to 90 min of left coronary occlusion followed by 30 min reperfusion. At the end of experiments transmural tissue blocks from the left ventricle containing ischemic, border and nonischemic area were frozen in liquid nitrogen for histochemistry. Small tissue blocks from epi-, mid-, and endo-cardium of all three regions were fixed with 2.5% glutaraldehyde for ultrastructure examination.
Results showed besides ordinary contractile cardiomyocytes and Purkinje fiber also presence of "transitional cells" in midmyocardium that likely correspond to electrophysiologically detected M cells. Importantly, these cells and particularly Purkinje fibers in mid- and subendocardium revealed reversible ischemia-related subcellular alterations different from majority of irreversibly injuried contractile cardiomyocytes. In correlation with these findings, in situ histochemistry revealed abolished glykogen-dependent phosphorylase activity in ischemic area, while still persistent in Purkinje fibers and small islands of cardiomyocytes. Moreover, coronary occlusion followed by reperfusion induced marked heterogeneity in activity of all selected enzymes as well as heterogeneity of subcellular alterations, within a border zone.
Conclusion: The results indicate that preserved viability of specialized conducting cells spanning severely ischemic ventricular wall can underlie anatomic substrate for electrical disturbances facilitating re-entry that consequently increase of susceptibility of the pig heart to ischemia- and reperfusion- induced lethal arrhythmias.

P1188 Complete abolishment of increased myocardial ischaemia-reperfusion injury conferred by hypercholesterolemia through inhibition of caspase-1 cascade
